Status and Conservation. Not globally threatened. Uncommon in Malay Peninsula and Borneo, and rare in Sumatra. Recently rediscovered in Singapore. Occurs in Khao Pra Bang Wildlife Sanctuary, in Thailand, and Taman Negara National Park, in Peninsular Malaysia; rare in Danum Valley Conservation Area, in Borneo.

Bibliography. Cheke & Mann (2001), Gretton (1990), Holmes (1996), Hornskov (1987), MacKinnon & Phillipps (1993), Mann (1996, 2008), van Marle & Voous (1988), Medway & Wells (1976), Robinson (1928), Robinson &

Kloss (1923), Robson (2000b), Sheldon *et al.* (2001), Smythies (1957, 1960), Smythies & Cranbrook (1981), Wells (2007).

125. Long-billed Spiderhunter

Arachnothera robusta

French: Arachnothère à long bec

Spanish: Arañero Piquilargo

German: Langschnabel-Spinnenjäger

Taxonomy. *Arachnothera robusta* S. Müller and Schlegel, 1845. Indrapura, western Sumatra. Proposed race *uraygialis*, described from Malay Archipelago, synonymized with nominate. Two subspecies recognized.

Subspecies and Distribution.

A. r. robusta S. Müller & Schlegel, 1845 – S Thailand (from Trang, once Kaeng Krachan National Park) and Peninsular Malaysia, Sumatra and Borneo.

A. r. armata S. Müller & Schlegel, 1845 – Java.

Descriptive notes. 21–22 cm. Male has very long bill. Male nominate race is olive above, slight dark scaling on crown, remiges edged yellowish, tail blackish-brown, outer two feather pairs tipped white; dull olive-yellow below, brighter yellow on belly and undertail-coverts, streaked olive on throat and breast, orange-yellow pectoral tufts; underwing-coverts pale yellow; iris brown; bill black; legs blackish-olive. Female is similar to male but smaller, and lacks pectoral tufts. Juvenile is inadequately described, probably lacks dark crown markings and also, apparently, dark streaking. Race *armata* is much smaller than nominate.

normally with slightly different streaking pattern. **Voice.** Song a rising “choi, choi, choi, choi...”. Flight call high-pitched “chit-chit, chit-chit”; harsh “chuu-luut chuu-luut” from high perch.

Habitat. Various forest types, including dipterocarp, heath forest, peatswamp-forest and coniferous forest, also plantations, forest edge, secondary growth and gardens; sea-level to 1520 m in Malay Peninsula, to 1700 m in Sumatra and to 1000 m in Borneo.

Food and Feeding. Diet includes caterpillars and other soft insects, mantids, also spiders (Araneae); also small flowers and fruits of creepers, and nectar, including from mistletoes (Loranthaceae). Forages singly, usually in canopy. Pollinates and takes nectar from durian trees (*Durio*).

Breeding. Season Feb–Jun/Jul in Malay Peninsula; laying recorded Sept in Sumatra (Jambi) and Jan, Apr–Aug and Dec in Java; in Borneo, laying May, Jun and Dec in NW (Sarawak), nesting in Mar and active gonads in Jun in N (Sabah), and young in Sept in S (Kalimantan Tengah). Nest bottle-shaped or trough-shaped with cup at end, up to 43 cm long including entrance tunnel (c. 22.5 cm long), entrance hole 11.5 cm wide, with chamber 10 × 65 cm, made from felted grass stems and other plant materials, woven together and held against underside of banana leaf by cobweb slings, knotted on surface of leaf, or built by sewing together the edges of a banana leaf to form tube, with entrance tunnel opening towards tip of leaf (or occasionally attached to epiphyte or creeper), 2–5 m above ground. Clutch 2 eggs, matt white or faintly glossed, with zone of black spots and lines around broadest part. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Rare in Thailand and Sumatra; fairly common in Peninsular Malaysia; scarce in Borneo; locally common at sea-level in Java, but generally rare.

Bibliography. Cheke & Mann (2001), Leliebregers & Hoogerwerf (1967), Holmes (1996), Hoogerwerf (1949, 1950), MacKinnon & Phillips (1993), Mann (2008), van Marle & Voous (1988), McClure (1998), Medway & Wells (1976), Robson (2000b), Sheldon *et al.* (2001), Smythies & Davison (1999), Wells (2007), Wilkinson *et al.* (1991), Yumoto (2000).

126. Spectacled Spiderhunter

Arachnothera flavigaster

French: Arachnothère à lunettes

German: Brillenspinnenjäger

Spanish: Arañero de Anteojos

Other common names: Greater Yellow-eared/Large Spiderhunter

Taxonomy. *Anthreptes flavigaster* Eyton, 1839, “Malaya”.

Proposed race *simillima* (from Malacca, in SW Malay Peninsula) considered inseparable from birds elsewhere in species’ range. Monotypic.

Distribution. S Thailand, Peninsular Malaysia, Sumatra and Borneo.

Descriptive notes. 21–22 cm; three adult males 44.4–49 g, one female 38.4 g. Has long, thick, curved bill. Plumage is mostly olive, more greenish above, and more yellow on flanks and belly, edges of remiges brighter olive-green, with yellow or bronzy tinge; large yellow ear patch, and broad yellow eyering; iris brown; bill blackish, reddish at base of lower mandible; legs yellowish-brown. Sexes similar. Juvenile undescribed. **Voice.** High-pitched “chit-chit”; from perch or in flight an explosive “tak”, “cha-tak”, “cha-ta-tak” and variants.

Habitat. Lowland dipterocarp forest, peatswamp-forest and secondary forest, forest

edge, clearings, plantations, cultivation and gardens; often around bananas (*Musa*) and gingers (Zingiberaceae). Sea-level to 300 m, perhaps to 1100 m, in Malay Peninsula; to 1500 m in Sumatra, and to 1600 m, possibly 1800 m, in Borneo.

Food and Feeding. Insects, spiders (Araneae), pollen, fruit and nectar. Forages singly, occasionally in pairs; sometimes in small groups at fruit. Usually in middle to upper storeys of vegetation. Recorded nectar sources include, among others, coconut, *Erythrina*, *Eugenia*, *Firmiana fulgens*, *Spathodea* and *Jacaranda*. Hovers in front of flowers; probes fruits. Pollinates and takes nectar from durian trees (*Durio*).

Breeding. In Malay Peninsula, nest-building in Feb, copulation seen mid-Apr, laying calculated as Mar, Jun, Sept and Nov; laying in Apr (and birds with enlarged testes Jul–Aug) in Borneo. Nest circular or with spout, of compacted plant fibre and lined with seed pappus, one nest 90 mm wide,

77 mm deep, egg-chamber 77 mm in diameter and 50 mm deep, sewn on to underside of coconut or other palm frond by silk or placed between large rubber tree leaves sewn together, 5.5–13 m above ground. Clutch 2 eggs, almost unglossed, dull greenish-grey with dark grey to brownish flecks, markings denser at broad end. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Locally common to uncommon in Malay Peninsula, where has possibly increased in S; extirpated from Singapore main island. Not uncommon in Sumatra; uncommon to rare in Borneo. Possible former presence in extreme S Vietnam requires further investigation. Occurs in Taman Negara National Park, in Peninsular Malaysia; rare in Danum Valley Conservation Area, in Borneo.

Bibliography. Cheke & Mann (2001), King *et al.* (1975), MacKinnon & Phillips (1993), Mann (1996, 2008), van Marle & Voous (1988), Medway & Wells (1976), Robson (2000b, 2002a), Sheldon *et al.* (2001), Wells (2007), Yumoto (2000).

127. Yellow-eared Spiderhunter

Arachnothera chrysogenys

French: Arachnothère à joues jaunes

Spanish: Arañero Carigualdo

German: Gelbwangen-Spinnenjäger

Other common names: Lesser Yellow-eared Spiderhunter

Taxonomy. *Nectarinia chrysogenys* Temminck, 1826, Bantam District, Java.

Additional proposed races are *astilpna* (described from Bokpyin, in Tenasserim), *intensiflava* (Kossoom, Tenasserim), *copha* (Tapanuli Bay, in NW Sumatra), *pleoxantha* (Mt Lembu, on Nias I) and *isoepga* (Pagai Is, off W Sumatra), all considered inseparable from nominate. Two subspecies recognized.

Subspecies and Distribution.

A. c. chrysogenys (Temminck, 1826) – Extreme S Myanmar (S Tenasserim), S Thailand, Peninsular Malaysia, Singapore, Riau and Lingga Archipelagos, Sumatra and most satellites, W Borneo and W Java.

A. c. harrissoni Deignan, 1957 – E Borneo.

Descriptive notes. 17–18 cm; 22–23.5 g. Male nominate race has head and upperparts olive-green, suffused golden on mantle, becoming brighter on rump, with large yellow cheek patch and narrow yellow filoplume eyering, much narrower on lower half; edges of remiges bright yellow or golden-bronze; throat to breast yellowish-green with indistinct greenish streaks, becoming brighter yellow on belly, lower flanks and undertail-coverts; pectoral tufts grey; iris brown; bill blackish with fleshy-pink base to lower mandible and often a long central orange to yellow line along cutting edges, becoming pale grey on gape; legs dull

fleshy-brown to pale brown. Female is similar to male but lacks pectoral tufts. Juvenile resembles adult, but lacks streaking and dark feather bases. Race *harrissoni* differs from nominate in almost completely lacking golden suffusion on mantle, which is nearly concolorous with crown, and has exposed parts of closed wing lighter and duller. **Voice.** Rough “chit”; flight call high-pitched “twit-twit-twit-tee-ee”, last note protracted.

Habitat. Various forest types, including peatswamp-forest, mangroves and secondary forest, forest edge, also plantations and gardens; sea-level to 1400 m, but to 2010 m in Peninsular Malaysia.

Food and Feeding. Insects, spiders (Araneae); nectar, pollen and small fruits. Forages singly, sometimes in pairs, and occasionally in small groups, mostly in canopy. Recorded nectar sources include gingers (Zingiberaceae), *Firmiana fulgens*, *Eugenia* and *Erythrina*, among others; pollinates and takes nectar from durian trees (*Durio*).

Breeding. Laying in Jan, Apr and May in Malay Peninsula, May–Jun in S Sumatra (Lampung) and Dec in Java; in Borneo, laying in Feb–Mar in N (Brunei) and Sept in NW (Sarawak), juveniles in Jun in S (SW Kalimantan), also birds with active gonads in May, Jul and Aug in Sabah. Nest basket-shaped, 39 × 13 cm, with or without long entrance tunnel, made from reddish-brown fibres from rotting leaf bases, with inner cup of finer material, sewn to underside of palm frond or banana leaf 1.5–20 m above ground. Clutch 2 eggs, white, ringed with fine black lines at broader end, or dirty greyish-white and flecked heavily (especially at broader end) with sepia and grey-brown. No other information.

Movements. None recorded. May cross water to and from Singapore.

Status and Conservation. Not globally threatened. Common to fairly common in S Myanmar and Malay Peninsula; rare in Singapore; local and uncommon in Sumatra; rare in Java and very scarce in Borneo. Occurs in Khao Pra Bang Wildlife Sanctuary, in Thailand, and Danum Valley Conservation Area, in Borneo.

Bibliography. Cheke & Mann (2001), Deignan (1957), Gibson-Hill (1950a), Harrison (1968b), Holmes (1996), MacKinnon & Phillips (1993), Mann (1996, 2008), van Marle & Voous (1988), Medway & Wells (1976), Mitra & Sheldon (1993), Nash & Nash (1988), Robson (1995, 1999a, 1999b, 2000a, 2000b, 2001, 2002b), Sheldon *et al.* (2001), Smythies (1957, 1960), Smythies & Cranbrook (1981), Smythies & Davison (1999), Wells (2007), Yumoto (2000).

128. Naked-faced Spiderhunter

Arachnothera clarae

French: Arachnothère à face nue

Spanish: Arañero Caricalvo

German: Nacktwangen-Spinnenjäger

Other common names: Bare-faced/Philippine Spiderhunter

Taxonomy. *Arachnothera clarae* A. W. H. Blasius, 1890, Davao, Mindanao, Philippines.

Birds on Basilan, currently included in race *malindangensis*, possibly belong to an as yet undescribed race. Four subspecies currently recognized.

Subspecies and Distribution.

A. c. luzonensis Alcasid & Gonzales, 1968 – EC & S Luzon (Sierra Madre Mts and Mt Isarog), in N Philippine Is.

A. c. philippinensis (Steere, 1890) – Samar, Biliran and Leyte, in EC Philippines.

A. c. malindangensis Rand & Rabor, 1957 – N & W Mindanao (including Mt Malindang) and Basilan, in S Philippines.

A. c. clarae A. W. H. Blasius, 1890 – C Mindanao (Davao).

Descriptive notes. 17.2 cm; 27.5–34.8 g. Very long-billed. Nominata race has lores and area around eye dark grey, bare skin in front of eye dark grey, naked submoustachial patch pinkish; rest of head and upperparts olive-green, edges of remiges olive-yellow to golden-olive; throat to breast brownish-grey with dark feather centres (giving indistinct streaking), rest of underparts greenish, paler, more yellowish, on belly and lower flanks; no pectoral tufts; iris dark brown to black; bill blackish, yellow gape; legs yellowish-brown to dark brown. Sexes similar. Juvenile undescribed. Race *luzonensis* differs from nominate in having

burnt-orange edging of remiges, and grey breast; *philippinensis* has pink naked skin on forehead, underparts greener than nominate; *malindangensis* is lighter olive-green above, has golden edges of remiges, and olive-grey underparts (darker and duller green above and greyer, less greenish, below than preceding race). Voice. Loud, raspy “serp-rp-rp-rp-rp-rp”, repeated a varying number of times, up to 15 per minute; very high, insect-like “seee”, also low, harsh croaking “crrr”; rapid insect-like “trrrrik”; and various rapid trills, rising, falling or evenly pitched.

Habitat. Forest, forest edge and scrub and clearings, particularly around plantains (*Musa*); to 1400 m. **Food and Feeding.** No information on diet; presumably includes nectar and small arthropods. Observed singly and in pairs.

Breeding. Birds with active gonads in Jan–May. No further information.

Movements. Nothing recorded.

Status and Conservation. Not globally threatened. Uncommon.

Bibliography. Alcasid & Gonzales (1968), Cheke & Mann (2001), Dickinson *et al.* (1991), Kennedy *et al.* (2000), McGregor (1909), duPont (1971b), Rand & Rabor (1957, 1960), Ripley & Rabor (1961).

129. Grey-breasted Spiderhunter *Arachnothera modesta*

French: Arachnothère modeste **German:** Graubrust-Spinnenjäger **Spanish:** Arañero Modesto

Taxonomy. *Antheptes modesta* Eyton, 1839, Peninsular Malaysia.

Sometimes considered to form a superspecies with *A. affinis*; the two overlap in range in Borneo, but are segregated by altitude. Present species and nominate race of latter have been treated as conspecific (with race *everetti* of *A. affinis* then treated as a separate species). Geographical variation not well marked; *caena* intergrades with nominate in S Myanmar (Tenasserim) and S Thailand and could perhaps be merged with it. Proposed race *heliophilus* (described from Loh Sidoh Bay, in NW Sumatra) considered indistinguishable from *concolor*. Three subspecies recognized.

Subspecies and Distribution.

A. m. caena Deignan, 1956 – extreme S Myanmar (S Tenasserim) and SW Thailand.

A. m. modesta (Eyton, 1839) – Malay Peninsula and Borneo.

A. m. concolor Snelleman, 1887 – Sumatra, including Mentawai Is.

Descriptive notes. 17–18 cm; male 20.5–24.9 g, female 20.1–25.5 g. Nominata race is golden olive-green above, crown with sooty-brown feather centres; remiges blackish-brown, edged yellowish-green, and tail green with blackish-brown tips, all except central feathers with white subterminal spots (visible from below) that become smaller and duller towards central tail; throat and underparts olive-grey to buffish (darker on some), chin to upper breast with variable narrow brown streaking; iris brown; longish bill medium brown to blackish-brown, paler lower mandible; legs flesh-coloured to brown. Sexes similar.

Juvenile lacks streaking. Race *caena* is paler, less streaked and more yellowish below than nominate, and has upperparts more golden or yellow-green; *concolor* is darker green above than nominate, and some are less streaked below. Voice. Song a continuous “tee-chu”, first note rising and second falling, similar to that of *A. longirostris*. Short rapid chatter.

Habitat. Dipterocarp forest, peat swamp-forest, secondary and dry coastal forests, forest edge, coastal scrub, banana (*Musa*) plantations, orchards and coconut groves; sea-level to 1200 m.

Food and Feeding. Spiders (Araneae), also insects, including crickets (Orthoptera) and ants (Formicidae); nectar. Forages singly and in pairs, in all storeys of forest, often at low to middle levels.

Breeding. Eggs recorded in late Apr and juveniles May–Aug in Peninsular Malaysia; laying in Feb in Borneo. Nest a shallow cup of wood bast placed inside layer of leaf skeletons, latter felted with cobweb to form asymmetrical basket, placed against trunk of palm or, more usually, on underside of large leaf (e.g. of banana) and attached by cobweb slings, 1.5–2.5 m above ground; one nest was supported by two leaves stapled together with twigs. Clutch 2 eggs, smooth and glossy, unevenly coloured olive-brown, with darker brown ring around broadest part; no information on incubation and nestling periods. Nests sometimes parasitized by Plaintive Cuckoo (*Cacomantis merulinus*) in Borneo.

Movements. No information.

Status and Conservation. Not globally threatened. Rare in Myanmar; common in Thailand and Malay Peninsula; common in Sumatra; uncommon in Borneo. Probably extinct in Singapore, where last confirmed record in 1940s, although reported there in 1981. Occurs in several protected areas, e.g. Khao Pra Bang Wildlife Sanctuary, in Thailand, and Taman Negara National Park, in Peninsular Malaysia.

Bibliography. Cheke & Mann (2001), Davison (2000), Gibson-Hill (1949), MacKinnon & Phillips (1993), Mann (1996, 2008), van Marle & Voous (1988), Medway & Wells (1976), Nash & Nash (1985), Robson (2000b), Smythies (1960), Smythies & Cranbrook (1981), Smythies & Davison (1999), Wells (2007).

130. Streaky-breasted Spiderhunter *Arachnothera affinis*

French: Arachnothère à poitrine grise **Spanish:** Arañero Pechiestriado
German: Strichelbrust-Spinnenjäger

Other common names: Bornean/Everett’s/Kinabalu Spiderhunter (*everetti*)

Taxonomy. *Cinnyris affinis* Horsfield, 1821, Java.

Sometimes considered to form a superspecies with *A. modesta*; the two overlap in range in Borneo, but are segregated by altitude. Nominata race of present species previously treated as conspecific with *A. modesta*; *everetti* then regarded as a separate, montane species, but evidence of occurrence of nominate as a mountain form in Java and Bali suggests that the two are conspecific, separated from lowland taxa (now combined in *A. modesta*). Proposed race *pars*, described from R Birang (N Kalimantan), in Borneo, considered to be inseparable from *everetti*. Two subspecies currently recognized.

Subspecies and Distribution.

A. a. everetti (Sharpe, 1893) – N & C Borneo.

A. a. affinis (Horsfield, 1821) – Java and Bali.

Descriptive notes. 21 cm. Nominata race is golden-green above, with dark scaling on crown; remiges and rectrices blackish-brown, edged green, central rectrices with much green (except at tips) and all except central pair with white subterminal spots (visible from below) that become smaller and duller towards central tail, tips brown; grey with slight yellow tinge below, heavily streaked brown from chin to belly, some streaking on flanks, undertail-coverts whitish with dark barring; iris hazel, chocolate-brown, dark brown or green; bill black or blackish-brown, paler lower mandible; legs flesh-coloured, pale brown or brownish-pink. Sexes similar. Juvenile differs from adult in lacking streaking below, and has more buffy subterminal tail spots. Race *everetti* is on average somewhat larger than nominate, also more green, less golden, above, lacks yellow tinge below, has ventral streaking grey-brown, darker brown tips on tail. Voice. Song “chee-wee-dee-weet...tee-ree, chee chee-chur”. Variety of piercing, ringing and raucous calls.

Habitat. Hill dipterocarp forest and lower montane forest, forest edge and around plantains (*Musa*); generally 900–1600 m, occasionally down to 305 m.

Food and Feeding. No specific information; diet presumably small arthropods and nectar. Forages singly, occasionally in pairs, mostly in higher levels of forest.

Breeding. Laying recorded in Feb and Mar in N Borneo and in Apr–May and Oct–Dec in Java. Nest (presumed of this species) a cup constructed from a bright brown silky substance from fern fronds, and plant down, and covered with small flower and plant stems stuck together with spider web, suspended by spider web from underside of large leaf. Clutch 1–2 eggs, smooth and glossy, liver-coloured with darker cap, or greenish-white or deep olive-brown and almost completely covered with dark brownish shade, with very pale (hardly visible) grey mottling largely concentrated at blunt end, forming faded cap of olive-greyish, occasionally a very few well-defined dark blackish-sepia scribbles or thread-like markings. No other information.

Movements. Nothing recorded.

Status and Conservation. Not globally threatened. Uncommon in Borneo; commoner in Java and Bali. Occurs at Poring Hot Springs, in Kinabalu Park, in Borneo.

Bibliography. Cheke & Mann (2001), Davison (2000), Hellebrekers & Hoogerwerf (1967), Hoogerwerf (1949, 1950), MacKinnon & Phillips (1993), Mann (2008), Smythies (1957, 1960), Smythies & Cranbrook (1981), Smythies & Davison (1999).

131. Streaked Spiderhunter *Arachnothera magna*

French: Grand Arachnothère **German:** Strichelspinnenjäger **Spanish:** Arañero Estriado

Taxonomy. *Cinnyris magna* Hodgson, 1836, Nepal.

Geographical variation mostly not well marked; race *pagodarum* perhaps not diagnosable and could be subsumed within *musarum*. Race *aurata* intergrades with *musarum* in S Myanmar (Karen Hills). Five subspecies recognized.

Subspecies and Distribution.

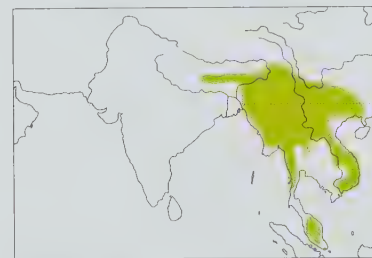

A. m. magna (Hodgson, 1836) – Nepal, Sikkim, Bhutan, E Bangladesh and NE India E to S China (SE Xizang E to W, S & SE Yunnan, SW Guizhou and W Guangxi) and N Myanmar.

A. m. aurata Blyth, 1855 – C & E Myanmar.

A. m. musarum Deignan, 1956 – SE Myanmar, N Thailand, Laos and N Vietnam (W Tonkin).

A. m. pagodarum Deignan, 1956 – W Myanmar, W Thailand and S Malay Peninsula.

A. m. remota Riley, 1940 – SC & S Vietnam.

Descriptive notes. 17–20.5 cm; male 28–34.5 g, female 23–9 g. Nominata race is golden yellowish-olive with black streaking above, tail tipped buff and with blackish subterminal band; below, very pale yellowish-white with bold black shaft streaks, undertail-coverts yellow or olive-yellow with bold blackish chevrons; iris brown; bill blackish-brown; legs chrome-yellow to orange with pale claws. Sexes similar. Juvenile is more buffy and greyish (less golden-green) above and less yellow below than adult. Race *aurata* is slightly smaller than nominate, has golden rump and uppertail-coverts, dusky olive undertail-coverts broadly tipped yellowish-white; *musarum* has less golden suffusion above than nominate, only faintly washed yellow below, ventral streaking broad and bold; *pagodarum* is duller, greener and less golden than previous, with streaking above less clear; *remota* is more green and less golden than nominate, with smaller black feather centres on head and back, deeper yellow on bend of wing and undertail-coverts, rest of underparts tend to be more yellowish. Voice. Song begins as soft “vijivitte vij”, then accelerating and becoming monotonous. Calls include sharp, metallic chirruping “chirirrik” or “chiruk, chirik”, also “chisikik” and “chee-chee-chee...”; also repeated “chittit, chittititit”; annoyance call soft “ug-ug-ug”; feeding call persistent “chip”; in flight repeated “kak-tik”, and loud musical trill.

Habitat. Various types of forest, including heavily disturbed and secondary forests, also forest edge, bamboo, scrub, thickets and gardens. In Nepal generally to 450 m, but recorded to 2135 m; in

India 600–2200 m, lower in winter; down to 500 m in N Vietnam, to 150 m in Cambodia; 800 m to at least 1890 m in Malay Peninsula.

Food and Feeding. Nectar, particularly of bananas (*Musa*); insects, and spiders (Araneae). Forages singly, sometimes in pairs; sometimes joins mixed-species parties. Forages frequently in canopy, also at lower levels. Seen to remove spiders from their webs.

Breeding. Laying recorded in Mar–Jul in India and Apr and Jul–Aug in Myanmar; nest-building late Feb, Mar and Sept, eggs and nestlings Mar and Apr and fledgling early May in Peninsular Malaysia; males with enlarged testes in Mar in Vietnam (S Annam). Nest a neat inverted dome or oblong, with one or two entrances (but no tunnel), constructed from leaf skeletons joined together with cobwebs, lined with grass and leaf skeletons, sewn by vegetable down and cobwebs to underside of broad leaf, usually of banana but also on underside of leaf of giant creeper, large ginger (Zingiberaceae), teak (*Tectona*), thorny creeper, or huge dock (*Rumex*) leaf; 0.5–2 m above ground. Clutch 2–3 eggs, brown to olive-brown, darker at broader end; no information on incubation and nestling periods. Nests parasitized by Large Hawk-cuckoo (*Cuculus sparverioideus*), Indian Cuckoo (*Cuculus micropterus*), Common Cuckoo (*Cuculus canorus*) and Asian Lesser Cuckoo (*Cuculus poliocephalus*).

Movements. Seasonal altitudinal movements in N parts of range. At least 22 birds seen moving along a ridge on a Nov morning in W Yunnan, China, and others lower down two days later. A night-flying individual, recorded once in Peninsular Malaysia, thought to be due to disturbance of a roosting bird.

Status and Conservation. Not globally threatened. Locally common in NE Indian Subcontinent, and frequent in parts of Bhutan; common in much of SE Asian range, but locally not uncommon to very rare in Myanmar; common in Malay Peninsula, locally common in S China. Occurs in several protected areas throughout range.

Bibliography. Ali & Ripley (1974), Birand & Pawar (2004), Cheke & Mann (2001), Étchécopar & Hüe (1983), Fleming & Traylor (1964), Fleming *et al.* (1976), Hodgson (1836), Inskipp & Inskipp (1985), Medway & Nisbet (1968), Medway & Wells (1976), Oates (1890a), Rasmussen & Anderton (2005b), Robson (2000a, 2000b), Smythies (1986), Wells (2007).

132. Whitehead’s Spiderhunter
Arachnothera juliae

French: Arachnothère de Whitehead **Spanish:** Arañero de Whitehead
German: Bergspinnenjäger

Taxonomy. *Arachnothera juliae* Sharpe, 1887, Mount Kinabalu, north Borneo. Very distinctive species with no obvious close relatives. Monotypic.

Distribution. Borneo: in Sarawak (Mt Dulit, Mt Kalulong, Mt Murud, Mt Selidang, Usun Apau Plateau, Kelabit Uplands and Mt Mulu), Sabah (Mt Kinabalu, Mt Trus Madi and Crocker Range) and Kalimantan Timur (upper R Bahau and Mt Lanjut).

Descriptive notes. Male 16.5–18 cm, female 15.5–16.5 cm. Plumage is mainly brown, crown streaked buffy white, neck and back narrowly streaked white, rump plain bright yellow; throat with small brownish-white streaks, rest of underparts broadly streaked white, except for unmarked bright orange-yellow undertail-coverts; iris brown; bill and legs black. Sexes similar. Juvenile undescribed. **VOICE.** High-pitched squeaking song. Calls include repeated loud shrieking in flight or when perched, and prolonged twittering; wheezy 2-note call, first note rising and second falling; “teeh-teeh-wee”, last note rising; “tee-tee-swee-ee”, third note rising and last falling; also “see-wee see-wee” and “swee-eee-eee”.

Habitat. Hill dipterocarp forest and montane forest, and forest edge; 930–3000 m.

Food and Feeding. Small arthropods, berries and nectar. Forages singly and in pairs, and occasionally in groups of up to five individuals; sometimes associates with mixed-species flocks. Feeds mostly in canopy, but also comes lower at forest edge; forages within foliage, especially among clumps of epiphytes on higher branches. Observed to probe rhododendron (*Rhododendron*) flowers for food.

Breeding. Active nest in canopy in Mar, and males with active testes in Jun and Nov. No other information.

Movements. Nothing recorded.

Status and Conservation. Not globally threatened. Formerly considered Near-threatened. Restricted-range species: present in Bornean Mountains EBA. Locally common. Possibly occurs on other mountains in Borneo. Present in the Rafflesia Forest Reserve, in the Crocker Range, and in Kinabalu Park (both in Sabah).

Bibliography. Babbington (1992), van Balen (1997), Cheke & Mann (2001), Collar *et al.* (1994), Davison (1992), MacKinnon & Phillips (1993), Mann (2008), Sheldon *et al.* (2001), Smythies (1957, 1960), Smythies & Cranbrook (1981).

Class AVES
Order PASSERIFORMES
Suborder OSCINES
Family MELANOCHARITIDAE
(BERRYPECKERS AND LONGBILLS)

- Small passerines, mostly rather dull-coloured, morphologically variable, two quite short-tailed and stubby-billed, three longer-tailed and with rather slender, straight bill, one with long straight bill, and four with short tail and proportionately long, decurved bill.
- 7.3–15 cm.

- New Guinea.
- Forest.
- 4 genera, 10 species, 32 taxa.
- No species threatened; none extinct since 1600.

Systematics

All of the berrypeckers and longbills are confined to New Guinea and its islands, and must presumably have originated there. They have not radiated out into adjoining areas away from the New Guinea continental plates. The members of what is currently recognized as the family Melanocharitidae have at different times been classified variously as flowerpeckers (Dicaeidae), honeyeaters (Meliphagidae) or sunbirds (Nectariniidae). Because of their morphological similarities with the flowerpeckers and the sunbirds, there were problems with their classification that lasted for more than a century. In the later decades of the twentieth century, C. G. Sibley and various co-workers were the first to reveal that the berrypeckers and longbills are, in fact, very basal within the oscine passerines, and associated with various “corvid” groups.

In two 1990 publications, Sibley and J. E. Ahlquist and Sibley and B. L. Monroe created a new family, Melanocharitidae, in which they placed six berrypeckers in the genus *Melanocharis*, together with the four longbills in the genera *Oedistoma* and *Toxorhamphus*. In the resurrected Paramythiidae they included the Crested Berrypecker (*Paramythia montium*) and the Tit Berrypecker (*Oreocharis arfaki*), these two species being known also as “painted berrypeckers”. Both families are closely allied to the sunbirds and the flowerpeckers. In his 1994–1996 CD ROM project, however, Sibley admitted that re-examination of the data obtained from DNA–DNA hybridization called into question the allocation of the Crested Berrypecker and the Tit Berrypecker and led to ongoing genetic studies, with the situation still not fully resolved at present. This is a fascinating time of massive flux within the classification of birds, as new techniques, data and discoveries continually emerge and cause earlier proposed definitions to be revised.

In their work *Phylogeny and Classification of Birds*, Sibley and Ahlquist divided the oscines into two monophyletic clades, to which they applied the respective names “parvorder Corvida” and “parvorder Passerida”. DNA–DNA hybridization, however, is a rather coarse and imprecise phylogenetic method in comparison with the newer one of DNA-sequencing, which has revealed that these authors’ Corvida is, in fact, paraphyletic. Although the monophyly of Passerida has been basically corroborated, F. K. Barker and colleagues, in 2002, showed that Corvida was not a clade as such but, rather, a grade, and that Corvida as a taxonomic group does not really exist. Three more

clades form a polytomy with Corvoidea and Passerida: these are the New Zealand wattlebirds (Callaeidae), the cnemophiline satinbirds, and the Melanocharitidae. Current research holds that berrypeckers, satinbirds and wattlebirds are closely related at the base of the “core Corvoidea”, all being sister to the Passerida, but the precise relationships remain unclear, as the results differ depending on which genes have been studied.

Barker and colleagues reconstructed the “parvorder Corvida” as a basal paraphyletic grade within the oscine passerines and found strong evidence that several family-level taxa, including Alaudidae, Irenidae and Melanocharitidae, were misplaced in the hybridization results. They postulate that the oscine passerines arose on the Australian continental plate while it was isolated by oceanic barriers, and that a major northern radiation of oscines, the “parvorder Passerida”, originated following dispersal from the south.

Berrypeckers and the two satinbird genera *Cnemophilus* and *Loboparadisea*, the last two classified as birds-of-paradise (Paradisaeidae) but perhaps better separated as the family Cnemophilidae, have sometimes been grouped with the ancient New Zealand wattlebirds. The association of one of the wattlebirds, the Saddleback (*Philesturnus carunculatus*), with the berrypeckers and the cnemophilines, however, received low statistical support, and the systematic position of the wattlebirds is currently best regarded as unresolved.

Earlier, in 1993, L. Christidis and colleagues had investigated the affinities of the aberrant genera *Toxorhamphus*, *Oedistoma*, *Timeliopsis* and *Epthianura*, all conventionally associated with the honeyeaters in the family Meliphagidae. The analyses corroborated results obtained in studies using DNA–DNA hybridization, which suggested that *Toxorhamphus* and *Oedistoma* are not honeyeaters but are, in fact, related to the *Melanocharis* berrypeckers and the *Dicaeum* flowerpeckers. The Dwarf Longbill (*Oedistoma iliolophus*) was found to be more closely allied to *Melanocharis* than to *Toxorhamphus*, which is consistent with its generic separation from the latter, and contrary to groupings interpreted from DNA–DNA hybridization data. *Timeliopsis* was identified as a typical honeyeater, despite the atypical form of its tongue. The genus *Epthianura* was likewise aligned with the honeyeaters but, contrary to analysis by means of DNA–DNA hybridization, only as a sister-group of the core honeyeater assemblage.

Recognition of the genus *Oedistoma* has not been universal, and many authors list all four longbill species in *Toxorhamphus*,

As currently composed, *Melanocharitidae* contains ten species divided into four genera. Given the phenotypic diversity within the family, however, it is likely to be subdivided in future revisions. Even the genus *Melanocharis* itself, containing five species, may be split into two groups. One of these contains two small, fairly short-tailed and stubby-billed species, including the **Black Berrypecker**. The male of this species, pictured here, is indeed largely black with white pectoral tufts. These are sometimes hidden under the wing, but can be revealed as two conspicuous spots, presumably with an important signal function.

[*Melanocharis nigra*

Photo: Brian J. Coates]

notwithstanding the facts that the former was described almost 40 years before *Toxorhamphus*, and that the Pygmy Longbill (*Oedistoma pygmaeum*) has long been recognized as being significantly different from the others. Furthermore, although currently placed in the same genus, the two *Oedistoma* longbills are very different from each other, with rather distinct foraging methods (see Food and Feeding), and they may well be better separated generically.

The Spotted Berrypecker (*Rhamphocharis crassirostris*) is placed in a monotypic genus, but this is sometimes merged with *Melanocharis*. This species, however, exhibits striking morphological and plumage distinctions and some behavioural traits which make this merger seem premature, especially as details of its breeding biology are unknown and its vocalizations poorly known. Genetic information is currently lacking.

It seems probable that the family Melanocharitidae as currently defined is polyphyletic. Such diverse groupings as are presently included within it are likely to have quite distinct evolutionary histories, despite the fact that they are at present united in one family. The longbills, in particular, appear very distinct and would repay further study, as would the poorly known Spotted Berrypecker. In the near future, as the results of further research are published and the evolutionary history of the various species becomes better known, it may be expected that the species composition of the family and its genus-level constituents will change.

What seems likely to be a new taxon belonging to this family has recently been discovered, evidently by accident. Since 1985, a specimen from the Eastern Highlands of New Guinea, and bearing superficial similarities to a longbill, had been contained in a jar of pickled *Toxorhamphus* and *Oedistoma* specimens, where it remained unnoticed. It was only after molecular analyses of the jar's contents had been carried out that it became clear that the specimen in question was different from the others. It appears to exhibit some morphological differences, too. Further information on this unexpected discovery will be published in due course.

Morphological Aspects

As currently constituted, the family comprises ten very diverse species divided among four genera, which reflect differences in morphology and feeding habits. The five primarily frugivorous *Melanocharis* can be further divided into two small, quite short-

tailed and stubby-billed species and three longer-tailed ones. The first two, the Black (*Melanocharis nigra*) and Obscure Berrypeckers (*Melanocharis arfakiana*), can be separated by the colour of the pectoral tufts, which are white in the case of the former and yellow in the latter. These tufts are usually quite conspicuous in the field, where they may serve some kind of visual signal function; they also suggest a curious convergence with the pectoral tufts of sunbirds and flowerpeckers.

The three longer-tailed *Melanocharis* are the Fan-tailed (*Melanocharis versteri*), Mid-mountain (*Melanocharis longicauda*) and Streaked Berrypeckers (*Melanocharis striativentris*), all of which have varying amounts of white in the tail. This white ranges from being almost totally concealed, as is so with the

Three species of *Melanocharis* berrypecker form a distinct group because of their relatively long tails. Males in two of these taxa are basically glossy black above and sooty grey below. Pectoral tuft colour provides a useful clue to species identification in this duo, those of the **Mid-mountain Berrypecker** being pale yellow. Another distinctive trait is the extent of white in the tail, which in this case is mainly confined to the outer rectrices. Like the pectoral tufts, white tail flashes probably function as signals in the dark forest understorey.

[*Melanocharis longicauda*
capitata,
Ubaigubi,
EC New Guinea.
Photo: William S. Peckover]

A fifth member of *Melanocharis*, the **Streaked Berrypecker**, differs from other members of the long-tailed trio because it is sexually monomorphic. The male is a non-descript brown bird, just like the female. The white tail patch is reduced and almost entirely concealed, as is the pale pectoral tuft. An absence of distinctive features would render this species easily overlooked, were it not for a tell-tale buff eyering and a streaked impression imparted by the whitish or yellowish edging to the ventral plumage. The bills of long-tailed *Melanocharis* berrypeckers are rather slender, straight and dark, although that of the Streaked Berrypecker has a yellowish gape line, even in the male.

[*Melanocharis striativentris striativentris*, Ubaigubi, EC New Guinea. Photo: William S. Peckover]

Streaked Berrypecker, to being very obvious, as on the male Fan-tailed Berrypecker, and it may, again, have some signal function in the dimly lit forest undergrowth. All three species have a rather slender, straight dark bill. As with the two short-tailed members of the genus, the pectoral tufts can be used as a means of distinguishing the Mid-mountain Berrypecker, on which they are pale yellow, from the really quite similar Fan-tailed Berrypecker, which has white or yellowish-white tufts. Two subspecies of the Black Berrypecker, the nominate race and *pallida*, are also similar to the Mid-mountain Berrypecker in both male and female plumages, but they are much shorter-tailed.

Among passerines, the Fan-tailed and Streaked Berrypeckers are unusual in that the female is larger than the male in both length and weight. Females of these two species weigh 16–20 g, as opposed to 12–15 g for males, although the males appear longer-tailed. The females of all five *Melanocharis* are nondescript in plumage and not particularly distinctive, with colour combinations of drab olive, grey and yellowish. The Streaked Berrypecker lacks a distinct male plumage, both sexes being female-like. Otherwise, the males are basically dark and glossy above and greyish below, characters shared to some extent by the male Spotted Berrypecker and which may have led to its being placed by some authors in the genus *Melanocharis*. Male Fan-tailed Berrypeckers have a marked bright bluish iridescence on the crown and shoulders, which can be very striking when seen in sunlight. The male Mid-mountain Berrypecker also has a bluish gloss on the crown and mantle, but this seems much less vividly iridescent than is the case with its congener.

Although sometimes united with the other berrypeckers in the genus *Melanocharis*, the Spotted Berrypecker is somewhat different from them. Its noticeably long straight bill and the striking spotted plumage of the female and immature are very distinctive, as are some of its foraging habits (see Food and Feeding).

With the long decurved bill a most striking feature, the four longbills comprise a morphologically very distinct subgroup, for many years classified with the honeyeaters (see Systematics).

They forage for arthropods, and feed extensively from flowers, with nectar a significant part of their diet. In terms of bill structure and habits, they seem to exhibit a convergence with such other families as the honeyeaters and the sunbirds. All four longbills are similar in plumage to female *Melanocharis* berrypeckers, having olive, yellow and grey colours, but they are somewhat brighter yellow than are the latter.

Habitat

All members of this family are endemic New Guinea forest-dwellers. They range from the lowlands up to the tree-line. The Black Berrypecker and the Yellow-bellied Longbill (*Toxorhamphus novaeguineae*) occur on some of the West Papuan Islands and in the Aru Islands, as well as on the Geelvink Bay island of Yapen. The Dwarf Longbill is likewise found on Yapen, and is present also in the D'Entrecasteaux Archipelago, where it lives on the islands of Normanby, Fergusson and Goodenough, with the Pygmy Longbill present on the last two and also on Waigeo and Misool, in the West Papuan Islands.

Berrypeckers and longbills utilize most types of forest, ranging from riparian forest in the lowlands to monsoon forest, hill forest, vine thickets, and the various types of montane forest, avoiding only the open eucalypt (*Eucalyptus*) savanna habitats of the Trans-Fly. One species, the Fan-tailed Berrypecker, will even visit tree-fern savanna at very high altitudes. They occur along the edges of forest, as well as in the interior, and most species seem to tolerate some degree of disturbance, so long as good forest remains nearby. Although they sometimes forage out into clearings and may visit native gardens, large-scale logging, an increasing problem in New Guinea, would be disastrous for them.

One interesting example of the possible use of distinctly different habitat strata by the two sexes of the Black Berrypecker was noted by H. L. Bell. In his studies at Brown River, near Port Moresby, Bell recorded that males of this species ascended higher

The **Fan-tailed Berrypecker** is unusual for a passerine in that the female is longer and heavier than the male.

In terms of plumage, however, the direction of sexual dimorphism is normal for the genus *Melanocharis*, with smartly clad black-and-grey males easily distinguished from drab greenish females.

Both sexes have a conspicuous fan-shaped tail with large flashes of white. This overall pattern often leads to this species being misidentified as the almost mythical Papuan Whipbird (*Androphobus viridis*), especially when birds are foraging on the ground, or moving low through dark understorey.

[*Melanocharis versteri virago*,
Huon Peninsula,

Peckover]

Sometimes placed in the genus *Melanocharis*, the **Spotted Berrypecker** is unique in several respects. The distinctively speckled plumage of females and immatures, shown here, is not found in any other member of the family. The rather long and straightish bill is also unusual, as is the habit of foraging in groups of up to 12 individuals at flowering trees. These divergent traits, along with the paucity of information about its song and breeding biology, suggest that the Spotted Berrypecker should probably be retained in a monotypic genus until its taxonomic relationships are clarified.

[*Rhamphocharis crassirostris piperata*, Saruwaged Range, Huon Peninsula, New Guinea. Photo: William S. Peckover/VIREO]

into the canopy than did females. A similar situation may apply also to this species' congeners, but this requires further investigation. Indeed, the ecological mechanisms of niche-partitioning in the genus *Melanocharis* offer a fruitful field of study.

Melanocharitid species that occur in the lowlands are the Yellow-bellied Longbill, the Pygmy and Dwarf Longbills and the Black Berrypecker. There is a guild of avian species that inhabit hill forest grading into lower montane formations, from about 600 m to 1900 m, and this includes the Obscure Berrypecker, which ascends to 1100 m, and the Mid-mountain Berrypecker, Streaked Berrypecker and Slaty-chinned Longbill (*Toxorhamphus poliopterus*), the Dwarf and Pygmy Longbills and the Black Berrypecker also ranging up into the lower hills. The higher-altitude species are the Spotted and Mid-mountain Berrypeckers, with the Fan-tailed Berrypecker at the highest elevations of all, up to the tree-line at about 3680 m.

General Habits

The *Melanocharis* berrypeckers tend to be fairly active but unobtrusive inhabitants of the lower and middle levels of the New Guinea forests, where they forage in trees, shrubs and vines for, primarily, small fruits (see Food and Feeding). They move rapidly from one feeding place to another, and seem to associate loosely with mixed-species flocks, rather than being core members of these. Some species have been reported in small groups of three or four individuals, presumably family parties. The Obscure Berrypecker is a more arboreal member of the family, resembling a flowerpecker in its habits, but male Black Berrypeckers, too, do ascend into the canopy of flowering trees, as does the Spotted Berrypecker, which has an unusually long bill and a slightly more honeyeater-like feeding strategy. The two small *Melanocharis* species, namely the Obscure and Black Berrypeckers, could be mistaken for flowerpeckers, while the Fan-tailed Berrypecker, especially if foraging low in the understorey or on the ground, is sometimes misidentified as the rare and almost unknown Papuan Whipbird (*Androphobus viridis*).

Longbills are rather different from the berrypeckers in their behaviour. The two *Toxorhamphus* species spend much of their time in feeding from flowers and are much more nectarivorous

and insectivorous than are berrypeckers, having an almost sunbird-like role within the forest and replacing each other altitudinally. The other two longbills, in the genus *Oedistoma*, are segregated clearly by habitat and feeding niche, the Dwarf Longbill in the understorey and middle levels and the Pygmy Longbill mainly in the upper levels to the canopy.

Relatively little else is known of the behaviour of the members of this family. Drinking and bathing have been reported for the Black Berrypecker, but neither activity has as yet been confirmed for any of the other berrypeckers or for the longbills. The Dwarf Longbill has been observed at forest pools, but it is uncertain whether it was drinking, bathing or, perhaps, merely foraging.

It may be that the diet of these birds provides sufficient in terms of the daily water requirements. The roosting behaviour remains unrecorded for all the species.

Melanocharitids appear to be primarily sedentary, with some suggestion of local movements or wandering recorded for the Mid-mountain Berrypecker and, perhaps, the Yellow-bellied Longbill. The degree of territoriality is little known.

Voice

None of the berrypeckers and longbills is remarkable for the beauty of its vocalizations, but most are quite poorly known and much remains to be learned about them. The berrypeckers are, on the whole, not particularly vocal birds. They do sing, but whether or not the females, as well as the males, do so is uncertain. The Obscure, Black and Mid-mountain Berrypeckers utter a similar but specifically distinct high-pitched rapid swizzling series, and their vocalizations may be related to the holding of breeding or feeding territories, as they are noted as singing from the same site over protracted periods of time. Moreover, Black and Obscure Berrypeckers respond well to playback of taped recordings, which again suggests territoriality. The Black Berrypecker is the best-known member of the family and seems to have several song types, with some degree of variation according to locality and/or subspecies. One of its calls is similar to that of the Green-backed Gerygone (*Gerygone chloronota*).

Apart from berrypeckers, the family Melanocharitidae contains four species of longbill. Their plumage is generally dull olive, in common with females of several berrypeckers, but their decurved bills are highly distinctive. Two common longbill species are placed in the genus *Oedistoma*. They are ecologically segregated by habitat, with the **Dwarf Longbill** occurring in the lower and middle storeys of evergreen forest. Although this is one of the most abundant of New Guinea passerines, the only vocalizations reported are scolds and flight calls. Indeed, the apparent lack of territorial song in both *Oedistoma* species suggests that they may be only weakly territorial.

[*Oedistoma iliolophus flavum*,
near Brown River,
SE New Guinea.
Photo: Brian J. Coates]

The voices of the Black and Mid-mountain Berrypeckers are sibilant and rather buzzy, and are similar in quality but again specifically distinct. One song of the former is a “whit-ee-chee whit-ee-chee whit-ee-chee” series, which may rise in volume after a quiet start. This species also emits a wheezy drawn-out note, which is often given in flight and closely resembles the call of the Variable Dwarf-kingfisher (*Ceyx lepidus*). A rather striking feature of the family is that many of its members have voices that are similar to those of other, unrelated species such as the aforementioned kingfisher, the Garnet Robin (*Eugerygone rubra*), gerygones, honeyeaters and jewel-babblers (*Ptilorrhoa*), or in some cases resemble those of the more closely related flowerpeckers. Mimicry, however, has not been noted for any of the family, despite the oddly plastic nature of some songs and calls, which resemble those of other species but seemingly without being copies.

Of the remaining two *Melanocharis* species, the Fan-tailed Berrypecker appears to have a somewhat different voice. One of its calls has been likened to the high-pitched call of a jewel-babbler, and a song of one of its subspecies is reminiscent of the reeling song of the Garnet Robin. In general, however, this species remains poorly known. Even less is known about the Streaked Berrypecker, but it is said to have a scratchy trisyllabic series, harsher than that of its congeners, and a distinctive loud “seep” call repeated every few seconds. Although in a different genus, the Spotted Berrypecker reportedly has a voice similar to that of the *Melanocharis* group, albeit rather insect-like, and with one call resembling that of the Red-collared Myzomela (*Myzomela rosenbergii*). It is not known what significance the calls of these three species may have with regard to the possible maintenance of feeding or breeding territories.

Compared with the berrypeckers, the four longbill species are much more vocal. The two *Toxorhamphus* longbills have distinct and frequently given songs, which may well play a part in territorial maintenance and advertising. They respond well to playback, too, which supports this notion. The songs of this species pair are quite similar to one another but specifically distinct, and are characteristic sounds of the New Guinea forests, where these birds are heard far more often than they are seen. The two species are similar also in the buzzy, rather flowerpecker-like notes that they utter. In addition, the Slaty-chinned Longbill has a song

not unlike one of the songs delivered by the Scrub White-eared Honeyeater (*Meliphaga albonotata*).

Finally, in the genus *Oedistoma*, the Dwarf Longbill is unusual in that it appears not to have any song as such, giving only scolding anxious-sounding “twik” notes and a sharp, dry flight call. It is one of the commonest birds of lowland and hill forests in New Guinea, and it seems strange that no song has yet been noted for it. This situation would repay further study. It may be that the Dwarf Longbill’s song has simply been overlooked or be very similar to that of another species, and, as the longbill is so active, it is hard to watch it for very long. The same applies to its congener, the Pygmy Longbill, another common species of lowland

Once treated as meliphagid honeyeaters, longbills also superficially resemble some spiderhunters or sunbirds (Nectariniidae). They are very distinct both in terms of morphology and behaviour, and it is possible that they warrant separation at the family level. Unlike their relatives in *Oedistoma*, the *Toxorhamphus* longbills have loud songs which are amongst the most familiar and distinctive sounds of New Guinea forests. For this reason, the **Yellow-bellied Longbill** is heard far more often than it is seen, and is suspected to be strongly territorial.

[*Toxorhamphus novaeguineae*
novaeguineae,
Prince Alexander Mts,
N New Guinea.

Photo: William S. Peckover]

The **Slaty-chinned Longbill** forms a species pair with the Yellow-bellied Longbill (*Toxorhamphus novaeguineae*). It is generally restricted to the montane zone, ascending in forested regions just as far as the lower boundary of mossy elfin forest, which it tends to avoid. It occurs down to around 1000 m, but can be found much lower where the Yellow-bellied Longbill is absent, as around Port Moresby. Indeed, these taxa often replace each other altitudinally with only limited overlap, a distributional pattern suggestive of competitive exclusion between ecologically similar species.

[*Toxorhamphus poliopterus poliopterus*, Heroana, EC New Guinea. Photo: William S. Peckover]

and hill forests. Likewise, no vocalization yet reported for this melanocharitid qualifies as a song; the only utterances reported are quiet musical chattering and a constant quiet clicking "chit chit" series, which seems to be a contact note for the flocks. It is perhaps possible, therefore, that the two *Oedistoma* species do not sing as such.

Food and Feeding

The berrypeckers are aptly named. Although detailed dietary studies are as yet lacking for the Melanocharitidae, it is evident that berries and small fruits form a significant proportion of their food. Arthropods are also important items in the diet, these being obtained mainly by gleaning from foliage. Some members of the family, such as the Black and Obscure Berrypeckers and the longbills, also use hovering as a means of capturing arthropods, and Black Berrypeckers have been seen to take spiders (Araneae) and trapped insects from spider webs.

Although generally foraging solitarily or as pairs, the *Melanocharis* berrypeckers may occasionally join mixed-species flocks. They seem rarely, however, to be an integral part of such feeding parties, keeping somewhat on the periphery. They are very active birds, seldom perching for long unless feeding on berries. Nevertheless, the Obscure Berrypecker has been observed as sitting motionless, perched up in the middle stratum of the forest, in the manner of a flycatcher of the petroicid genus *Microeca*. This species' feeding habits, involving much arboreal foraging, seem perhaps more akin to those of the flowerpeckers than to those of the rest of the Melanocharitidae.

Quite how the Mid-mountain Berrypecker is ecologically segregated from the Black Berrypecker or the Fan-tailed Berrypecker where it overlaps with either of these congeners is uncertain, although in general they seem to be largely separated by altitude. In addition, the Fan-tailed Berrypecker is quite regularly observed to forage very low down or on the ground, far more so than are any of its congeners, which seem rarely to descend that low. It is possible that the somewhat patchily distrib-

uted Mid-mountain Berrypecker is competitively excluded from some sites by the sympatric Streaked and Fan-tailed Berrypeckers, but again the details of niche-partitioning are almost unknown.

Field studies have suggested that the sexes of the Black Berrypecker may differ somewhat in their preferred foraging methods, the males often ascending into the canopy to exploit fruiting or flowering trees and the females keeping more to the middle storey and lower levels of the forest. This apparent difference in foraging habits may apply also to the other two *Melanocharis* species that exhibit distinct sexual plumage dimorphism, the Fan-tailed and Mid-mountain Berrypeckers, but it is poorly known and requires further investigation.

The Spotted Berrypecker, in the monotypic genus *Rhamphocharis*, is unusual within the family in being the only species reported to form flocks, up to twelve individuals having been noted together at flowering trees. Whether nectar is a feature of its diet or whether it is attracted instead by insects that gather at the flowering trees is not known. The diet of this melanocharitid seems to consist of berries and small fruits, such as figs (*Ficus*), and arthropods, but it is a poorly known species, rather honeyeater-like in its habits and with an unusually long straight bill. Further study of its behaviour could prove enlightening.

The two *Toxorhamphus* longbills form a neat species pair, replacing each other altitudinally, but they have similar feeding strategies, moving continually and sometimes joining mixed-species feeding flocks with monarch-flycatchers (Monarchidae) and gerygones. It is likely that competition between them has an influence on whether or not they are present at a given place, the Slaty-chinned Longbill occurring at much lower levels than normal when the Yellow-bellied Longbill is absent. The former species comes down to about 300 m in the hinterland of Port Moresby, where the latter is absent, but hill or montane forest is a preferred habitat over much of the range and may determine altitudinal limits elsewhere. Both species are insectivorous and also nectarivorous, as the shape of the bill would suggest, although details of the diet are poorly known. They occupy a rather sunbird-type niche within the forest, with forest-interior inhabitants of the family Nectariniidae being absent in New Guinea.

Berrypeckers and longbills inhabit the lower and middle strata of New Guinea forests, moving restlessly, rarely staying long in one location, and often associating only loosely with multi-species foraging parties. Partly because of their unobtrusive nature, very little is known about their behaviour and ecology. Their roosting, bathing and breeding behaviour is almost unknown, their seasonal or altitudinal movements are obscure, and even the extent to which they defend territories is unclear. To date, the only species which has been reported drinking and bathing is the **Black Berrypecker** (a female is pictured here). It is likely that similar activity will be reported in other species of berrypecker and longbill.

[*Melanocharis nigra unicolor*,
near Brown River,
SE New Guinea.
Photos: Brian J. Coates]

Although currently treated in the same genus, the two *Oedistoma* longbills are very different from each other in several respects, including foraging methods. The Dwarf Longbill is a very active forager in the understorey and shrub layer, also occupying, as do the two *Toxorhamphus* longbills, a niche approximating to that of a forest sunbird; it is frequently seen to probe at flowers of trees, shrubs, vines and gingers (Zingiberaceae), presumably taking nectar. It will also take arthropods by gleaning and hover-gleaning, and it has, in common with the Black Berrypecker, been seen to raid spider webs. It will sometimes associate loosely with mixed-species feeding flocks, but its very active behaviour seems to preclude it from spending much time at any one site. The Dwarf Longbill has been recorded at forest pools, but it is not known whether it was foraging at this level.

Conversely, the Pygmy Longbill is a much more arboreal species, keeping in the middle and canopy layers and rarely descending lower. It is thus largely segregated by foraging height from its congener and from the *Toxorhamphus* species. The rather short but decurved bill suggests that nectar is a significant part of its diet, and it is often seen to feed from flowers in the canopy. In addition, it takes arthropods by gleaning and while hovering, but the dietary details are largely unknown. The Pygmy Longbill is often seen in small groups of from four to, sometimes, as many as ten individuals. It occurs at flowering trees with other nectarivorous species, such as honeyeaters and lorikeets (Psittacidae), and sometimes joins mixed foraging flocks with Black-fronted White-eyes (*Zosterops minor*), Hooded Pitohuis (*Pitohui dichrous*) and Green-backed Gerygones.

Breeding

Breeding records for the Melanocharitidae are extremely few, this aspect of the life of these species being either very little known or virtually unknown. Very little information is available on nests and clutch size, and there are no data on fledging and incubation periods. The extent to which the members of this family are territorial during nesting is uncertain, but their vocalizations (see Voice) do suggest clearly that some species, at least, maintain breeding territories.

Nests have been found more or less throughout the year, with no distinct temporal pattern, and with records from both wet and dry seasons, as is typical of many tropical passerines. It may well be the case that the female alone constructs the nest, although this has been noted so far only for the Black Berrypecker. Both sexes of this species feed the young, but such details are lacking for the rest of the family. Both the Streaked Berrypecker and the Black Berrypecker are known to lay two eggs; nests containing single eggs, as reported for Fan-tailed and Black Berrypeckers, may well represent incomplete clutches. It is not known whether these species are single-brooded or multiple-brooded.

The few berrypecker nests found have been cup-shaped and bound to branches or vines. Fern stems and fronds are important construction materials for Black, Fan-tailed and Streaked Berrypeckers, all of which also decorate the outside of the nest with patches of pale greenish lichen. These pale patches perhaps have a camouflaging function, helping to reflect light and break up the outline of the nest, even if there are no lichens on the branch itself. The Mid-mountain Berrypecker is reported to build a high-sided cup-shaped nest slightly constricted at the top and quite large for the size of the bird, but the eggs of this species are unknown. This berrypecker has been noted as nesting in January, and a female was in breeding condition in September.

Nothing is known of the breeding behaviour of the Spotted Berrypecker except for the fact that a juvenile was found in September. Similarly, the Obscure Berrypecker is virtually unknown, although there are now two records of what are likely to be juvenile-plumaged individuals in July and October.

The Yellow-bellied Longbill is one of the characteristic and commonest members of the avifauna of lowland rainforest, yet its nesting habits are essentially undescribed. Its more montane congener, the Slaty-chinned Longbill, makes a cup-shaped nest similar to that of the berrypeckers, bound with spider web, decorated with spider egg sacs, and lined with plant down. Nests of the latter

The berrypeckers are aptly named, as small fruits are an important component of their diet. The **Fan-tailed Berrypecker**, for example, often plucks berries directly from fruiting shrubs and trees, either while perched or when hovering. It usually forages in the lower or middle storeys of forest, but will ascend to the canopy when fruits are present. It has also been noted gleaning arthropods from foliage, often close to the ground. Indeed, behavioural observations suggest that this species, and most other berrypeckers, regularly consume insects.

[*Melanocharis versteri*,
W New Guinea.

species are noted from the late wet season to the early dry season, varying with local conditions. They have reportedly contained a single egg, though this may represent an incomplete clutch.

One of the commonest of New Guinea's hill-forest birds is the Dwarf Longbill, yet the only nest of which details are available is from Fergusson Island, as long ago as 1896. This, too, was cup-shaped, made of dried grass and lined with soft vegetable silk, and it held a single egg. The Pygmy Longbill, another common bird of the lowland and hill forests, is even less known, and its nest has not yet been described.

Thus, the breeding biology of two of the four longbills is still largely unknown, and that of the other two is very little known. This represents a major gap in knowledge of the family, and efforts to elucidate these aspects of the two genera concerned, *Oedistoma* and *Toxorhamphus*, could be invaluable in helping to resolve the systematic position of all four species.

Accurate data on the longevity of the family's members are, predictably, extremely few. Ringing studies have revealed that a Black Berrypecker lived for longer than 6 years and 6 months, but no comparable information exists for the remaining nine species.

Movements

Melanocharitids appear to be primarily sedentary, with some suggestion of local movements or wandering recorded for the Mid-mountain Berrypecker and, perhaps, the Yellow-bellied Longbill. There is a need for some long-term ringing studies as a means of shedding light on this poorly known phenomenon.

Living in the rich environment of the tropical rainforests of New Guinea, these birds have no need for migration, or even much in the way of local movements if the food resources are as plentiful as they usually are for the Melanocharitidae. Berrypeckers and longbills, whether they are lowland, middle-altitude or highland species, appear to stick to their regular patches, with very little reported in the way of dispersal. The Spotted Berrypecker occasionally gathers in small flocks at flowering trees, which could indicate some sort of nomadism linked with the fruiting or flowering of trees, but such observations are at present rather few and incidental in nature. An immature Mid-mountain Berrypecker is known to have wandered down to the lowlands of Central Province, suggesting that dispersal may occur at times. Both this species and the Black Berrypecker are very occasionally reported at about 750 m near Tabubil, in Western Province, in an area in which they are not usually seen; these are unobtrusive birds, however,

In comparison with berrypeckers, the longbills tend to consume less fruit but more nectar and insects.

The *Toxorhamphus* species have an ecological niche more akin to sunbirds (*Nectariniidae*), which are absent from the forests of New Guinea.

The **Slaty-chinned Longbill**, for example, regularly probes the flowers of trees, vines and shrubs, including gingers (*Zingiberaceae*), presumably in search of nectar. It will also take arthropods by gleaning and hover-gleaning, occasionally stealing items from spiders' webs.

[*Toxorhamphus poliopterus poliopterus*,
Ubaigubi,
EC New Guinea.
Photo: William S. Peckover]

The breeding behaviour of berrypeckers and longbills is very poorly known, as only a few relevant observations have been reported. Sketchy details are known for the *Melanocharis* berrypeckers, including the **Fan-tailed Berrypecker**. Their nests are cup-shaped structures bound to a vine, placed in an upright fork or balanced on top of a branch. They are typically built with fine plant fibres, fern fronds and moss, and bound and strengthened with the silk of spiders' webs. Exterior walls are usually decorated with fragments of pale green lichen, presumably as camouflage. It is thought that only the female constructs the nest and incubates, but that both sexes feed the young. Further observations are required to confirm this hypothesis. Another focus for future research is the breeding behaviour of the *Oedistoma* and *Toxorhamphus* longbills, about which almost nothing is known. Some details about nest architecture in this group may help to elucidate their taxonomic relationships.

[*Melanocharis versteri*
virago,
Tari Gap, New Guinea.

Dawn Frith]

Very little is known about the basic breeding biology of berrypeckers and longbills. In particular, no data are available for fledging and incubation periods in any member of the family, nor is it known whether they are single-brooded or multiple-brooded. On the basis of very few reports, the typical clutch size appears to be two eggs. Previous observations of nests containing one egg may represent incomplete clutches, but it seems likely that single-egg clutches do occur, as this photograph of a hatching Fan-tailed Berrypecker attests.

Dawn Frith]

and this apparent absence of records could simply be a reflection of lack of observer coverage.

Mid-mountain Berrypeckers are reported as being absent sometimes from areas where they normally occur, suggesting that some kind of local nomadism may be involved, but details are few and the species is secretive and easily overlooked. As with the two berrypeckers mentioned in the preceding paragraph, Yellow-bellied Longbills have been seen at about 750 m near Tabubil, in an area where they are not usually found, again raising the prospect of sporadic local wandering. The phenomenon is largely unknown and hitherto little reported, and it certainly merits further study. It may well be that some local movements do occur at times, perhaps associated with weather conditions such as drought or prolonged heavy rain, or there could be some kind of altitudinal or age-related dispersal. Only longer-term ringing studies are likely to provide much-needed information on this poorly understood aspect of berrypecker biology.

Relationship with Man

The berrypeckers and longbills do not figure much in the lives of the people of New Guinea, beyond the occasional snaring or catapulting of one for later consumption as food. Their dull plumages and small size mean that they are not suited for *bilas*, personal adornments, which are still important in some areas and have an adverse effect on some of the larger, showier species such as parrots (Psittacidae) and birds-of-paradise.

Since the taxonomic status of the berrypeckers and longbills was elevated to that of family rank (see Systematics), a recent development has been a rise in their "significance profile" for visiting birdwatchers. Many of these are anxious to add to their lists of collective bird families observed, and the Melanocharitidae, along with the other endemic New Guinea families the Paramythiidae and – often treated as a family – the Cnemophilidae, are now an important part of their birding agenda.

The mysterious Obscure Berrypecker, until recently one of the least-known birds in the world, has also been the subject of several articles in popular magazines. These have detailed the circumstances of its original collection, its apparent disappearance for more than 50 years during the middle of the twentieth century, and its subsequent rediscovery in the late 1970s.

The family is also something of a challenge for avian taxonomists. As mentioned earlier (see Systematics), some of the

species have been assigned to various families over the years, and there is continuing uncertainty over their final placement. The resolution of this is dependent on further research, but a number of taxonomic alterations can be expected in due course.

Status and Conservation

Nine of the ten species of Melanocharitidae are considered by BirdLife International to be of Least Concern. They all have wide distributional ranges on the very large island of New Guinea and are not faced with any obvious immediate wide-ranging threats. There are, nevertheless, some local and recently increasing losses as a result of logging, mining activities and forest clearance for gardens, as the human population grows at an alarming rate, so there is no room for complacency.

Logging and a systemic failure to follow environmental planning processes, both in the Indonesian part of the island, West Papua, and in Papua New Guinea itself, are serious and growing problems, with high-level corruption evident in both countries. This is likely to worsen as demand for timber increases, prices rise, and rapacious Chinese and Malaysian commercial companies do whatever is necessary in order to maintain a ready supply of raw timber, often with potentially disastrous long-term consequences for the environment and local human communities. It is becoming urgent that a properly certificated international system be put in place in order to ensure that logs derive only from sustainable and properly run ventures, and not from short-term "rip-and-run" exploitation. All of this has profound long-term environmental implications for the New Guinea ecosystems, of which the berrypeckers and longbills are an essential component.

One melanocharitid, the aptly named Obscure Berrypecker, is a Data-deficient species and one of the most mysterious of New Guinea birds. Originally described from the Arfak Mountains, in the Vogelkop of north-west New Guinea, it seems not to have been recorded there since. Otherwise, it has been found at five widely separated areas in the eastern half of New Guinea. It is possibly simply a cryptic arboreal species that has been frequently overlooked, as recent records of this berrypecker, or of a very similar but as yet undescribed taxon, from several widely separated sites suggest that it is, in fact, fairly common. Nevertheless, as some doubts have expressed as to the validity of some of these recent reports, study of the type specimen, held in the Natural History Museum of Leiden, in the Netherlands, is being carried out.

Both the Streaked and the Spotted Berrypeckers appear to be decidedly uncommon species, occurring at low density overall, but the Black, Mid-mountain and Fan-tailed Berrypeckers are all often quite common. At a study site in lowland rainforest at the Brown River, near Port Moresby, the estimated density of Black Berrypeckers was as high as 20 individuals per 10 ha.

Similarly, the four species in the longbill subgroup are all quite common forest-dwellers, with no immediate concerns for their conservation. Indeed, the Slaty-chinned Longbill was reported as being the most abundant bird in the forest at 1200–1700 m on Mount Karimui, accounting for some 9% of the total avifauna in that locality. Yellow-bellied, Pygmy and Dwarf Longbills are likewise common birds of the lowland forest, the first and last of these three often being among the most numerous small passerines in this habitat.

Genus *MELANOCHARIS* P. L. Selater, 1858

1. Obscure Berrypecker

Melanocharis arfakiana

French: Piquebaie obscur **German:** Arfakbeerpenpicker **Spanish:** Picabayas Oscuro
Other common names: Arfak Berrypecker

Taxonomy. *Dicaeum arfakianum* Finsch, 1900, Arfak Mountains, New Guinea.

Perhaps forms a species pair with *M. nigra*. Birds from Boana, in S Huon Peninsula, exhibit better-marked pale eyering than those in rest of range, but taxonomic significance, if any, of this is uncertain. Monotypic.

Distribution. E half of New Guinea: Tabubil area (in Western Province), Keki (in Adelbert Mts), Boana (near Lae), and near Port Moresby at Efogi (on the Kokoda Trail) and Varirata. Also Arfak Mts (NW New Guinea), but no records subsequent to its original discovery there.

Descriptive notes. 11.5 cm; 11.5 g. Very small, quite short-tailed arboreal berrypecker with distinctively pale stubby bill. Upperparts are dull brownish to olive-greenish, with markedly greyish head, and grey crown, nape and mantle; dingy olive-grey below, with paler throat, yellowish wash on flanks, whitish-grey belly (sometimes washed yellow), bright lemon-yellow pectoral tufts; undertail-coverts and underside of tail grey, underwing-coverts whitish; iris dark, sometimes pale brown, with very thin faint orange eyering (visible in the hand); bill horn-coloured or pinkish-horn, sometimes brownish-grey above and dull orange below, gape yellow-orange; legs olive-green (appear brownish in the field) with slightly paler soles. Distinguished from similar female-plumaged *M. nigra* mainly by bright yellow (not white or yellowish-white) pectoral tufts, greyish head, pale bill, also by voice. Sexes alike. Immature not certainly described; Jul and Oct individuals resembling adult but with faint narrow dark streaks on dingy yellowish underparts were possibly immatures. Voice. Very rapid swizzling "swizzly swizzly swizzly" series, sometimes shortened, given from high in trees; resembles that of *M. nigra*, but distinctively much faster and higher-pitched. Sharp "zit-zit-zit" call noted from birds at Efogi.

Habitat. Hill forest, forest edge and secondary growth, also native gardens adjacent to forest; from 640 m to at least 1100 m.

Food and Feeding. Few data on diet. Known to take small berries; one specimen had arthropod remains in stomach. Seen singly or in presumed pairs. Strongly arboreal, frequenting middle levels and lower canopy; descends to shrub layer to take berries. Active, usually keeping quite high up, flying rapidly from tree to tree, behaviour not unlike that of Red-capped Flowerpecker (*Dicaeum geelvinkianum*); will also sit motionless for minutes on end at c. 5–8 m, rather in manner of a *Microeca* flycatcher (Petroicidae). Has been noted as hovering and gleaning from foliage, presumably for arthropods.

Breeding. Probable juveniles seen in Jul and Oct, mutual chasing by presumed paired individuals in May–Aug, and family party of four at Efogi in Sept. Strong response to playback of tape recording at these times suggests territoriality; apparent territories quite large, c. 200 m in linear dimension. No other information.

Movements. Resident, perhaps moving locally in response to fruiting of trees. Found in same sites around Tabubil throughout year.

Status and Conservation. Data-deficient. Restricted-range species: present in West Papuan Highlands EBA and Central Papuan Mountains EBA. One of the least-known New Guinea birds; very easily overlooked as it is quite strongly arboreal, active, and hard to see well. Originally described from the Arfak Mts, in NW New Guinea, but not recorded there since; otherwise recorded from five widely separated areas in Papua New Guinea. Only two specimens, one dated 1867 from the Arfaks and one in 1933 from SE part of the island, until some reported sightings from the Kokoda Trail, near Port Moresby (in 1978/79 and 1980/81), and from Tabubil, in Western Province (1978, 1987). These later reports, widely doubted at the time, now seem perfectly plausible in light of subsequent discoveries. Individuals found at Boana, near Lae, in 1991 and near Tabubil in 1992 appear to be of this species, and are clearly not *M. nigra* or *M. versteri*, suspicions of which clouded some of the earlier reports; the possibility that they represent an undescribed taxon very similar to present species seems exceedingly remote. Two males tape-recorded and collected in Jul 1994 above Tabubil appear to fit the scanty published descriptions of present species, but confirmation of their identity requires comparison with the type specimen (the 1933 specimen was preserved in alcohol, and may likewise never have been compared with the type; it is likely to have become faded over the years). The species is widespread at a number of sites around Tabubil from 640 m up to c. 1100 m, and has been found at Keki, in foothills of Adelbert Mts, at c. 1000 m, and at a similar altitude at Boana, near Lae; it has also been heard at c. 800 m in Varirata National Park, adding credence to earlier reports from the Efogi and Ower's Corner area from late 1970s to 1981. Probability is that this species is fairly widespread but cryptic and has simply been overlooked.

Bibliography. Anon. (2007a), Beehler *et al.* (1986), Butchart & Stattersfield (2004), Coates (1990), Coates & Lindgren (1978), Coates & Peckover (2001), Collar *et al.* (2001), Finch (1979, 1980a, 1982a), Gregory (1995a, 1995b, 1997), Gregory & Eastwood (1994), Gregory & Webster (2004), Mayr & Rand (1936), Murray (1988a), Opi (1975), Rand & Gilliard (1967), Salomonsen (1960a), Schodde (1978a), Shackelford (2006), Stattersfield & Capper (2000).

2. Black Berrypecker

Melanocharis nigra

French: Piquebaie noir **German:** Weißbüschel-Beerenpicker **Spanish:** Picabayas Negro

Taxonomy. *Dicaeum niger* Lesson, 1830, Manokwari, western New Guinea.

Perhaps forms a species pair with *M. arfakiana*. Four subspecies recognized.

Subspecies and Distribution.

M. n. pallida Stresemann & Paludan, 1932 – Waigao I, in West Papuan Is.

M. n. nigra (Lesson, 1830) – West Papuan Is (Salawati and Misool) and NW New Guinea (Vogelkop).

M. n. unicolor Salvadori, 1878 – Geelvink Bay (Yapen I) and N, E & SE New Guinea.

M. n. chloroptera Salvadori, 1876 – Aru Is, and SC New Guinea from Mimika R E to Fly R.

Descriptive notes. 11.5 cm. Small, active, quite short-tailed and stubby-billed forest berrypecker. Male nominate race is shiny blue-black above and dark grey below, with white pectoral tufts and whitish underwing-coverts; iris brown; bill black; legs grey. Female is rather nondescript, dull olive-green above, olive-grey below, with white or yellowish-white pectoral tufts and underwing-coverts. Immature is like female, but underparts lightly washed yellowish, pectoral tufts and underwing-coverts yellowish-white, paler base of lower mandible. Races differ mainly in plumage colour of males: *chloroptera* is like nominate but with upperwing-coverts and remiges edged green, contrasting with black of back; *pallida* has black upperparts and grey underparts; *unicolor* is entirely shiny blue-black, apart from pectoral tufts. Voice. Song a rapid high-pitched stuttering twittering sequence, e.g. "whit-ee-chee whit-ee-chee whit-ee-chee", with variations on patterns within each song; may begin quietly but quickly gains volume, and often stops suddenly. Gives very fast, jumbled "chee-per-chee-per-chee", similar to call of presumed *M. arfakiana* but lower-pitched and slower. A common call is a rather wheezy drawn-out note very like call of Variable Dwarf-kingfisher (*Ceyx lepidus*), scolding upslurred and rather wheezy "schree", also a series of short high-pitched insect-like "tsee-see-tsee" notes at variable speed which may be given by two individuals antiphonally. Some regional variation, but all calls fall broadly within same structure; in Adelbert Mts (race *unicolor*) a trisyllabic "wi ti tiieew" followed by reeling "tiddler-tiddler-tiddler"; race *chloroptera* at Mt Karimui said to utter a very rapid series of thin twittering notes the pitch of which "describes a perfect sine wave".

Habitat. Rainforest, hill forest, monsoon forest, tall secondary growth; also visits canopy of mature teak (*Tectona*) plantations. Sea-level to c. 1200 m; locally to 1450 m where congeners absent.

Food and Feeding. Small berries, also insects and spiders (Araneae). An active feeder, frequently moving and rarely still for long, except when feeding on berries. Gleans from branches and foliage; also hovers at times, and observed to take insects from spider webs. Studies suggest that males may forage at higher levels than those preferred by females; former often recorded high in canopy of fruiting or flowering trees, whereas females forage more in middle and lower storeys of forest.

Breeding. Recorded in May, Jun, Sept, Oct, Dec and Jan, and may occur in both wet and dry seasons; noted in pairs from Apr to Dec in Port Moresby area. Vocalizes from perch in middle storey and then shifts rapidly to another, behaviour possibly associated with territoriality. Nest, built by female alone, cup-shaped, neat and woven from thin brown fibrous fern parts and/or fine epiphyte roots, decorated with pieces of pale-coloured lichen, c. 50 mm wide and 50–60 mm deep, bound to bare twig fork of sapling in shaded site c. 2.25–12 m above ground. Clutch 1 or 2 eggs, pinkish-white to creamy, with dark streaks and blotches mainly in zone around larger end; no information on duration of incubation and fledging periods; young fed by both sexes. Recorded longevity in excess of 6 years and 6 months.

Movements. Mainly sedentary, as indicated by recoveries of ringed individuals. Some local wandering possible, as the species is only rarely seen at a site near Tabubil, in C New Guinea.

Status and Conservation. Not globally threatened. Fairly common to common, and widespread. Heard far more often than it is seen, as both secretive and very active; possibly more common than it appears. Estimated density 20 birds/10 ha at one study site in lowland rainforest at Brown R, near Port Moresby.

Bibliography. Beehler *et al.* (1986), Bell (1982a), Berlepsch (1911), Coates (1990), Coates & Peckover (2001), Diamond (1972a), Gyldestolpe (1955b), Madarász (1899), Mayr & Rand (1937), Mees (1965a), Parker (1963), Rand & Gilliard (1967), Salomonsen (1960a), Seale (1977), Stresemann & Paludan (1932a, 1932b), Symes & Marsden (2005).

3. Mid-mountain Berrypecker

Melanocharis longicauda

French: Piquebaie à longue queue **Spanish:** Picabayas Colilargo **German:** Gelbbüschel-Beerenpicker

Other common names: Lemon-breasted/Yellow-bellied Berrypecker, Long-tailed (Black) Berrypecker

Taxonomy. *Melanocharis longicauda* Salvadori, 1876, Arfak Mountains, New Guinea.

Five subspecies recognized.

Subspecies and Distribution.

M. l. longicauda Salvadori, 1876 – NW New Guinea (Vogelkop and Wandammen Mts).

M. l. chloris Stresemann & Paludan, 1934 – WC & SW New Guinea.

M. l. umbrosa Rand, 1941 – NC New Guinea around R Idenburg.

M. l. capitata Mayr, 1931 – mountains of C & NE New Guinea, including Huon Peninsula.

M. l. orientalis Mayr, 1931 – mountains of SE New Guinea.

Descriptive notes. 12.5 cm. Small berrypecker with medium-length tail. Male nominate race is black above, glossed blue-green on crown and mantle; outer web of outer tail feathers white on basal three-quarters (often hard to see in field); pale olive-grey below, flanks tinged yellow, belly paler and yellower, pectoral tufts pale yellow, underwing-coverts white; iris brown; bill black; legs black to dark brown. Distinguished from similar *M. nigra* mainly by longer tail with white in outer rectrix, yellow (not white) pectoral tufts; from *M. versteri* by smaller size, shorter tail, yellower underparts, pale yellow (not white) pectoral tufts. Female is slightly bigger and appears proportionately shorter-tailed than male, plumage rather nondescript, dull olive-green above, tail brownish with basal white outer webs as male, pale olive-grey below, with pale chin, yellowish flanks and paler yellow belly; bill black with paler base. Immature is similar to female, but gape and base of lower mandible yellowish; young male acquires black first on tail, before upperparts. Races

On following pages: 4. Fan-tailed Berrypecker (*Melanocharis versteri*); 5. Streaked Berrypecker (*Melanocharis striativentris*); 6. Spotted Berrypecker (*Rhamphocharis crassirostris*); 7. Dwarf Longbill (*Oedistoma iliolophus*); 8. Pygmy Longbill (*Oedistoma pygmaeum*); 9. Yellow-bellied Longbill (*Toxorhamphus novaeguineae*); 10. Slaty-chinned Longbill (*Toxorhamphus poliopterus*).

chippy-chip-chippy-chip" song, not unlike that of described as similar to the "sine-wave twittering" of *M. nigra*.

Habitat. Forest and secondary growth in mountains; has a liking for dense shrubs and thickets, particularly on forest edge, and will forage around native gardens adjacent to forest. Found from 700 m to c. 2100 m, largely between *M. nigra* of lower elevations and *M. versteri* of higher levels, with marginal overlap with both; absent from some areas, perhaps owing to exclusion by those species.

Food and Feeding. Small berries, also spiders (Araneae), and likely to take insects. Diet and behaviour similar to those of congeners. Inconspicuous and active. Forages mainly on berries in understorey and middle levels of forest, sometimes to lower canopy. Feeds also by gleaning, and occasionally while hovering. Usually seen singly; adult males observed less often than female-plumaged birds. May be seen with other species in fruiting trees, but seems not to join mixed-species foraging flocks.

Breeding. Poorly known. Nesting recorded in Jan and female in breeding condition in Sept. One nest known, large for size of bird, a quite neat cup with high sides, slightly constricted at top, bound to horizontal branch fork 7.5 m above ground. No other information.

Movements. Presumed to be resident; some altitudinal dispersal possible, as wandering immature male recorded in lowlands of Central Province.

Status and Conservation. Not globally threatened. Quite common in some areas, uncommon in others, and seemingly absent from quite large areas. A patchily distributed species, inconspicuous and easily overlooked. Occupies a wide range on the main island of New Guinea.

Bibliography. Beehler *et al.* (1986), Coates (1990), Coates & Peckover (2001), Diamond (1972a), Filewood *et al.* (1972), Gould (1885a), Gyldenstolpe (1955a), Hartert *et al.* (1936), Mayr (1931c), Rand (1941), Rand & Gilliard (1967), Salomonsen (1960a), Salvadori (1876).

4. Fan-tailed Berrypecker

Melanocharis versteri

French: Piquebaie éventail **German:** Fächerschwanz-Beerenpöcker **Spanish:** Picabayas Abanico
Other common names: Verster's Berrypecker

Taxonomy. *Pristorhamphus versteri* Finsch, 1876, Arfak Mountains, New Guinea.

Birds of this species present on Mt Bosavi and in Torricelli Range of undetermined race, but presumed to belong with *virago*. Individuals from higher elevations notably larger than those from lower altitudes, but this is not considered taxonomically significant. Four subspecies recognized.

Subspecies and Distribution.

M. v. versteri (Finsch, 1876) – mountains of Vogelkop, in NW New Guinea.

M. v. meeki (Rothschild & E. J. O. Hartert, 1911) – mountains of WC & C New Guinea from Weyland Mts E to Hindenburg Range.

M. v. virago (Stressmann, 1923) – mountains of N, EC & NE New Guinea, including Cyclops Mts, Torricelli Range, and Sepik Mts E to Huon Peninsula.

M. v. maculiceps (De Vis, 1898) – mountains of SE New Guinea, including Herzog Mts.

wing-coverts; iris dark brown; bill black, gape yellow; legs black. Distinguished from similar *M. longicauda* by larger size, longer tail, white (not yellow) pectoral tufts, lack of yellow tones on underparts. Female is somewhat larger than male but with proportionately shorter tail, plumage nondescript, dull olive-green above, olive-grey below, fading to paler on lower underparts, belly yellowish with sometimes slightly streaked appearance; has less white in tail than male, with spots about mid-point of feathers (often very inconspicuous). Immature resembles female. Races exhibit minor plumage differences, based on colour of underparts and extent of white in tail: *meeki* is similar to nominate but darker below, with altitudinal variation in size; *maculiceps* has palest underparts and most white in tail of all the races; *virago* is intermediate between preceding two. **VOICE.** Harsh, rasping "schwet dee-dee-dee", scratchy querulous "dee dee dee", high-pitched nasal "ee" and upslurred "chee-chee-chee"; also faint high-pitched notes, including a "ts ts" series; thin drawn-out whistle rather like call of a jewel-babbler (*Ptilorhoa*) reported.

Habitat. Forest and dense secondary growth in mountains; visits fruiting trees in native gardens adjacent to forest, also tree-fern patches in alpine savanna. From c. 1250 m to 3680 m, mainly above 1700 m; perhaps most common at 2300–2600 m. Overlaps with *M. longicauda* in some areas, at lower levels of its own altitudinal range, and may replace that species entirely in others.

Food and Feeding. Feeds on small berries and arthropods. Frequents lower levels, shrubbery and forest edge, ascending to canopy at times when fruit is present; regularly observed to forage very low down or on ground, far more so than congeners. Typical active berrypecker, seldom pausing for long except when feeding. Gleans and hover-gleans. Female-plumaged individuals seem to outnumber males, and latter perhaps occupy a narrower elevational zone, perhaps more towards middle levels of altitudinal range. Usually seen singly, sometimes in pairs. May associ-

ate loosely and temporarily with mixed-species flocks that are passing through, but seems seldom to join them.

Breeding. Poorly known for so common a species. Nesting recorded in Jul and Nov, and young seen in Aug. Nest a smooth, neat, deep, thick-walled cup, large for size of bird, made of felted fibres (presumably from ferns), with thick felted lining of orange-brown fluff from bases of fern leaves, bound with "animal silk" and extensively decorated with pale green, tan or buff lichens which help to camouflage it; bound to horizontal branch or vine fork. Clutch size uncertain, one nest held 1 egg, whitish, spotted and blotched dark, most heavily at larger end; no information on incubation and fledging periods.

Movements. Resident; no movements or wandering known.

Status and Conservation. Not globally threatened. Common to quite common, and widespread over much of its range. Occupies a reasonably wide range on main island of New Guinea.

Bibliography. Beehler (1978a), Beehler *et al.* (1986), Bell (1971b), Coates (1990), Coates & Peckover (2001), Diamond (1972a), Dupond (1937), Gilliard & LeCroy (1961, 1968), Gould (1885a), Gyldenstolpe (1955a, 1955b), Hartert *et al.* (1936), Hicks (1988a), Junge (1953), Mayr (1931c), Mayr & Gilliard (1954), Mayr & Rand (1937), Melville (1979), Morioka (1992), Rand (1961), Rand & Gilliard (1967), Salomonsen (1960a), Salvadori (1876).

exhibit minor differences in plumage colour and tail patterning: *chloris* is yellow below than nominate; *umbrosa* has underparts darker than previous; *orientalis* is similar to nominate, but male has white patch on inner web of outer rectrices; *capitata* is like last but with larger white spot on inner webs (forming a bar).

VOICE. A rapidly repeated buzzy "jjeteeleet jjeteeleet jjeteeleet" or "weetcha weetcha tink"; repeated trisyllabic slightly raspy "tree ti tsee" of typical *Melanocharis* quality, also a downslurred "bzhsst" and incessant twittering sibilant notes; harsh, quite deep raspy "tschree" also given. Has a thin, trilled, reeling "whee Garnet Robin (*Eugeryone rubra*); song also described as similar to the "sine-wave twittering" of *M. nigra*.

Food and Feeding. Small berries, also spiders (Araneae), and likely to take insects. Diet and behaviour similar to those of congeners. Inconspicuous and active. Forages mainly on berries in understorey and middle levels of forest, sometimes to lower canopy. Feeds also by gleaning, and occasionally while hovering. Usually seen singly; adult males observed less often than female-plumaged birds. May be seen with other species in fruiting trees, but seems not to join mixed-species foraging flocks.

Breeding. Poorly known. Nesting recorded in Jan and female in breeding condition in Sept. One nest known, large for size of bird, a quite neat cup with high sides, slightly constricted at top, bound to horizontal branch fork 7.5 m above ground. No other information.

Movements. Presumed to be resident; some altitudinal dispersal possible, as wandering immature male recorded in lowlands of Central Province.

Status and Conservation. Not globally threatened. Quite common in some areas, uncommon in others, and seemingly absent from quite large areas. A patchily distributed species, inconspicuous and easily overlooked. Occupies a wide range on the main island of New Guinea.

5. Streaked Berrypecker

Melanocharis striativentris

French: Piquebaie strié **German:** Streifenbauch-Beerenpöcker **Spanish:** Picabayas Estriado
Other common names: Striated/Green Berrypecker

Taxonomy. *Melanocharis striativentris* Salvadori, 1894, Moroka, Owen Stanley Range, south-east New Guinea.

Proposed races *prasina* and *albicauda*, from N slopes of SE New Guinea, are synonymous with nominate. Three subspecies recognized.

Subspecies and Distribution.

M. s. axillaris (Mayr, 1931) – W & WC New Guinea (Weyland Mts and Snow Mts).

M. s. striativentris Salvadori, 1894 – mountains of EC & SE New Guinea.

M. s. chrysocome (Mayr, 1931) – mountains of Huon Peninsula, in NE New Guinea.

Descriptive notes. 12.7–14 cm. Medium-sized dull-coloured berrypecker lacking distinct male plumage. Male nominate race is olive-green above, outer rectrices with well-concealed white at bases; throat and underparts olive-grey, many feathers edged whitish or yellowish, giving streaked appearance (especially on lower breast and abdomen); underwing-coverts olive grey-brown; iris dark brown, distinctive dull buff eyering; bill blackish-brown, gape-line and nares orange-buff; legs dark brown. Distinguished from females of *M. longicauda* and *M. versteri* mainly by buff eyering, orange-buff gape and streaked appearance of underparts. Female is larger than male, but with shorter tail; plumage very similar, white at tail bases much reduced or absent. Immature is similar to adult, with tail as female, but gape and nares dull yellowish (not orange-tinged); young male has white in tail vestigial or absent. Races exhibit minor differences in coloration and tail patterning: *axillaris* has underparts heavily streaked, axillaries and underwing-coverts white, lacks white in tail; *chrysocome* is similar to nominate but slightly larger in size, with underparts darker, streaking less marked. **VOICE.** Little known. A scratchy "schree schree schree", supposedly harsher than similar sounds of congeners; also has distinctive loud "seep", repeated every few seconds.

Habitat. Forest, forest edge and secondary growth in mountains, from c. 1150 m to 2300 m, rarely as low as 500 m and as high as 2600 m. Overlaps with *M. longicauda* in lower-lying parts of range, and with *M. versteri* at higher levels.

Food and Feeding. Few data. Known to take small berries. Frequents shrubs and middle levels of habitat. Quite a secretive species, easily overlooked or misidentified; seems less active than congeners. In parts of range where co-exists with *M. longicauda* and *M. versteri*, habitat-partitioning mechanism not known.

Breeding. Poorly known. Nests have been found in Dec in SE New Guinea. Nest a cup-shaped structure, similar to that of *M. nigra* but larger and tapering a little below, built of fine fibre-like fern parts, smoothly felted, covered externally with plant down and spider silk, which bind nest to supporting branch, and decorated on outside with green lichen, which may help to camouflage it; two nests were placed on downward-sloping twigs or stems. Clutch 2 eggs, pinkish-white with dark streaking and blotching mainly in zone around larger end, like those of *M. nigra* but larger and with darker markings. No other information.

Movements. Poorly understood. Has been suggested as being locally nomadic, as it seems to be absent from some areas at times; secretive behaviour, however, complicates the picture.

Status and Conservation. Not globally threatened. Mostly uncommon to rare; described as common to abundant in a few areas. Has wide, albeit patchy, distribution, and seemingly absent from many areas. A rather poorly known species; conservation status possibly merits reassessment and may be better considered Data-deficient.

Bibliography. Beehler *et al.* (1986), Coates (1990), Coates & Peckover (2001), Finch (1981a), Gyldenstolpe (1955a), Harrison & Friith (1970), Hartert *et al.* (1936), Mayr (1931c), Mayr & Gilliard (1952b, 1954), Rand & Gilliard (1967), Salomonsen (1960a), Salvadori (1894), Schodde (1978a).

Genus RHAMPHOCHARIS Salvadori, 1876

6. Spotted Berrypecker

Rhamphocharis crassirostris

French: Piquebaie tacheté **Spanish:** Picabayas Moteado
German: Schlankschnabel-Beerenpöcker
Other common names: Thick-billed Berrypecker

Taxonomy. *Rhamphocharis crassirostris* Salvadori, 1876, Hatam, Arfak Mountains, New Guinea.

SPECIES ACCOUNTS

True affinities uncertain, and genus sometimes subsumed in *Melanocharis*; molecular studies required. Birds of this species from Huon Peninsula, currently included in race *piperata*, may represent a separate taxon. Three subspecies recognized.

Subspecies and Distribution.

R. c. crassirostris Salvadori, 1876 – NW & W New Guinea (Vogelkop and Snow Mts).

R. c. piperata (De Vis, 1898) – C ranges of E New Guinea, including Huon Peninsula.

R. c. viridescens Mayr, 1931 – EC New Guinea (Herzog Mts; possibly also Kuper Range).

Descriptive notes. 11–14 cm. Distinctive berrypecker with peculiar long, stout bill and a narrow squared-off tail; striking sexual plumage dimorphism. Male nominate race is olive-green with oily greenish gloss above, darker on crown; uppertail-coverts and tail blackish; pale pearly grey below, slightly washed with yellow on flanks; pectoral tufts and underwing-coverts white or yellowish-white, axillaries pale yellow; iris red, olive-brown or dark brown; bill black; legs brownish-black. Female is very distinctive, with dark brownish-black head and body heavily marked with whitish apical spots, particularly on breast and throat,

the spots smaller on head and somewhat larger and triangular-shaped on body; median upperwing-coverts tipped white, producing single rather variable wingbar (poorly marked on some); remiges edged olive-yellow, outer rectrices with variable white tipping; iris dark brown, small white surrounding feathers giving appearance of an eyering; bill black to blackish-brown, sometimes paler base; legs grey to black. Female distinguished from rather similar Spotted Honeyeater (*Xanthotis polygrammus*) by lack of yellow ear patch and absence of black markings on underparts. Immature is similar to female, but upperparts almost lacking in spots, flight-feathers more clearly edged olive-yellow, spotting below duller and much less distinct, bill with obvious pale base of lower mandible, dark eye with pale eyering; may show pale gape-line when very young. Races differ in minor degrees of size or in plumage marking and coloration: *piperata* is larger than nominate, has longer bill, more white at base of rectrices; *viridescens* is darker and with smaller white spots than previous. **VOICE.** A rapid downslurred series of “seeu-seeu-seeu” notes, of typical berrypecker quality but also suggestive of an insect. Also, an indrawn, sibilant series similar to that of Red-collared Myzomela (*Myzomela rosenbergii*) reported.

Habitat. Forest, forest edge and secondary growth, also in native gardens adjacent to forest; mountains from 850 m to 2700 m, mainly 1150–2300 m.

Food and Feeding. Poorly known. Takes berries and small fruits, such as figs (*Ficus*), also gleans arthropods from foliage and epiphytes; behaviour like that of a honeyeater (Meliphagidae). Tends to keep to middle levels and lower canopy, rarely descending to shrub layer. Visits flowering trees, where it remains inside dense foliage. Usually seen singly; reported as gathering in small flocks of up to twelve individuals at fruiting trees. Associates with other species only when they happen to be feeding in same flowering or fruiting tree.

Breeding. Juvenile in Sept in EC New Guinea. No other information available.

Movements. Presumed to be resident; possibly some local wandering in association with fruiting or flowering of trees.

Status and Conservation. Not globally threatened. Very uncommon to rather rare, and poorly known. Occurs at low density. Considered unlikely to be at risk, as it is distributed over a wide range.

Bibliography. Beehler (1978a), Beehler *et al.* (1986), Coates (1990), Coates & Peckover (2001), Gilliard & LeCroy (1961), Gould (1885b), Gyldestolpe (1955a), Mayr (1931c), Mayr & Gilliard (1954), Rand & Gilliard (1967), Salomonsen (1960a), Salvadori (1876), Schodde (1978a).

Genus *OEDISTOMA* Salvadori, 1876

7. Dwarf Longbill

Oedistoma iliolophus

French: Toxorampe à ventre gris

Spanish: Picudo Pechigris

German: Graubauch-Pfriemschnabel

Other common names: Plumbed Longbill, Grey-bellied Longbill/Honeyeater, Dwarf Honeyeater, Long-plumbed False-sunbird

Taxonomy. *Melilestes iliolophus* Salvadori, 1876, Meos Num and Yapen Island, Geelvink Bay, New Guinea.

Genus was in the past usually placed in the honeyeater family (Meliphagidae), but DNA studies indicate that it belongs with current family. Has sometimes been subsumed in genus *Toxorhamphus*, despite the fact that it predates latter by almost 40 years. Present species sometimes placed in genus *Melanocharis*, and phylogenetic analysis based on protein allozymes suggested closer affiliation to that genus than to *Toxorhamphus*. Relationship with *O. pygmaeum*, however, uncertain, and further genetic work required in order to reveal true taxonomic positions of the two. Species name often listed as *iliolophus*, but should be treated as a noun, and thus invariable; race *fergussoni* often listed as *fergussone*, but this name is not demonstrably adjectival and should be treated as a noun in genitive case, therefore invariable. Five subspecies recognized.

Subspecies and Distribution.

O. i. cinerascens (Stresemann & Paludan, 1932) – Waigeo, in N West Papuan Is.

O. i. affine (Salvadori, 1876) – mountains of Vogelkop, in NW New Guinea.

O. i. iliolophus (Salvadori, 1876) – Geelvink Is (Meos Num, Yapen), and mainland N & C New Guinea from Geelvink Bay E, including Weyland Mts, Victor Emanuel Mts and Sepik Mts, to Huon Peninsula.

O. i. flavum (Mayr & Rand, 1935) – S & SE New Guinea lowlands.

O. i. fergussoni (E. J. O. Hartert, 1896) – D'Entrecasteaux Archipelago (Goodenough, Fergusson and Normanby), off SE New Guinea.

Descriptive notes. 11 cm. Very small, very drab-looking passerine with long decurved bill. Nominant race is dark olive-green above, olive-grey below, washed with yellow on flanks; iris dark brown, conspicuous but narrow fleshy yellow eyering; bill black, paler yellowish base; legs dull slaty blue. Sexes similar. Immature undescribed. Races differ only slightly in size or coloration, or

both: *cinerascens* has crown grey, not dark olive-green; *affine* is smaller, has crown olive-green; *flavum* resembles previous, but has more yellowish underparts; *fergussone* is largest race. **VOICE.** A scolding, anxious-sounding “twik twik” series; also, typically, a dry, sharp “chirrit” in flight, often first indicator of presence of species. No published reports of song as such.

Habitat. Rainforest and, locally, monsoon forest, in lowlands and hills; found also at forest edge and in secondary growth, visiting flowering shrubs. To c. 1200 m, locally to 1750 m in lower montane zone.

Food and Feeding. Feeds on insects, nectar and sometimes fruit. Forages in lower levels of vegetation, also at flowering trees and shrubs. Very active, and hard to see well; often glimpsed as it darts across a path or through forest understorey. Frequently flicks wings, and is seldom still for long. Best observed at flowering trees and shrubs, where it takes nectar. Probes into flowers of shrubs, trees, vines and wild bananas (*Musa*); also gleans from branches and trunks, and hovers occasionally. Takes insects from spider webs, and often seen to face vertically downwards on trunks. Recorded as visiting forest pools during dry weather, but uncertain if drinking, bathing or merely foraging. Usually seen singly, sometimes in pairs. Will associate loosely with mixed-species flocks with Yellow-bellied Gerygone (*Gerygone chrysogaster*), Frilled Monarch (*Arses telescopthalmus*) and Chestnut-bellied Fantail (*Rhipidura hyperythra*), but not a core member of such assemblages.

Breeding. Poorly known. Noted as breeding at Brown R., near Port Moresby, in Aug–Sept dry season and as being in breeding condition in Oct. One nest from Fergusson I (race *fergussone*), in Dec 1896, was a cup of dried grass lined with snow-white soft vegetable silk, the exterior covered with partly decayed dried leaves, attached to a twig; contained 1 egg, creamy white, with reddish spots forming ring around larger end and with few brown hair-like lines around middle. Maximum recorded longevity at R Brown study site 7 years 4 months. No other information.

Movements. Resident; in study at Brown R., individuals frequently retrapped at site of ringing.

Status and Conservation. Not globally threatened. Generally common within its widely distributed habitat, and often one of the most abundant birds of lowland forest and hill forest, but seemingly absent from much of S Trans-Fly. At study site at Brown R., density of c. 40 birds/10 ha, similar to that recorded for Yellow-bellied Gerygone and Little Shrike-thrush (*Colluricincla megarrhyncha*).

Bibliography. Beehler *et al.* (1986), Bell (1982a, 1982b, 1984a), Christidis *et al.* (1993), Coates (1990), Coates & Peckover (2001), Dupond (1937), Gilliard & LeCroy (1961), Gregory (1995a, 1995b), Gyldestolpe (1955b), Hopkins & Hiaso (1994), Mayr (1931c), Mayr & Rand (1937), Rand & Gilliard (1967), Rothschild & Hartert (1896b), Stresemann & Paludan (1932a, 1932b), Symes & Marsden (2005).

8. Pygmy Longbill

Oedistoma pygmaeum

French: Toxorampe pygmée

German: Zwergpfriemschnabel

Spanish: Picudo Pigmeo

Other common names: Pygmy Honeyeater

Taxonomy. *Oedistoma pygmaeum* Salvadori, 1876, Arfak Mountains, New Guinea.

Genus was in the past usually placed in the honeyeater family (Meliphagidae), but DNA studies indicate that it belongs with current family. Has sometimes been subsumed in genus *Toxorhamphus*, despite the fact that it predates latter by almost 40 years. Relationship between present species and its sole congener, *O. iliolophus*, uncertain, and further genetic work required in order to reveal true taxonomic positions of the two. Described races *flavipectus* (S New Guinea E from Etna Bay) and *olivascens* (NE coast E from Huon Peninsula) considered synonyms of nominate. Three subspecies recognized.

Subspecies and Distribution.

O. p. waigeuense Salomonsen, 1966 – Waigeo, in N West Papuan Is.

O. p. pygmaeum Salvadori, 1876 – S West Papuan Is (Misool) and mainland New Guinea.

O. p. meeki (E. J. O. Hartert, 1896) – D'Entrecasteaux Archipelago (Goodenough I, Fergusson I), off SE New Guinea.

Descriptive notes. 7.3 cm; 5 g. Tiny, very short-tailed, canopy-dwelling passerine, the smallest of New Guinea birds; resembles a cormorant (*Sylvietta*), but with decurved shortish bill and odd body shape. Nominant race is yellowish-olive above, greyish below, abdomen and flanks washed with pale lemon-yellow; throat whitish, and chest slightly darker than rest of underparts; iris brown; bill black, whitish at base of lower mandible; legs blue-grey. Sexes similar, female slightly smaller and duller than male. Immature undescribed. Races differ minimally: *meeki* is slightly larger than others, more whitish below, and with crown grey (not green). **VOICE.** Usual call a continual fairly quiet clicking “chit chit chit” series, given by several individuals together and perhaps a contact call; also a quiet, more musical chattering. No apparent song documented.

Habitat. Rainforest, monsoon forest (in Trans-Fly region), forest edges and clearings, and gallery forest. Lowlands and hill forest from sea-level to c. 800 m, locally to c. 1370 m.

Food and Feeding. Diet poorly known, but insects, spiders (Araneae) and nectar taken. Seems to forage mainly in canopy, where highly vocal and usually heard as it calls from high in flowering trees; seldom seen in middle level or lower, but occasionally comes down to feed at forest edge. Feeds by gleaning and probing, also while hovering. Occurs in presumed pairs, or in small flocks of four or five or sometimes up to ten individuals. Found at flowering trees among flocks of other nectarivorous species, including Rainbow (*Trichoglossus haematodus*) and Red-flanked Lorikeets (*Charmosyna placensis*), Meyer's (*Philemon meyeri*) and Helmeted Friarbirds (*Philemon hucaroides*) and other honeyeaters (e.g. *Myzomela* and *Xanthotis* species), and Red-capped Flowerpeckers (*Dicaeum geelvinkianum*); sometimes occurs also in mixed flocks with Black-fronted White-eyes (*Zosterops minor*), Hooded Pitohuis (*Pitohui dichrous*) and Green-backed Gerygones (*Gerygone chloronota*).

Breeding. Female in breeding condition in Oct in Central Province of Papua New Guinea. No other information.

Movements. Appears to be resident; may move locally in response to flowering of trees.

Status and Conservation. Not globally threatened. Fairly common but unobtrusive; very vocal, and often located by its calls. Has very wide range in New Guinea, being present over much of mainland and on a few satellite islands, and considered not to be at any immediate risk.

Bibliography. Beehler *et al.* (1986), Christidis *et al.* (1993), Coates (1990), Coates & Peckover (2001), Dupond (1937), Gregory (1995a, 1995b), Gyldestolpe (1955b), Hopkins & Hiaso (1994), Mayr & Rand (1937), Rand & Gilliard (1967), Stresemann & Paludan (1932a).

Genus *TOXORHAMPHUS* Stresemann, 1914

9. Yellow-bellied Longbill

Toxorhamphus novaeguineae

French: Toxorampe à ventre jaune

Spanish: Picudo Ventrigualdo

German: Gelbbauch-Pfriemschnabel

Other common names: Green-crowned/Canary/New Guinea Longbill, Canary Bowbill/False-sunbird

Taxonomy. *Cinnyris Novaeguineae* Lesson, 1827, Manokwari, north-west New Guinea.

Genus was in the past usually included within the honeyeater family (Meliphagidae), but DNA studies indicate that it belongs with present family. Present species and *T. poliopterus* form a species pair, the two replacing each other altitudinally, with only marginal overlap. Two subspecies recognized.

Subspecies and Distribution.

T. n. novaeguineae (Lesson, 1827) – West Papuan Is (Waigeo, Batanta, Salawati, Misool), Yapen I (in Geelvink Bay) and N & W mainland New Guinea (E to Astrolabe Bay and Ramu R and, in S, to Etna Bay).

T. n. flaviventris (Rothschild & E. J. O. Hartert, 1911) – Aru Is. and S New Guinea from Utakwa E to Lakekamu R.

Descriptive notes. 12.5 cm. A small passerine with a strongly decurved long dark bill. Nominate race is olive-green above, outer tail feathers with narrow whitish terminal margins (not visible on folded tail, best seen during flight); throat and underparts citrine-yellow, washed olive on breast; iris brown, narrow whitish eyering; bill blackish, paler base of lower mandible; legs mid-grey to blue-grey. Differs from *T. poliopterus* in having less dark-looking, more olive (not grey) head and wings, yellow chin and throat; readily told from superficially similar female of Olive-backed Sunbird (*Cinnyris jugularis*) by lack of yellow supercilia.

much longer and more decurved bill, also forest-dwelling habits. Sexes similar, female smaller and slightly shorter billed than male. Immature undescribed. Race *flaviventris* is similar to nominate, but more yellowish and less olivaceous below, with more greyish-yellow chin, and with ill-defined light yellow patch in centre of throat. **Voice.** Vocal, heard more often than seen. Song, one of characteristic sounds of lowland forests, a sweet, slightly mournful descendent “twee twee twee twee” series, also a similar “pitchew pitchew pitchew pitchew”. Calls a raspy “zwik” note, and high-pitched buzzy “tsweet tsweet” like that of a flowerpecker (Dicaeidae).

Habitat. Lowland forest, hill forest and monsoon forest with abundant vines, also secondary growth if still fairly dense. In S of range occurs in lowlands to c. 500 m, rarely to 750 m; in N also mainly in lowlands, but in Central Highlands to 1200 m at Baiyer R, a site where other mainly lowland species, e.g. Large-billed Gerygone (*Gerygone magnirostris*), have an outpost.

Food and Feeding. Insectivorous, and also takes nectar, but dietary details not known. Very active, constantly moving from perch to perch; responds to playback of taped song, but wary. Frequents middle levels and understorey, and ascends to canopy to visit flowering trees. Probes among foliage for arthropods. Usually seen singly or in pairs. Occasionally joins mixed-species flocks with Frilled Monarch (*Arses telescopthalmus*), Wallace’s Wren (*Sipodotus wallacii*), Yellow-bellied Gerygone (*Gerygone chrysogaster*) and sometimes *Melanocharis nigra*.

Breeding. No information. Apparently on territory at Kiunga (Western Province) and Karawari (West Sepik) in Jul–Aug.

Movements. Resident, but some local movements may occur; in Western Province, has been found rarely near Tabubil, at 750 m.

Status and Conservation. Not globally threatened. A fairly common to common species, although frequently elusive; perhaps more numerous than it may appear. Occupies a wide range, and considered not to be at any immediate risk.

Bibliography. Beehler *et al.* (1986), Christidis *et al.* (1993), Coates (1990), Coates & Peckover (2001), Gregory (1995a, 1995b), Gyldestolpe (1955b), Hopkins & Hiaso (1994), Mees (1965a), Rand & Gilliard (1967), Stresemann & Paludan (1932a, 1932b).

10. Slaty-chinned Longbill

Toxorhamphus poliopterus

French: Toxorampe à tête grise

Spanish: Picudo Cabecigrís

German: Graukinn-Pfriemschnabel

Other common names: Grey-winged Longbill, Grey-winged Bowbill/False-sunbird

Taxonomy. *Melilestes poliopterus* Sharpe, 1882, Astrolabe Mountains, south-east New Guinea. Genus was in the past usually included within the honeyeater family (Meliphagidae), but DNA studies indicate that it belongs with present family. This species and *T. novaeguineae* form a species pair, the two replacing each other altitudinally, with only marginal overlap. Proposed race *septentrionalis* (described from Huon Peninsula) included within nominate. Two subspecies currently recognized.

Subspecies and Distribution.

T. p. maximus Rand, 1941 – mountains of W & C New Guinea (N slope of Weyland Mts and Snow Mts).

T. p. poliopterus (Sharpe, 1882) – mountains of E & SE New Guinea, including Central Highlands, Mt Bosavi, Adelbert Mts, and Saruwaged Mts (in Huon Peninsula).

Descriptive notes. 12.5 cm; 14–15 g. A small passerine with a long, dark, strongly decurved bill and a dark head. Male nominate race has head and nape dark bluish-grey, upperparts dark olive-green; upperwing and tail dark grey, outer tail feathers narrowly tipped white; chin and upper throat slaty grey, prominent citrine-yellow spot on lower throat, underparts pale yellowish-olive; iris red-brown or dark brown; bill black; legs slate-blue, dark olive-grey or dusky brown. Distinguished from *T. novaeguineae* by dark head, grey wings and citrine throat spot; readily told from superficially similar female of Olive-backed Sunbird (*Cinnyris jugularis*) by grey head, lack of yellow supercilia, much longer and more decurved bill, and forest-dwelling habits. Adult female is similar to male, but smaller and paler. Immature undescribed. Races differ marginally in intensity of coloration and size; *maximus* is slightly bigger than nominate. **Voice.** Heard more often than seen; varied vocalizations, some of which reminiscent of a sunbird (Nectariniidae) in quality. Song seems to be variable, generally sweet and slurred, with disyllabic notes and repeated single notes; one song reported as being very similar to that of Scrub White-eared Honeyeater (*Meliphaga albonotata*). Calls include a sweet “tsip”, a “tsee-tsee tsee-tsee” series, also a dry scold, and an incisive slightly metallic “chik” that can be extended into distinctly syllabized scolding series, which seems to function as an alarm; one flight call is a disyllabic sneezing series similar to that of *Oedistoma iliolophus*.

Habitat. Primary forest in hills and lower mountains, also secondary growth and edges of gardens in forest; recorded also at forest edge in highlands and in scattered trees in mid-mountain grassland. Occurs mostly from c. 500 m to c. 2000 m but altitudinal limits vary; can occur as low as 300 m and as high as 2450 m. Occurrence influenced by lower altitudinal limits of favoured forest habitats, and presumably by competition with *T. novaeguineae*, which seems to be absent inland from Port Moresby (where present species occurs down to 300 m) and erratic in occurrence at Tabubil, in Western Province (where present species found irregularly down to c. 500 m); both species occur at c. 1200 m at Baiyer R (in Central Highlands), but probably separated there by altitude, with present species somewhat higher up.

Food and Feeding. Diet poorly known: feeds on arthropods and nectar. Tends to be shy and hard to see; responds to playback of taped song, but always very active and very wary, and seldom perches for long in one place. Darts about swiftly. Forages mainly in understorey and middle levels, and visits canopy to exploit flowering trees; frequently observed in the substorey, feeding from flowers of wild gingers (Zingiberaceae) and a white lily-like species. Usually seen singly.

Breeding. Breeding recorded in May, Jun, Aug and Oct in highlands and in Apr and Sept at Sogeri Plateau (near Port Moresby), suggesting a wide range of local timing including late wet season to early dry season, but varying with local conditions. Nest is a distinctive neat, smoothly finished cup of fine greenish vegetation and fibres, interwoven with spider webs and externally decorated with spider egg sacs, lined with thick layer of white plant down, sited in crotch of sapling, or on slender branch (with base of nest built around branch); one was at 1.8 m over a forest stream, another was 2.7 m up in a vine stem growing from a small tree in partly cleared forest. Nests containing 1 white egg recorded, but these may represent incomplete clutches. No other information available.

Movements. Resident; no movements reported.

Status and Conservation. Not globally threatened. Fairly common to common, but elusive; occupies large range in New Guinea, in widely distributed habitat, but absent from Vogelkop. Often common at the higher altitudes; reported as being the most abundant bird species on Mt Karimui between 1200 m and 1700 m, where it comprised c. 9% of the total avifauna.

Bibliography. Beehler *et al.* (1986), Christidis *et al.* (1993), Coates (1990), Coates & Peckover (2001), Diamond (1972a), Gilliard & LeCroy (1961, 1967a), Gregory (1995a, 1995b), Gyldestolpe (1955a), Hopkins & Hiaso (1994), Mayr (1931c), Mayr & Gilliard (1954), Melville (1979), Rand (1941, 1961), Rand & Gilliard (1967), Watson *et al.* (1962).

Class AVES
Order PASSERIFORMES
Suborder OSCINES
Family PARAMYTHIIDAE
(PAINTED BERRYPECKERS)

- Rather robust small to medium-sized passerines with long wiry black filoplumes on flanks; colour patterns bold and contrasting.
- 12–22 cm.

- New Guinea.
- Montane forest.
- 2 genera, 2 species, 5 taxa.
- No species threatened; none extinct since 1600.

Systematics

The two enigmatic species that constitute the Paramythiidae are confined to the mountains of New Guinea, with much of the altitudinal range of the Crested Berrypecker (*Paramythia montium*) lying above that of its smaller relative, the Tit Berrypecker (*Oreocharis arfaki*). Of diverse appearance, the affinities of these two species within the passerines have for long been uncertain.

The male Tit Berrypecker bears a strong superficial resemblance to the Great Tit (*Parus major*) of Eurasia, and in 1875 it was originally described by A. B. Meyer as "*Parus (?) arfaki*". Around the same time, T. Salvadori named it *Oreocharis stictoptera* and referred it to the family Dicaeidae, containing the flowerpeckers and allies. A decade or so later, R. B. Sharpe, in his *Catalogue of the Birds in the British Museum*, incorporated this species in the Dicaeidae, along with an eclectic assemblage of genera that included also *Melanocharis* and *Rhamphocharis* of the melanocharitid berrypeckers. The Tit Berrypecker remained an aberrant member of the Dicaeidae for the next hundred years, although at least one subsequent author was inclined to associate this species with the tits in the family Paridae.

When the unique Crested Berrypecker was first described, in 1892, C. W. De Vis referred it to the starling family (Sturnidae). Later, Sharpe placed this species in its own monotypic family, Paramythiidae, between two sturnid groups, namely the glossy starlings, at that time treated as a family Eulabetidae, and the oxpeckers, then treated as the family Buphagidae. This treatment of the Crested Berrypecker in a monotypic family was retained for the next three decades.

As the preceding paragraphs imply, the Tit Berrypecker and the Crested Berrypecker differ from each other in several respects. One species is small and sexually dimorphic, whereas the other is medium-sized, sexually monomorphic and crested. One species is strong-flying and is often conspicuous; the other flies only short distances and is generally skulking. The two are linked, however, by their possession of specialized long wiry black filoplumes on the flanks, a peculiarity of Paramythiidae. In addition, the bill of the Crested Berrypecker is similar to that of the Tit Berrypecker, both species have a vestigial tenth primary (see Morphological Aspects), and both feed almost exclu-

sively on berries (see Food and Feeding). The bills of these species lack the serrated cutting edges that are a feature of the melanocharitid berrypeckers and the *Dicaeum* flowerpeckers, and the tongue structure, unlike that of the flowerpeckers, is simple. The vestigial outermost primary, P10, is a character which they share with typical *Dicaeum* flowerpeckers, although not with the melanocharitid berrypeckers. By 1933, E. Mayr had formed the opinion that the Crested Berrypecker is closely allied to the Tit Berrypecker, and he considered that the colour pattern of the former bore a close resemblance to that of the male Tit Berrypecker. "Common to the two genera are the black head and throat, the green, contrasting upper parts and wings, the bluish tail, and the yellow under tail-coverts. The main difference in coloration is the exchange of yellow with blue on the abdomen, breast and cheeks in *Paramythia*". In his *List of New Guinea Birds*, Mayr included the Crested Berrypecker in the Dicaeidae, following the flowerpeckers, the melanocharitid berrypeckers and the Tit Berrypecker in taxonomic sequence. This treatment set the standard for most authors and students of New Guinea birds for the next four-and-a-half decades, including F. Salomonsen in his 1967 text for J. L. Peters's *Check-list of Birds of the World*.

During this time, C. J. O. Harrison and S. A. Parker made a study of the morphological evidence and nest structure of these species, and proposed that the Tit and Crested Berrypeckers be regarded as aberrant bulbuls (Pycnonotidae), but this view failed to gain acceptance. Clearly, however, these birds are well differentiated from the flowerpeckers, and also from the melanocharitid berrypeckers, both in external morphology and in aspects of nidification.

The analytical work based on DNA–DNA hybridization, pioneered by C. G. Sibley and J. E. Ahlquist during the 1970s and 1980s, indicated that the genera *Oreocharis* and *Paramythia* are, indeed, closely related to each other and sufficiently well differentiated from the Dicaeidae to warrant placement in a separate family, the resurrected Paramythiidae. Interestingly, Sibley and Ahlquist also placed the melanocharitid berrypeckers in a family of their own, the Melanocharitidae, together with the longbills of the genera *Toxorhamphus* and *Oedistoma*, a small group of species that, prior to these authors' studies, had traditionally been considered to be honeyeaters and had therefore been included in Meliphagidae.

Recent research by F. K. Barker, A. Cibois and their colleagues, based on the sequencing of nuclear genes, supports the view that the painted berrypeckers are well removed from the flowerpeckers. Moreover, this work reveals for the first time that the paramythyids belong with the "core Corvoidea" radiation, which roughly corresponds to Sibley and Ahlquist's "parvorder Corvida", in contrast to the flowerpeckers, which belong with the "Passerida" radiation, roughly corresponding to Sibley and Ahlquist's "parvorder Passerida". Its findings indicate also that the paramythyid berrypeckers are not closely related to the melancharitid berrypeckers. Their nearest allies now appear to be the Old World orioles and figbirds (Oriolidae), another family comprised of partially to wholly frugivorous species.

Across its geographical range the Tit Berrypecker exhibits minor variations in plumage between populations, but it also exhibits widespread individual variation that defies attempts to separate these populations as subspecies. For example, Mayr and A. L. Rand, of the American Museum of Natural History, examined a series of specimens from the mountains of New Guinea's south-east and compared them with a series from the Huon Peninsula, in the north-east, and with two individuals from the Arfak Mountains of the Vogelkop, in the far west of the island. They found that the males from south-east New Guinea tended to have the black of the crown extending farther down the back of the head than was the case with those from the two other regions, although one of the Arfak males resembled the south-east individuals in this character; further, two of the south-eastern specimens were similar to the Arfak and Huon Peninsula specimens in having the green of the back extending up on

to the nape. In addition, Mayr and Rand found that, in their series of south-eastern specimens, some females had a more whitish belly and others a more greyish belly. N. Gyldenstolpe, working at the State Museum of Natural History, in Stockholm, Sweden, believed, however, that Tit Berrypeckers from the Wahgi Valley of east-central New Guinea, and representing all New Guinea populations east of the Vogelkop Peninsula, are sufficiently distinct from those of the Arfak Mountains of the Vogelkop to be separated as a subspecies, for which he proposed the name *bloodi*. Incidentally, Gyldenstolpe noted that adult females of his proposed race are darker green on the upperparts, darker grey on the throat and chest, greyer on the middle of the abdomen, and deeper yellowish on the sides of the body than are adult females from the Arfak Mountains, while males are blacker on the crown and much darker chestnut on the abdomen than are Arfak males.

Subsequently, other authors, including F. Salomonsen, also compared specimens of Tit Berrypeckers from the Vogelkop with series of skins from various other parts of New Guinea. All are in agreement that this species displays too much individual variation, and that the differences between populations are too weakly marked, to justify separation into subspecies. Furthermore, some Vogelkop specimens were found to match exactly specimens of "*bloodi*". The outcome is that the Tit Berrypecker is considered a monotypic species.

In contrast, the Crested Berrypecker is a polytypic species with two groups of races, a western group and an eastern one. Each group is remarkably uniform in its external morphology over much of its range. In eastern New Guinea, a single subspecies, the nominate race, extends along the central ranges from

Taxonomists have long struggled to determine the evolutionary relationships of the painted berrypeckers, which have been variously allied to starlings (Sturnidae), tits (Paridae) and flowerpeckers (Dicaeidae). Recent molecular analyses place them in the "core Corvoidea" radiation, and suggest that their closest relatives are the Old World orioles and figbirds (Oriolidae). There are only two extant species of painted berrypecker. Although they are clearly divergent in plumage pattern and size, they are linked by one peculiar feature: their flanks bear elongated black filoplumes which are generally hidden beneath the wing. The function of these specialized feathers is unknown. The **Crested Berrypecker** is typical of the family in having a fairly short and robust bill. With a striking head pattern and an expressive crest, it is one of the most attractive of New Guinea's birds.

at least the Star Mountains eastwards to the mountains of the south-east peninsula, individuals in the western part of this distributional area differing only slightly from those in the south-east in having the undertail-coverts slightly lighter, more lemon-yellow, rather than dull golden-yellow, and the wing on average slightly longer. In the south-east, Mayr and Rand found that this subspecies also exhibited a slight variation in size with altitude, especially noticeable in the females. In the north-east, the isolated subspecies *brevicauda* is confined to the outlying mountain ranges of the Huon Peninsula. It is distinguished from the nominate race only by its slightly shorter tail. The western form of the Crested Berrypecker, *olivacea*, was described by E. D. van Oort in 1910. Soon after its discovery, W. R. Ogilvie-Grant regarded this very distinctive taxon as a separate species. Otherwise it has been treated only as a subspecies of *P. montium*, although evidence of intergradation between the western "*olivacea* group" and the eastern "nominate group" is lacking. Specimens from the area between the Snow Mountains and the Star Mountains of west-central New Guinea are required in order to enable a proper investigation of the two groups to be undertaken.

Rand, reporting on a series of *olivacea* collected in the Snow Mountains during the 1938–1939 Archbold Expedition to New Guinea, noted a correlation between increase in size and increase in altitude, and also that the individuals from lower altitude, besides being smaller, were on average slightly more olive on the upperparts than were those from higher elevations. He remarked that Crested Berrypeckers from the Weyland Mountains are also small and on average slightly more olive above than those from the Snow Mountains. Rand concluded, however, that it would be inadvisable to separate these populations as additional races. Subsequently, Salomonsen, using the characters detailed by Rand, considered that the larger individuals were separable as an altitudinal subspecies, *alpina*, confined to the area surrounding Mount Wilhelmina and the mountains bordering the Baliem Valley, and at least partially isolated from the lower-altitude *olivacea*. A few years later, in the mountains bordering the Ilaga Valley, farther to the west, S. D. Ripley obtained a series of specimens that, in terms of measurements, agreed with the proposed *alpina*, except that the lower size limit of these birds overlaps marginally with measurements used by Salomonsen to define *olivacea*. Salomonsen's and Ripley's combined wing-length measurements for *alpina* are 112–123 mm for males, compared with 100–108 mm for male *olivacea*, and 104–120 mm for females, compared with 97–106 mm for female *olivacea*. It is not clear if this overlap in size represents a cline. The proposed subspecies *alpina* has been recognized by some authors, although not by others. Further analysis of Ripley's specimens may help to resolve the matter.

Finally, the proposed race *occidentis*, for Crested Berrypeckers from the Hellwig Mountains, on the southern watershed of the Snow Mountains, was shown by Salomonsen to be, technically, a synonym of *olivacea*.

Morphological Aspects

The painted berrypeckers are handsomely plumaged, arboreal, berry-eating passerines. Of the two species in the family, one, the Tit Berrypecker, is small and robust, 12–14 cm in total length and 16.5–21.7 g in weight. The other species, the Crested Berrypecker, is medium-sized, 19–22 cm in length and 36–61 g in weight, and somewhat similar in size and proportions to a plump bulbul. The variation in size shown by the Crested Berrypecker generally reflects an increase in size correlated with an increase in altitude. In addition, Crested Berrypecker males tend to be slightly larger, on average, than females.

These birds have a short neck and a plump body. The tail of the Tit Berrypecker is shortish and square, that of the Crested Berrypecker being longish, rounded and somewhat graduated. The wing of both species is moderately long and moderately broad, and the wingtip is rounded. The Tit Berrypecker has a wing length of 68–76 mm, and the larger Crested Berrypecker a wing length of 91–123 mm. The longest primary is P7 in the

case of the Tit Berrypecker, and P6 in the Crested Berrypecker. On both of these species, the outermost primary, P10, is vestigial. As noted by Harrison and Parker, a vestigial P10, when associated with a longer, narrower wing, is characteristic of species requiring sustained or long-distance flight, whereas a long P10 is associated with a short rounded wing that is characteristic of sedentary birds. Furthermore, a long narrow wing is usually evolved from a shorter rounded wing, the process being accompanied by a reduction in size of P10. Tit Berrypeckers are often seen in flocks flying into and out of the crowns of fruiting trees, often flying strongly above the canopy, and sometimes heading across a forested or semi-cleared mountainside towards the next spur or ridge. Such behaviour may be in keeping with the possession by this species of a reduced P10. The Crested Berrypecker, however, is never seen in sustained flight above the canopy; instead, it moves through vegetation in the upper, middle and lower levels of the forest and forest edge, flying only short distances between trees and bushes and across small open spaces. The possession of a vestigial P10 by this species must, therefore, be considered an anomaly. It is most likely, as speculated by Harrison and Parker, that the vestigial outermost primary of paramythiids is a relict character, derived from a long-winged form no longer extant. The flight behaviour of the Tit Berrypecker would seem to support opinion that it represents a lower evolutionary stage than that presented by the Crested Berrypecker (see Systematics).

Both members of the family have a fairly strong bill that is distinctly shorter than the head. That of the Crested Berrypecker tapers evenly towards the tip, with the culmen curved; it is broad basally at the nostrils, but towards the tip it is laterally compressed. The upper mandible is slightly notched at its tip and projects a little beyond the lower mandible. The Tit Berrypecker's bill is similar but is proportionately shorter, with the notch at the tip of the upper mandible poorly defined. In both species, the bill is black. The nostrils are partially covered by an operculum, leaving a transverse narrow aperture at the lower edge. Rictal bristles are lacking in the case of the Tit Berrypecker, and those of the Crested Berrypecker are short, fine, very sparse and difficult to detect. The tongue of the Crested Berrypecker is described as being relatively broad and tapering, with a small median notch at the tip.

The legs and feet of the Tit Berrypecker are moderately strong, with well-curved claws and smooth tarsi, those of the male being greyish-brown to dark brown and those of the female grey-brown to light brown or pale grey. The Crested Berrypecker has quite strong legs and feet, with similarly curved claws and smooth tarsi, but the leg colour of both sexes is black. Male Tit Berrypeckers have a dark olive-brown iris colour, whereas the females of this species have brownish-grey eyes, while both sexes of the Crested Berrypecker have the iris dark blue-grey to dark slate-brown.

The plumage of painted berrypeckers is soft and downy. A peculiarity of these two species, one that is not visible in the field, is the presence of long wiry black filoplumes on the flanks, the function of which is unknown. One species, the Tit Berrypecker, is sexually dimorphic in plumage, whereas the sexes of the Crested Berrypecker are alike. The colour patterns of the male Tit Berrypecker and the Crested Berrypecker are bold and the coloration distinctive: both have black on the crown, a black throat and bib, and yellow undertail-coverts. In addition, as with all paramythiid plumages, the back is green, the upper surface of the tail is blue-grey, and the main colour of the underwing is distinctively delineated on the underside of the flight-feathers. Apart from these similarities in colour and pattern, the two species are, however, quite different from each other in appearance.

At a glance, the male Tit Berrypecker resembles a Great Tit, a widespread species of Europe, Asia and north Africa. It has a contrasting large yellow area on the side of the head encompassing the cheek and the ear-coverts, and the abdomen is bright yellow with a large burnt-orange central area. It also has distinctive pale yellow terminal spots in the outer webs of the tertials, a character which it shares with the female. The underwing is mainly yellow. The female Tit Berrypecker is sub-

The **Tit Berrypecker** is fairly plump with a relatively short, square tail. It is dichromatic, the male being much brighter than the female, with a black head offset by yellow cheeks. The male's pattern gives the species its name, as it resembles that of the Great Tit (*Parus major*). The sexual dichromatism extends as far as iris colour, the male having a dark olive-brown iris, while the female has brownish-grey eyes. Both sexes have distinctive yellow patches on the outer webs of the tertials, and these are clearly visible in this photo. Like the Crested Berrypecker (*Paramythia montium*), the Tit Berrypecker is restricted to the mountains of New Guinea, where it is usually found between 2000 m and 3000 m. It tends to be fairly common, living in pairs or small flocks in the understorey of humid forest.

[*Oreocharis arfaki*,
Ubaigubi,
EC New Guinea.

dued in coloration and somewhat undistinguished in appearance. Its crown is green, like the back, the throat and bib are plain grey, and the cheeks and ear-coverts are grey, lightly mottled whitish; it has dusky scalloping on the yellow flanks and abdomen, perhaps indicating a relict pattern. The underwing of the female is mainly pale yellow.

Immature Tit Berrypeckers of both sexes are like the adult female in plumage. The young male begins to acquire adult plumage first on the head and throat, and finally on the underparts. The juvenile plumage of this species is also similar to that of the adult female, although it has not been described in detail.

The Crested Berrypecker is unique in appearance. Ornithologists generally regard it as being among the most attractive of New Guinea birds and, as noted by Rand and E. T. Gilliard, its coloration harmonizes beautifully with the mossy forests of its high mountain home. It seems a pity, therefore, to liken this evocative species to a bulbul. The feathers of the forecrown are elongated and rounded at their tips, and form an erectile crest. The forecrown and crest are black, contrasting with the whitish to pale grey hindcrown and nape; these last two regions are usually partially covered by the flattened crest, resulting in the pale area appearing as a long broad stripe extending backwards from above each eye. The underparts are blue-grey, this coloration extending to the neck and ear-coverts, and the underwing is mainly pale grey. The two groups of subspecies presently treated as forms of the Crested Berrypecker (see Systematics) are easily distinguished: both members of the western "*olivacea* group" have a longer crest, and the white feathers of the nape are heavily tipped black, whereas the two members of the eastern "nominate group" have an area of golden olive-yellow on the flanks, though this is normally concealed under the closed wing.

Young Crested Berrypeckers resemble the adults, but are much duller. The immature of the eastern, nominate race has the hindneck and nape dark olive-green, like the back, and the pale grey area on the head is confined to a small patch above and backwards from the eye; the underparts are dull olive-tinged bluish-grey, becoming sooty on the upper throat and chin, and with the feathers of the abdomen fringed yellowish-olive, becoming dull olive-yellow ventrally. The juvenile of the western race *alpina* is described as being largely grey below, with a black throat and pale, whitish-yellow lower underparts.

Little has been documented with regard to the moult of paramythiids. An assessment of the meagre data available for the Tit Berrypecker suggests that this species probably commences the moult in October, although information is lacking for the period from November to March. For the Crested Berrypecker, the available data appear to suggest that moult may occur mainly during the period March–May, extending into June, probably following breeding, and also that a minority of the population may moult during the rest of the year, with least moult activity occurring during July–September, prior to breeding. This, however, does not take into account the lack of information for the period December–February. There is also the possibility that, for both species, there may be some variation in the timing of moult among the various populations.

Habitat

The distribution of the paramythiid berrypeckers is centred on New Guinea's central mountain ranges, a cordillera that extends the length of the main body of that island. The Tit Berrypecker, occurring at lower montane elevations than those occupied by its relative, has a virtually unbroken distribution along this cordillera, from the Weyland Mountains in the west to the area about Mount Simpson in the far south-east. It is found also on most outlying ranges, being present in the Tamrau and Arfak Mountains of the Vogelkop Peninsula, the Wandammen Mountains, the Gauttier Mountains, the Torricelli Mountains, and all ranges of the Huon Peninsula. The presence of this species on these outlying ranges appears to represent a relict distribution: during glacial periods of the Pleistocene Epoch, montane forest extended down to much lower elevations than it does today, facilitating the colonization of these ranges. Similarly, the

Crested Berrypecker is found along the length of the Central Ranges, from the Weyland Mountains in the west eastwards to Mount Suckling in the far south-east, although, being restricted to higher elevations, its distribution is broken in a number of areas. The only outlying ranges in which this species is found are those of the Huon Peninsula. Apparently, these are the only ones that are at present high enough to support sufficient suitable habitat for this species.

Painted berrypeckers inhabit montane forests in the temperate to alpine zones. The Tit Berrypecker is found mainly in mossy forest, primarily from around 2200 m up to 2800 m; occasionally it occurs as low as 850 m and as high as 3650 m. It also visits nearby disturbed and partly cleared habitats. The Crested Berrypecker is found in mossy montane forest, forest edge, stunted subalpine forest and alpine thickets, from around 2150 m, but mainly above 2450 m, up to the tree-line at around 3800–4100 m. Local variations in the lower limit of occurrence of both of these species appear to be correlated with the varying downward extent of moss forest.

The two species overlap broadly in altitudinal range, and are generally sympatric in mossy forest. Moreover, both frequent the upper and lower strata of the forest and forest edge, although they do not associate with each other. The Tit Berrypecker is seen mostly in the canopy, and it readily visits the crowns of emergent and isolated fruiting trees; it also spends time in the middle stage and occasionally the substage of the forest. The Crested Berrypecker moves freely between the crowns of bushy trees in the canopy and shrubs in the substage, and it occasionally visits the ground.

General Habits

Both members of this family are arboreal and frugivorous, and are encountered most often when they are visiting fruiting trees and shrubs. They are generally common and are frequently observed, although our knowledge of the behaviour of these birds remains limited. So far as is known, both are diurnal, being active solely by day.

The Tit Berrypecker moves about in pairs, in small groups and in loose, vocal, single-species flocks of five to 30 or more individuals. According to one authority, flock-members are generally paired. They move quickly and nervously through the canopy in the manner of white-eyes (*Zosteropidae*), and they often fly together as a flock above the canopy from one group of trees to another. Although flock-members attract attention with their frequent wheezy calls, they are often difficult to observe in the thick foliage. They visit various fruiting trees, shrubs and plants, mostly in the canopy but also in the middle storey and forest-edge shrubbery. Some of the fruiting trees which they visit are frequented at the same time by other bird species, including melanocharitid berrypeckers, honeyeaters and birds-of-paradise (*Paradisaeidae*). One observer noted that, even when feeding in some fruiting tree along with other species, Tit Berrypeckers were continually moving in and out of the tree, so that the flocks may have been much larger than was suspected. Solitary pairs loafing in the middle and lower stages of the forest are less active, and sometimes inactive; they call infrequently and, although not particularly shy, are often difficult to locate.

The Crested Berrypecker is usually seen in small parties and single-species flocks containing up to ten or more individuals, but when breeding it is more often found in pairs. On Mount Albert Edward, on one occasion when a flock crossed a small glade, Rand was able to count the individuals and he found that there were more than 75 birds in the flock. As observed by Rand, flocks of this species are occasionally accompanied by mainly or partially insectivorous bird species, including the Blue-capped Ifrit (*Ifrita kowaldi*), the Black-throated Honeyeater (*Lichenostomus subfrenatus*) and the Friendly Fantail (*Rhipidura albolimbata*). Such flocks are loose and scattered, and move rather quickly through the forest, the berrypeckers pausing only briefly to feed on berries of trees and taller shrubs. The Crested Berrypecker is a moderately active, rather restless bird that re-

Both members of the family feed almost exclusively on small fruits, which they generally ingest whole. The **Crested Berrypecker** forages restlessly in groups of up to 75 individuals, usually keeping low in dense cover, where it can be surprisingly difficult to observe. It moves acrobatically through branches, stopping to investigate the tips of twigs, and occasionally capturing insects. There is little information about food plants, but field observations suggest that it visits a wide range of trees and shrubs, typically consuming a few berries before moving on.

mains for only a short time in any one fruiting tree or plant. It is generally quiet, and its calls are mostly subdued and usually given infrequently. Sometimes it is conspicuous and easy to observe, especially when it visits a fruiting plant in an exposed situation. It is also more conspicuous at higher elevations, where the trees are stunted.

Although it is not shy, the Crested Berrypecker is often unobtrusive and it skulks in bushy vegetation, where it may briefly loaf and preen. Two partners may then perch close to or next to each other, and allopreening has been observed between two individuals. The crest is usually depressed, but it is sometimes raised when the bird is excited or alarmed, and sometimes the tail is held cocked. The flight of this species is described as being jerky and noisy. In contrast to the Tit Berrypecker, Crested Berrypeckers fly only short distances, within the forest and low across forest glades, and not above the canopy. According to one authority, this species has "a bizarre habit of plucking certain large ericaceous flowers and rubbing its plumage with the crushed corollas". Such unusual behaviour requires an explanation (see Food and Feeding).

Nothing has been documented with regard to the agonistic or territorial behaviour of these two species. Likewise, there is no available information on their drinking, bathing and roosting habits.

Voice

Painted berrypeckers appear to have a limited repertoire, although their vocalizations are not very well known, and no songs have been described or identified as such. Typically, their calls are subdued, but they differ markedly between the two species.

The Tit Berrypecker is much more vocal than is its larger relative. Its usual calls are shrill and wheezy, and are frequently uttered by flock-members while feeding or in flight. They are reminiscent of those of a pygmy-parrot (*Micrositta*) and in-

clude a fine "tzee-tzee" and a long fine wheeze. This latter call is also given weakly, infrequently and with a ventriloquial quality by individuals loafing quietly in the lower strata of the forest, apparently in alarm or when they are disturbed. The aforementioned calls have been described by other authors variously as a very high, drawn-out "sss" or "z-z-z", similar to the call of the Cedar Waxwing (*Bombicilla cedrorum*) of North America, and as a "continuous high nasal buzz".

The usual call of the Crested Berrypecker in eastern New Guinea is a short low scratchy note, like the sound of dry leaves and twigs scraping together. This is probably a contact call. It has been described by other authors as a faint squeaking, kissing or rasping note, and has been likened also to the sounds made by birdwatchers when "squeaking" or sucking on the back of a hand in order to attract birds. Other calls given by this paramythiid include a nasal "swetch" or "zek", a very harsh "schhh", perhaps in alarm, and a "pzee" note, the last usually given by adults when arriving at the nest-site together.

Food and Feeding

These birds feed almost exclusively on small fruits, which they usually swallow whole. Both species visit a variety of fruiting trees and shrubs, although there is very little available information on which species of plant they frequent. In an avifaunal study by J. M. Diamond, the size of fruits in the stomachs of a number of Tit Berrypeckers was found to range in diameter from 1 mm to 7 mm, and the stomachs of a small number of Crested Berrypeckers contained fruits 2–8 mm in diameter.

The stomach contents of Tit Berrypeckers would appear to indicate that this species feeds entirely on small fruits. Its berry diet is, however, at times supplemented with other plant parts and products. For example, I. S. Majnep and R. Bulmer report that this species feeds also on the blossoms of a stinging tree, possibly of the genus *Fleurya*, and it has been observed to hang

upside-down in order to probe a flower. The Tit Berrypecker feeds mostly on berries in the canopy, but it also exploits those in the forest middle storey and, occasionally, in forest-edge shrubbery. The fruit-bearing plants that it visits include a tree of the genus *Pipturus*, a vine of the genus *Nothocnide*, and species of the epiphytic and free-standing umbrella tree/shrub (*Schefflera*).

The diet of the Crested Berrypecker is composed almost entirely of small fruits, of many kinds. Included in the plant items consumed by this species are the fruits of umbrella trees, the fruit of a wild raspberry (*Rubus*), the hard immature seed "cones" that are produced at the tips of twigs of a *Dacrycarpus* tree and concealed from below by short, needle-like leaves, and the fruits and/or seeds of sedges (Cyperaceae). On rare occasions, insects have been recorded in the stomach contents of this species, and it has been observed by the present writer to devour the contents of an arthropod cocoon. The nestling is fed with fruit and insects (see Breeding).

When foraging, the Crested Berrypecker is continually moving among branches and often investigates the tips of twigs acrobatically, as though searching for insects or for an obscure plant product. When visiting a fruiting tree, it takes only a few berries before moving on, even though other, seemingly suitable berries are within reach. This suggests either that it feeds unsystematically or, perhaps more likely, that it is highly selective with regard to the quality and/or ripeness of the fruit that it chooses to eat. A berry-bearing tree may hold fruit continuously over a period of many weeks and be visited by this species, and probably by the same individuals, on successive days.

Unlike the Tit Berrypecker, the Crested Berrypecker has not been reported as eating flower parts. One may speculate, however, that its reported habit of rubbing its plumage with the crushed corollas of certain large ericaceous flowers (see General Habits) could possibly be related to the consumption of such items.

Breeding

The breeding habits of these two species are only partly known, and nothing has been documented in respect of their courtship behaviour. Apparently, both species form monogamous pairs when nesting. Each species builds an open cup-shaped nest composed of moss, and both sexes feed the young.

The breeding season of the Tit Berrypecker is poorly known. Specimen data from 43 individuals, comprising 22 adult males, 14 females and seven immature males, collected in eastern New Guinea between late May and early October, indicate that the gonads were enlarged only in all August–October males, including an immature male in female-like plumage, and in one female collected in early October. This suggests that breeding in that region probably begins in October–November, in the late dry season to early wet season. The observation of fledged young in mid-July indicates that nesting had taken place also in June, early in the dry season. Of five male and three female specimens of this species from the Snow Mountains region of western New Guinea in October and early January to early February, only two males had enlarged gonads, one in October and the other in February. Little is known of the breeding habits of the Tit Berrypecker. It is presumed to form monogamous pairs when nesting. Its nest, as reported by Majnep and Bulmer, is an open cup composed of moss, and, as also reported by local people, both male and female undertake the task of incubation. The clutch size and the appearance of the egg, however, are undescribed, as also is the nestling, although two fledglings were seen to be attended and fed by both parents.

Active nests of the Crested Berrypecker were found in the Lake Habbema area of western New Guinea in August, and also in mountains south of the Tari Valley, in eastern New Guinea, in late August, October to December, and February. In addition, females from south-east New Guinea had enlarged gonads in September. The breeding season would seem, therefore, to extend from August to February. A juvenile specimen of unknown

age was obtained in the Snow Mountains region of western New Guinea in early September, suggesting that breeding may occur at some time earlier in the year, too.

Most of what is known of the nesting habits of the Crested Berrypecker is derived from data obtained by Rand in the Snow Mountains region of western New Guinea, and by C. B. Frith and D. W. Frith in the Tari Gap area of eastern New Guinea. This species forms monogamous pairs when breeding. It is not known if both sexes contribute to nest-building, but the female alone incubates; the male stays nearby and accompanies her while she is off the nest. The nestling Crested Berrypecker has abundant grey down, both above and below. It is fed by both parents, with fruits and insects, and both also remove the nestling's faeces.

The Crested Berrypecker's nest is cup-shaped, bulky, deep, loose and untidy, and is large for the size of the bird. One nest was composed of a coarse moss-like liverwort, or mosses, with some lichens and semi-woody stems throughout, and was scantily lined with fine grass stems, rootlets and semi-woody stems; in the bottom of the nest was a thick cushion, 50 mm thick, of chaff from tree-ferns. This nest measured 140 mm in diameter and 160 mm in depth externally, and 90 mm across by 50 mm deep inside. Another nest had external dimensions of 155 mm by 148 mm, and internally was 78 mm by 47 mm. Nests are sited 0.9–4 m above ground, placed either in the fork of a small lightly to densely foliated sapling or in the dense branches of a shrubby bush or sapling, in the latter case being supported on all sides by dense twigs. Nests are usually found at the forest edge, although the difficulty of detecting them within forest may give a false impression that this is the preferred situation.

This species lays a single egg, ovate in shape, with no gloss. The egg is white, off-white or very pale buff, sparsely and finely spotted throughout with dark browns and greys, or dark purple-browns and purple-greys, or purples, browns and russet. The markings are denser around the larger end, where they often form a wreath, with or without purple-grey blotches. The egg dimensions are 29.5–30.2 × 20.6–21.1 mm, and the weight 6.2 g. The incubation period is apparently more than 12 days, but information on the fledging period is lacking. Similarly, there is no information on the breeding success of this species, although the rate of predation of eggs and small young seems to be lower for Crested Berrypeckers than it is for species that build open nests at low altitudes.

Movements

Painted berrypeckers are resident throughout the year in New Guinea. At certain montane locations regularly visited by ornithologists both species may be found at any time, although the Tit Berrypecker is more variable in abundance, can be elusive, and may occasionally go unrecorded. It has not been determined for either species whether populations are wholly or partially sedentary or are to any extent nomadic. Nothing is known of local movements, and neither species undertakes long-distance migration.

The Tit Berrypecker is strong-flying, often forms flocks, and readily overflies forest and semi-cleared areas. This suggests that it is probably locally nomadic in its search for fruiting trees. Further, the lack of recognizable racial variation in this species across its entire range (see Systematics) may be an indication that populations are in flux as a result of nomadism or dispersal. Its presence on most outlying mountain ranges, however, is not considered evidence of a propensity to colonize these isolated ecological islands by flying directly from the Central Ranges. Rather, this is more likely a relict of a former much more extensive, non-fragmented distribution during glacial periods of the Pleistocene (see Habitat).

When not breeding, the Crested Berrypecker often occurs in small single-species flocks of up to ten or more individuals. On one occasion, a flock was found to contain more than 75 of these berrypeckers (see General Habits). Such behaviour suggests that this species, too, is likely to be at least partially nomadic. Moreover, the high level of uniformity in external

Although both species of painted berrypecker forage communally, they tend to breed in socially monogamous pairs.

The **Crested Berrypecker** is typical of the duo in building a bulky, mossy, cup-shaped nest, roughly 1–4 m above the ground in the fork of a sapling. The female of this species apparently lays a single egg which it incubates alone. The egg hatches after at least 12 days, after which the nestling is provisioned with fruit and insects by both sexes, as seen here.

[*Paramythia montium montium*, Tari Gap, Papua New Guinea. Photo: Clifford & Dawn Frith]

morphology within each group of races (see Systematics) could, again, be due to nomadism or dispersal. This species' colonization of the outlying high mountain ranges of the Huon Peninsula presumably occurred during glacial periods of the Pleistocene when montane forest extended down to much lower altitudes than it does today, allowing an expansion of this berrypecker's range.

Relationship with Man

The relationship that the paramythiid berrypeckers have with humans is very limited. Traditional stories relating to these birds probably exist in Papuan folklore but await formal documentation. Furthermore, and unlike some other avian species, such as plumed birds-of-paradise and brightly coloured parrots (Psittacidae), they are not usually sought after for their plumage for use in, for example, head-dresses. On the other hand, in the mountains of New Guinea where native peoples traditionally live off the land, mainly by gardening, even the smallest birds are opportunistically hunted for food. This would include both paramythiid species. In the only reported instance of such activity, Rand noted, during the 1933–1934 Archbold Expedition to south-east New Guinea, that the natives who visited the expedition's camps on top of the Wharton Range found the Crested Berrypecker a favourite food. "They shot them with their four-pronged arrows, removed the entrails, and strung the birds on a piece of fibre by threading through the nostrils."

The knowledge which the traditional mountain Papuans have of the animals and plants of their local area is often remarkable and encyclopaedic. Often, they have a name for every bird found regularly in that area, and they distinguish the female of a sexually dimorphic species by using a name different from that used for the male. Surprisingly, the Kalam people of the highlands of east-central New Guinea even recognize a close kinship between the two paramythiids. According to Majnep and Bulmer, the name of the Tit Berrypecker in the Kalam language is *tbwm-kab-ket*, meaning "it haunts the fruit of *Schefflera* species"; the male is referred to as *tbwm-kab-ket pok*, meaning "brightly col-

oured", or *tbwm-kab-ket klwak*, "yellow", while the female is called *tbwm-kab-ket kl*, which translates as "mottled". The name of the Crested Berrypecker is *tbwm-kab-ket nonm*, which means "mother of *tbwm-kab-ket*".

It is worth noting also that the painted berrypeckers, especially the Crested Berrypecker, are among the species most sought after by birdwatchers visiting New Guinea. As a result, these birds play a small but important role in ecotourism, by drawing the visitors to favoured sites.

Status and Conservation

Painted berrypeckers are generally moderately common to locally abundant within their geographical range and specific habitat. Because large expanses of suitable habitat remain along the entire length of New Guinea, there is presently no concern about the status of any paramythiid taxa, even though their population sizes are unknown.

Nevertheless, in some areas, especially at mid-montane elevations up to around 2100 m, forests have been extensively converted to agriculture or turned into man-made grasslands. Much of the range of paramythiids lies above this zone, although cultivation occurs locally also up to around 2700 m. At higher elevations, during exceptional periods of dry weather, grass fires lit by man frequently result in severe damage to areas of high-mountain forest and alpine thickets, and an associated expansion of high-mountain grasslands. For paramythiids, the effect of such an event is likely to be a long-term or permanent reduction in the size of local populations. Despite this, however, these two species are considered not to be at any immediate risk.

PLATE 24

Family PARAMYTHIIDAE (PAINTED BERRYPECKERS) SPECIES ACCOUNTS

Genus *OREOCHARIS* Salvadori, 1876

1. Tit Berrypecker

Oreocharis arfaki

French: Oréochare des Arfak **Spanish:** Picabayas de las Arfak
German: Gelbbauch-Beerenpicker
Other common names: Painted/Arfak/New Guinea Berrypecker, Arfak Flowerpecker

Taxonomy. *Parus* (?) *Arfaki* A. B. Meyer, 1875, Arfak Mountains, New Guinea. *O. stictoptera* is a synonym of current name for this species. Affinities of this genus and *Paramythia* have long been uncertain; traditionally placed in flowerpecker family (Dicaeidae), and suggested by some authors as being aberrant bulbuls (Pycnonotidae), while present species initially thought possibly to belong with the tits (Paridae); recently, both genera included with berrypeckers and longbills in family Melanocharitidae. Both, however, are well differentiated from these other families in external morphology and in aspects of nidification, and molecular-genetic analyses also support treatment as a separate family. Present species exhibits widespread individual variation; proposed race *bloodi* (Western Highlands) unwarranted. Monotypic.

Distribution. Mountains of New Guinea: Vogelkop (Tamrau Mts, Arfak Mts), Wandammen Mts, Gaultier Mts, Torricelli Mts, Central Ranges, and mountains of Huon Peninsula.

Descriptive notes. 12–14 cm; 16.5–21.7 g. Male has large yellow area on side of head (encompassing cheek and ear-coverts); rest of head, side of lower neck, throat and bib on upper breast black; upperparts olive-green, uppertail-coverts blue-grey; flight-feathers black with green edges, tertials each with prominent pale yellow terminal spot on outer web; upper surface of tail blue-grey, becoming darker towards tip; underparts below bib bright yellow, large central area on abdomen burnt orange; iris dark olive-brown; bill black; legs greyish-brown to dark brown. Female is obscure-looking, but with diagnostic yellow

spotting on tertials (as in male) and scalloping on flanks; top of head olive-green with or without indistinct darker mottling, yellow on cap and sides of neck, rest of upper surface similar to that of male; cheek and ear-coverts grey, lightly mottled whitish, throat and bib (on upper breast) plain grey, lower breast and flanks yellow with dusky scalloping, abdomen yellowish-white with obscure dusky scalloping; iris brownish-grey; bill black; legs grey-brown to light brown or pale grey. Juvenile and immature are similar to female. **Voice.** Calls typically shrill and wheezy, and frequently uttered, including fine “tzee-tzee” and long fine wheeze, reminiscent of calls of a pygmy-parrot (*Micropsitta*); described also as a very high, drawn-out “sss” or “z-z-z”, similar to call of Cedar Waxwing (*Bombicilla cedrorum*).

Habitat. Montane forest, especially mossy forest; also visits disturbed and partly cleared habitat. Mainly between 2200 m and 2800 m, occasionally as low as 850 m and as high as 3650 m.

Food and Feeding. Diet as indicated by stomach contents entirely small fruits. Observed to probe a flower, and reported also as feeding on blossoms of a stinging tree. Fruits, from a variety of trees and shrubs, usually swallowed whole. Moves about in pairs, in small groups and in loose flocks of five to 30 or more individuals. Visits various fruiting trees, shrubs and plants, including *Schefflera*, a *Pipturus* tree and a *Nothocnide* vine. Forages mostly in canopy but also at middle level of forest, and occasionally in forest-edge shrubbery.

Breeding. Few data collected to date. In W part of range, two males with enlarged gonads in Oct and Feb; in E, males with enlarged gonads in Aug–Oct, female in breeding condition in Oct, and fledged young observed in Jul. Nest reported as cup-shaped, composed of moss; incubation said to be undertaken by both sexes; two fledglings seen to be fed by both parents. No other information available.

Movements. Resident; probably locally nomadic.

Status and Conservation. Not globally threatened. Generally common throughout range. No known threats, but some habitat loss in some parts of range.

Bibliography. Beehler (1988), Beehler *et al.* (1986), Coates (1990), Coates & Peckover (2001), Diamond (1972a), Frith & Frith (1992, 1993b), Gilliard & LeCroy (1961, 1970), Gyldenstolpe (1955a, 1955b), Majnep & Bulmer (1977), Mayr & Rand (1937), Salomonsen (1961b), Salvadori (1876), Thorpe (1975).

Genus *PARAMYTHIA* De Vis, 1892

2. Crested Berrypecker

Paramythia montium

French: Paramythie huppée **German:** Schopfbeerenfresser **Spanish:** Picabayas Crestado
Other common names: Mountain Berrypecker, Olivaceous Berrypecker (“*olivacea* group”)

Taxonomy. *Paramythia montium* De Vis, 1892, Mount Suckling, south-eastern New Guinea. Affinities of this genus and *Oreocharis* have long been uncertain; traditionally placed in flowerpecker family (Dicaeidae), and suggested by some authors as being aberrant bulbuls (Pycnonotidae); recently, both genera included with berrypeckers and longbills in family Melanocharitidae. Both, however, are well differentiated from these other families in external morphology and in aspects of nidification, and molecular-genetic analyses also support treatment as a separate family. Races form two groups, “*olivacea* group” (with *alpina*) in W and “*nominate* group” (with *brevicauda*) in E; these sometimes considered two separate species, and evidence of intergradation between the two groups is lacking, but specimens from area between Snow Mts and Star Mts of WC New Guinea required for further study. Subspecific separation of populations in Weyland Mts and Snow Mts region of W New Guinea has been considered inadvisable, and recognition of altitudinal race *alpina* therefore made with reservation; further analysis of specimens needed. Proposed race *occidentis* (from Hellwig Mts, on S slopes of Snow Mts) regarded as a synonym of *olivacea*. Four subspecies tentatively recognized.

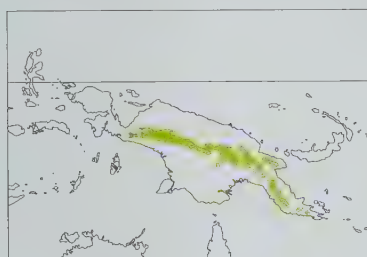

Subspecies and Distribution.

P. m. olivacea van Oort, 1910 – W New Guinea (Weyland Mts and Snow Mts).

P. m. alpina Salomonsen, 1961 – area surrounding Mt Wilhelmina (= Mt Trikora) and Mt Carstenz (= Mt Jaya), on upper slopes of Snow Mts (Nassau Range), in W New Guinea.

P. m. montium De Vis, 1892 – mountains of C, E & SE New Guinea (E from Star Mts).

P. m. brevicauda Mayr & Gilliard, 1954 – mountains of Huon Peninsula, in NE New Guinea.

Descriptive notes. 19–22 cm; 36–61 g. Highly distinctive passerine; feathers of crown elongated, forming flattened, erectile crest. Nominative race has forehead, forecrown, crest, face and bib on upper breast black, hindcrown to nape whitish to pale grey (usually partially covered by flattened crest, pale area appearing as contrasting long broad stripe extending backwards from above eye); upperparts and upperwing green, wingtip blackish-brown, tail blue-grey; ear-coverts, hindneck and underparts to belly blue-grey, area on flanks (often hidden under wing) and area on lower abdomen to undertail-coverts golden olive-yellow;

iris dark blue-grey to dark slate-brown; bill and legs black. Sexes alike, female on average smaller than male. Immature is much duller than adult, has hindneck and nape dark olive-green, as back, pale grey area on head confined to small patch above and back from eye; dull olive-tinged bluish-grey below, becoming blackish on upper throat and chin, feathers of abdomen fringed yellowish-olive, becoming dull olive-yellow ventrally. Race *brevicauda* is like nominate but with shorter tail; *olivacea* is distinctive, with longer crest, streak above eye to nape white, feathers of nape white basally with black tips, back olive-green, and flanks wholly greyish-blue; *alpina* is like previous but larger (male wing 112–123 mm, compared with 100–108 mm), with upperparts clearer green, less olive-green, juvenile largely grey below with black throat and pale whitish-yellow lower underparts. **VOICE.** Usual call in E of range a short low scratchy note, like sound made by dry leaves and twigs scraping together; also described as a faint squeaking, kissing or rasping note. Other calls include a nasal “swetch” and a very harsh “schhh”.

Habitat. Mossy montane forest, forest edge and alpine thickets; from c. 2150 m, mainly above 2450 m, up to tree-line at c. 3800–4100 m.

Food and Feeding. Food almost entirely small fruits of a variety of trees and shrubs; also fruits of umbrella trees (*Schefflera*), immature seed “cones” of *Dacrycarpus* species, and fruits/seeds of sedges (Cyperaceae). Insects recorded rarely in stomach contents; observed to devour contents of an arthropod cocoon. Nestling fed with fruit and insects. Fruits swallowed whole. Usually in pairs; also in loose parties of up to ten or more individuals, and sometimes in dispersed flocks of up to at least 75 birds. Flocks occasionally accompanied by mainly or partially insectivorous species, including Blue-capped Ifrit (*Ifrita kowaldi*), Black-throated Honeyeater (*Lichenostomus subfrenatus*) and Friendly Fantail (*Rhipidura albolimbata*). Active; ranges from canopy to shrubby levels, and occasionally descends to the ground. When feeding, takes only a few berries in one tree before moving on. Often explores ends of twigs acrobatically.

Breeding. Season Aug–Feb. Nest cup-shaped, bulky, deep, loose and untidy, composed of a coarse moss-like liverwort, or mosses, with some lichens and semi-woody stems throughout, scantily lined with fine grass stems, rootlets and semi-woody stems and a thick cushion of chaff from tree-ferns; placed 0.9–4 m above ground in dense branches of shrubby bush or sapling and supported on all sides by dense twigs, or in fork of lightly to densely foliated small sapling. Clutch 1 egg; incubation by female alone, period apparently more than 12 days; chick fed by both parents, no information on duration of nestling period.

Movements. Resident; perhaps locally nomadic.

Status and Conservation. Not globally threatened. Generally common, especially at higher elevations. Despite suffering some loss of habitat, present species is considered not to be at any immediate risk.

Beehler *et al.* (1986), Clapp (1986b, 1993), Coates (1973, 1990), Coates & Peckover (2001), David & Gosselin (2002a, 2002b), Diamond (1972a), Frith & Frith (1992, 1993b), Gilliard & LeCroy (1961), Gyllenstolpe (1955a), Hartert *et al.* (1936), Hopkins (1992), Mayr & Gilliard (1954), Mayr & Rand (1937), Mees (1964b), Rand (1936b, 1942b), Rand & Gilliard (1967), Ripley (1964), Rothschild & Hartert (1896a), Salomonsen (1961b), Sclater (1893), Sims (1956), Strange (2001).

Class AVES
Order PASSERIFORMES
Suborder OSCINES
Family DICAETIDAE (FLOWERPECKERS)

- Very small to small passerines, with short, sometimes rather deep bill, short tail, sometimes brightly coloured and occasionally with some iridescence.
- 7–13 cm.

- Oriental and Australasian Regions and south-west Pacific islands.
- Forests, including mangroves, occasionally scrub, plantations, gardens.
- 2 genera, 44 species, 147 taxa.
- 3 species threatened; none extinct since 1600.

Systematics

This family of small passerines is confined to the Oriental and Australasian zoogeographical regions, except for two species in the Solomon Islands. Which genera should be included in the family Dicaetidae, and to which other groups the family is related, have for long been matters of dispute among taxonomists.

In 1872, C. J. Sundevall grouped the flowerpeckers with the *Zosterops* white-eyes, some Neotropical honeycreepers of the family *Thraupidae*, the New World warblers (*Parulidae*) and the pardalotes (*Pardalotus*) in the “cohort Cichlomorphae”, on the basis of the bill form and the fact that all of these possess just nine long primaries. The sunbirds (*Nectariniidae*), however, he placed in another cohort, the “Cinnyrimorphae” or “Tubilingues”, along with four other families comprising other Neotropical honeycreepers (the nectarivorous tanagers), the Hawaiian honeycreepers (*Drepanididae*), Australian honeyeaters (*Meliphagidae*) and the sugarbirds (*Promerops*) of southern Africa, a grouping based on tongue structure and preferred diet. H. Gadow, writing a decade or so after Sundevall, also thought that the flowerpeckers were close to the *Zosteropidae*. R. B. Sharpe, on the other hand, placed the flowerpeckers in the *Fringilliformes*, and included within his family Dicaetidae an unlikely assortment of taxa. In addition to the two flowerpecker genera, *Prionochilus* and *Dicaeum*, he incorporated: the painted berrypecker genus *Oreocharis* (*Paramythiidae*); the *Melanocharis* and *Rhamphocharis* berrypeckers (*Melanocharitidae*); the waxbill genus *Parmoptila* (*Estrildidae*); the monospecific *Pholidornis*, which is of uncertain affinities but currently treated as a penduline-tit (*Remizidae*); the Hawaiian honeycreepers; the Central American *Pinaroloxias* (*Emberizidae*); and *Pardalotus*. Later, he removed the Hawaiian honeycreepers and the genera *Pholidornis* and *Parmoptila* from the Dicaetidae.

Some decades thereafter, in the 1940s, J. Delacour believed that the flowerpeckers were close to the nectariniid sunbirds, as did E. Mayr and D. Amadon. In 1953, W. J. Beecher placed the flowerpeckers with the sunbirds and white-eyes in a group that he termed the “sylvioid nectar feeders”, which he suggested as being derived from the bulbuls (*Pycnonotidae*); all of these he included in a large family *Sylviidae*. In J. L. Peters’s *Check-list of Birds of the World*, published in 1967, F. Salomonsen included the genera *Melanocharis*, *Rhamphocharis*, *Oreocharis*, *Paramythia* and *Pardalotus* with *Prionochilus* and *Dicaeum* in the Dicaetidae. In the following year, A. L. Rand and E. T. Gilliard

included *Rhamphocharis*, *Oreocharis* and *Paramythia* in the Dicaetidae, and W. S. Peckover and L. W. C. Filewood, in 1976, included these three genera along with *Melanocharis* in the family. The latter course was followed by B. M. Beecher and B. W. Finch in their 1985 New Guinea checklist.

With the advent, in the 1980s, of molecular-genetic methods of attempting to understand the relationships of living organisms, there have been numerous, and often surprising, revelations. Nevertheless, relatively little light has been shed on the affiliations of the flowerpeckers. C. G. Sibley and J. E. Ahlquist, from their studies based on analysis of DNA–DNA hybridization, placed the flowerpeckers in a tribe Dicaetini, containing only *Prionochilus* and *Dicaeum*, within a subfamily Nectariniinae of an enlarged family Nectariniidae, which included also a subfamily Promeropinae for the two sugarbirds. In this arrangement, the subfamily Nectariniinae contained a second tribe, the Nectariniini, for the sunbirds and spiderhunters. R. A. Cheke and C. F. Mann,

The two genera that form the Dicaetidae comprise 44 species of small, thick-necked, short-tailed, long-winged passerines. The less speciose genus is *Prionochilus*, with six species including this **Yellow-rumped Flowerpecker**.

Prionochilus flowerpeckers exhibit a few morphological differences from those of the sister genus *Dicaeum*. For example, their outer primary is long, rather than absent or vestigial as in *Dicaeum*. All *Prionochilus* have short, deep, broad bills, and a four-pronged tip to the tongue.

[*Prionochilus xanthopygius*, Samarakan, Bintulu, Sarawak, Borneo. Photo: Doug Wechsler/VIREO]

Dicaeum flowerpeckers are typically dumpy creatures with short legs. The size and shape of the bill vary across the genus: in some it is short and stout, while in others it is fairly long and slim, as in the case of the **Black-sided Flowerpecker**.

Plumage varies from being dull to brightly coloured, with some forms showing a single splash of vibrancy such as the scarlet throat and breast of this species. Some 16 *dicaeids*, including the **Black-sided Flowerpecker**, possess white pectoral tufts. Although frequently hidden away, they are important adornments used in display.

[*Dicaeum monticulum*, Kinabalu Park, Sabah, Borneo.
Photo: Jimmy Chew]

in their monograph dealing with all of these avian groups, followed the taxonomic treatment of Sibley and Ahlquist.

Clearly, there is still much to be learnt about the true affiliations of the flowerpeckers. In the meantime, and notwithstanding the limited genetic findings of recent years, it seems preferable to accord them a family of their own, Dicaetidae, a treatment preferred by most authors since the middle of the last century.

As currently constituted, the Dicaetidae consists of 44 species, divided between two genera. Interestingly, quantitative analyses of the vocalizations of flowerpeckers, carried out as part of a phylogenetic study by K. N. Iddi, indicate that the calls of the *Prionochilus* species fit into a separate clade from those of *Dicaeum* species. Iddi suggests that, on the basis of vocalizations, *Prionochilus* is the basal genus in the family.

The genus *Prionochilus* contains six species, occurring in South-east Asia, the Greater Sundas and the Philippines, one being restricted to Borneo and two to the Philippines. All have a short, broad and deep bill, with the nasal opening circular or oval, and non-operculate. The tongue forms an elongate, slightly concave triangle, the distal fifth of which is cleft, and each prong thus produced is split again over the distal half of its length, such that the tongue has a four-pronged tip. There are ten long primaries, as opposed to the nine possessed by *Dicaeum* flowerpeckers. The proventriculus of the Scarlet-breasted Flowerpecker (*Prionochilus thoracicus*) is markedly broader than the oesophagus, and is much thicker-walled, and the proximal part of the duodenum is quite narrow. As this observation is based on only one species, however, the genus will be difficult to characterize until further anatomical material becomes available. In terms of plumage characters, a white or pale malar stripe is exhibited by four of the six species, although only by the female of the Scarlet-breasted Flowerpecker, and is perhaps an ancestral character that has become lost in the other two species, namely the Yellow-rumped Flowerpecker (*Prionochilus xanthopygius*) and the Olive-backed Flowerpecker (*Prionochilus olivaceus*). As well as lacking a pale malar stripe, the Olive-backed Flowerpecker is the only member of the genus that does not have a red or orange crown patch in one or both sexes. Three species, the Palawan (*Prionochilus plateni*), Yellow-rumped and Crimson-breasted Flowerpeckers (*Prionochilus percussus*), share many characters and may constitute a superspecies, but there is some overlap in distribution in a few parts of Borneo, probably resulting from habitat destruction in recent decades.

Dicaeum, the other genus in the family, contains 38 species, with a total range covering tropical Asia, Wallacea, the New Guinea region and Australia. All except one have a vestigial tenth, outermost primary, the exception being the Yellow-bellied Flowerpecker (*Dicaeum melanoxanthum*), the tenth primary of which is more obvious but still very short. These species have the nasal opening oval and non-operculate. The bill is often short, deep and broad, but it may be narrow, or much less deep, and in some cases it is decurved. At least four tongue types are recognizable, with some slight intraspecific variation. The Bicoloured (*Dicaeum bicolor*), Thick-billed (*Dicaeum agile*), Yellow-sided (*Dicaeum aureolimbatum*) and Grey-sided Flowerpeckers (*Dicaeum celebicum*) have a broad, flat, slightly concave, two-pronged non-tubular tongue. The Red-striped (*Dicaeum australe*), Yellow-bellied and Buzzing Flowerpeckers (*Dicaeum hypoleucum*), on the other hand, have a narrow to medium-broad tongue, with the lateral edges curled inwards and forming a tube on each side of the flat central plate, the distal end of which extends to form two prongs. The tongue of the Olive-capped Flowerpecker (*Dicaeum nigrilore*) is narrow, four-pronged, and with the outer edges fringed with fine hairs (fimbriated). The fourth type, a long, narrow tubular tongue with the distal third bifurcated to form two incomplete tubes, is possessed by the Orange-bellied (*Dicaeum trigonostigma*), Flame-breasted (*Dicaeum erythrothorax*), Blood-breasted (*Dicaeum sanguinolentum*), Pygmy (*Dicaeum pygmaeum*), Midget (*Dicaeum aeneum*) and Scarlet-backed Flowerpeckers (*Dicaeum cruentatum*). This marked variation in tongue structure suggests that the members of this genus as currently constituted do not form a natural group, and that *Dicaeum* should be split into perhaps four or more genera, but lack of comprehensive anatomical material precludes such a move at present.

Otherwise, the proventriculus is broader than the oesophagus, but, unlike the condition in *Prionochilus*, is not noticeably thickened. The proximal part of the duodenum is considerably broader than that of *Prionochilus*, but this observation is based on examination of only one species, the Mistletoebird (*Dicaeum hirundinaceum*).

The relationships of the 14 recognized taxa that together make up the Thick-billed and Brown-backed Flowerpeckers (*Dicaeum everetti*) are problematic. One form, the subspecies *finschi* of the Thick-billed Flowerpecker, could perhaps be raised to species rank, or all 14 forms could be considered conspecific. The latter solution, however, would seem unacceptable owing to the apparent sympatry of the subspecies *modestum* of the Thick-billed Flowerpecker with Brown-backed Flowerpeckers of the race *sordidum* in Peninsular Malaysia and of the nominate race in Borneo. The subspecies *bungurensis* of the latter is somewhat intermediate between the two species. The three Philippine subspecies of the Thick-billed Flowerpecker, *aeruginosum*, *affine* and *striatissimum*, were previously separated at the species level, as the "Striped Flowerpecker".

Two forms of the Plain Flowerpecker (*Dicaeum concolor*), the nominate race of south-west India and *virescens* of the Andaman Islands, are rather distinctive and may perhaps represent separate species. Indeed, this was the treatment preferred by P. C. Rasmussen and J. C. Anderton in their 2005 work on the birds of the Indian Subcontinent, in which the remaining five subspecies are treated under the name of "*D. minullum*".

Relationships among the species in this genus are not always clear. The Whiskered (*Dicaeum proprium*), Yellow-vented (*Dicaeum chrysorrheum*), Yellow-bellied and White-throated Flowerpeckers (*Dicaeum vincens*) appear not to be particularly close, although a relationship between the last two has been suggested on the grounds of their superficial plumage resemblance. The Yellow-bellied Flowerpecker, however, is much larger than all other flowerpeckers, and, as stated above, it is unique within the genus in having an obvious, albeit rather small, tenth primary. The Yellow-sided and Olive-capped Flowerpeckers exhibit some resemblances to each other in plumage, but they differ markedly in bill shape and tongue structure.

A group of six species is confined to the Philippines, and all appear to be closely related. These are the Flame-crowned (*Dicaeum anthonyi*), Bicoloured, Cebu (*Dicaeum quadricolor*), Red-striped, Black-bellied (*Dicaeum haematostictum*) and Scarlet-collared Flowerpeckers (*Dicaeum retrocinctum*). The Bicoloured and Cebu Flowerpeckers could be considered as one

superspecies, and the last three as another, although the bill shape of the Scarlet-collared Flowerpecker is rather different from that of the others.

Far more widespread in its distribution, the Orange-bellied Flowerpecker consists of 17 subspecies in two groups, one in mainland southern Asia and the Sundas and the other in the Philippine Islands. The species perhaps evolved in the Philippines, which is its area of greatest differentiation, and spread from there westwards through Borneo to other parts of the Sundas and to mainland southern Asia as far west as Bangladesh. It does not appear to be very close to any other members of the genus. On the other hand, the allopatric Buzzing and Plain Flowerpeckers are possibly closely related to each other, one subspecies of the former being particularly similar to the latter in plumage. The Pale-billed Flowerpecker (*Dicaeum erythrorhynchos*) may also be closely allied to these, but it has a markedly downcurved bill. The Pygmy Flowerpecker, however, appears not to have any close relatives.

The allopatric Crimson-crowned (*Dicaeum nehrkorni*), Flame-breasted, Ashy (*Dicaeum vulneratum*), Olive-crowned (*Dicaeum pectorale*), Red-capped (*Dicaeum geelvinkianum*), Louisiade (*Dicaeum nitidum*), Red-banded (*Dicaeum eximium*) and Midget Flowerpeckers constitute a well-marked superspecies from the region bounded by Wallacea, New Guinea and the Solomon Islands. Some authorities would accept fewer species. Males of all eight have some red on the breast and, in some species, also on the crown and/or rump. The bill varies from being short and stout to being of medium length and rather slender, and that of one species, the Flame-breasted Flowerpecker, is slightly decurved. Eastwards from this region, on the island of San Cristobal, in the south-easternmost Solomons, is found the Mottled Flowerpecker (*Dicaeum tristrami*), a relatively dull, mainly brownish species with no bright colours in its plumage. It has the most easterly distribution of all members of the genus, and has no obvious close relatives.

In the Lesser Sundas, the Black-fronted (*Dicaeum igniferum*) and Red-chested Flowerpeckers (*Dicaeum maugei*) constitute a further superspecies. The former has a longish, slender bill and the latter a short bill of medium thickness. The males of both species have plumage colours of black, white and red, whereas the females are more greyish and brownish, having less black and less red.

This **Yellow-bellied Flowerpecker** is a good example of the more brightly coloured group of *Dicaeum* flowerpeckers. In this species, the male's head, mantle and wings are blue-black, slightly glossy in suitable light, while the bright yellow belly, flanks, vent and undertail-coverts are offset by a greyish-black breast and throat sides and a white centre to the breast and throat. Females are similar but duller. Iris colour varies considerably across the genus, being white, yellow, orange, hazel, brown or, as here, a deep chestnut.

[*Dicaeum melanoxanthum*, Zhang Mu, Xizang, China. Photo: Dong Lei]

There has been little consensus among taxonomists over species limits within the next superspecies, which ranges from the Himalayas eastwards to Australia. Here, five species are involved: the Fire-breasted (*Dicaeum ignipectus*), Black-sided (*Dicaeum monticolum*), Grey-sided and Blood-breasted Flowerpeckers, and the Mistletoebird. The bills of these five vary from short to medium in length, and from slender to medium in thickness. Marked racial differences exhibited by some of the species suggest that further splitting would be appropriate; on the other hand, some authorities may consider that all five species should be merged into one.

Although the Scarlet-backed Flowerpecker and the Scarlet-headed Flowerpecker (*Dicaeum trochileum*) have similar bills

Several species of *Dicaeum* flowerpecker have rather dull-coloured plumage, but none is more aptly named than the **Plain Flowerpecker**.

While this species is not quite as concolorous as its scientific name implies, it nevertheless has an uninspiring combination of olive-grey upperparts and yellowish-buff underparts. Its seven subspecies are spread across a vast swathe of Asia, but differ in little more than plumage tone, the brightest being the race virescens of the Andaman Islands. Intriguingly, *Dicaeum* flowerpeckers exhibit four distinct tongue types, suggesting that more than one genus may actually be involved.

[*Dicaeum concolor concolor*, Bondla, Goa, India. Photo: Jussi Vakkala]

The **Orange-bellied Flowerpecker** is one of the more brightly coloured members of the family. Its range extends from Bangladesh down through the Malay Peninsula to the Greater Sundas and the Philippines. Such an expansive distribution, encompassing so many islands, has resulted in significant differentiation at subspecies level. Altogether 17 races are recognized, some endemic to specific islands and others to archipelagos or island groups. These taxa fall into two broad groups: the "dorsale group" in the Philippines and the "nominale group", to which the bird seen here belongs.

[*Dicaeum trigonostigma dayakanum*,
Sinsuron Road,
Crocker Range Park,
Sabah, Borneo.

Photo: D. Wechsler/VIREO]

and share some plumage characters, they are perhaps not sufficiently closely related to warrant recognition as a superspecies. Moreover, although their ranges are largely discrete, there is some overlap in distribution in the Sundas, which may be a phenomenon of recent origin. As a point of interest, these two species have hybridized in the wild in Borneo, and the Scarlet-backed Flowerpecker has hybridized also with the Fire-breasted Flowerpecker in south-east China, but it is difficult to evaluate the significance of such events.

There is clearly a need for much research on the systematics and relationships of the Dicaetidae. As further studies are conducted, and additional genetic data are uncovered, it seems very

likely that several modifications will be made in the classification of these interesting birds.

Morphological Aspects

The family contains 44 species of very small to small, short-necked, arboreal oscine passerines ranging in length from about 7 cm to 13 cm, and in mass from approximately 4 g to 13 g. The flowerpeckers have rather long wings. The outermost primary of the *Prionochilus* species is long, whereas that of the Yellow-bellied Flowerpecker is present but very short, and that of all other *Dicaeum* species is only vestigial. The tail is rather short, and never elongated, measuring about 18–24 mm in *Dicaeum* species except for the larger Yellow-bellied Flowerpecker, which has a tail of up to 47 mm; the tail of *Prionochilus* is up to 33·5 mm long. The number of rectrices varies from eight to twelve.

The legs of all flowerpeckers are short. The bill is generally rather short, serrated distally, frequently broad, deep and blunt, but in some cases thinner and much less deep, and occasionally slightly downcurved. The shape may even vary somewhat among different subspecies of a species, as illustrated by the Thick-billed Flowerpecker. The nasal opening is circular or oval, and non-operculate, but partly covered by a membrane. Rictal bristles are very short. The tongue generally forms an elongate, flattened, slightly concave, two-pronged or four-pronged triangle, that of some of the species being more tubular. Details of the tongue and variations in its morphology, have already been given (see Systematics). Tongue and bill shapes are obviously adaptive, and presumably polygenic. Tongue shape would also be influenced by bill shape, such that a narrow bill would result in a narrow tongue.

Although their diet contains other items, such as invertebrates (see Food and Feeding), almost all flowerpeckers seem to be closely associated, at least part of the time, with mistletoes (Loranthaceae), of which they eat the fruit and probably other plant parts. The birds have a blind-ending stomach, the muscular lower part of which, the ventriculus, or gizzard, can be closed off by a sphincter. Arthropod food passes from the oesophagus through the glandular first part of the stomach, the proventriculus, and into the ventriculus for muscular and peptic digestion.

While some flowerpeckers are brightly coloured and others dull, a large majority of family members combine both traits by being sexually dimorphic. In such species, males have the bright garb, often in complex patterns, while the females are relatively non-descript. The **Fire-breasted Flowerpecker** is a good example. The male (left) is responsible for the species' English name, several races having flaming red on the breast, as well as on the tips of some throat feathers. The pinkish-buff belly is bisected by a fairly broad black stripe. The crown and upperparts are an iridescent blue-black, turning to black on the ear-coverts and the sides of the neck and breast. The female (right) is a much plainer bird, with a greyish-olive head, olive mantle and yellowish-buff underparts.

[*Dicaeum ignipectus formosum*,
Lishan, Taiwan.
Photos: Penshing Liao]

The proventriculus in *Prionochilus* is noticeably broader and thicker-walled than the oesophagus, whereas, in *Dicaeum*, it is similarly broader but its walls are not noticeably thicker than those of the oesophagus, and the proximal part of the duodenum is very much broader than that of *Prionochilus*. In both genera, mistletoe berries are swallowed whole and the viscous seeds bypass the ventriculus, which is closed by the sphincter, and pass directly from the proventriculus to the duodenum, and, aided by the laxative effects of the berries, complete their journey through the gut in a few minutes. Such an adaptation is found also in unrelated birds, such as some meliphagid honeyeaters, that feed in extensively on mistletoes.

Whereas the plumage of some flowerpeckers may be dull, many members of the family have bright coloration, occasionally with iridescence, and many species are sexually dichromatic. There appear not to be any seasonal differences in plumage. Sexual dichromatism is marked in 27 species, examples being the Crimson-breasted Flowerpecker in *Prionochilus* and the Cebu and Scarlet-backed Flowerpeckers in *Dicaeum*. The females are much less brightly coloured, and often the complexity of patterning is reduced, as are iridescence and areas of red. With three further species, the Golden-rumped (*Dicaeum annae*), Whiskered and Pygmy Flowerpeckers, the phenomenon occurs but is not so obvious. The remaining 14 species exhibit no sexual dichromatism.

Juvenile plumage of seven species is unknown. In some cases, where there is no sexual dichromatism, as with the Thick-billed and Pale-billed Flowerpeckers, differences from the adult plumage are slight, the juvenile being somewhat duller, whereas in others, such as the Red-striped and Black-belted Flowerpeckers, the differences are more pronounced. Where sexual dichromatism exists, the juvenile may be quite similar to the female but usually duller, as with the White-throated, Cebu and Orange-bellied Flowerpeckers. Among some species displaying marked sexual dichromatism, however, the juvenile may differ significantly from both sexes, as demonstrated by the Scarlet-breasted, Crimson-crowned and Ashy Flowerpeckers.

Pectoral tufts, invariably white, have been recorded as present on both sexes of five species, namely the Thick-billed, Red-striped, Black-belted, Black-sided and Blood-breasted Flowerpeckers. For eleven species, among them the Crimson-breasted

Flowerpeckers are not renowned for their vocal talents. While this may partly reflect the paucity of studies of their vocalizations, it does appear that their relative silence reflects a real phenomenon. The song of the **Red-chested Flowerpecker** is relatively simple, comprising two or three high-pitched whistles, and this can be considered fairly typical for the family. Along with the **Black-fronted Flowerpecker** (*Dicaeum igniferum*), this species forms a superspecies endemic to the Lesser Sundas.

[*Dicaeum maugei maugei*, West Timor, Indonesia. Photo: Morten Strange]

and Yellow-rumped Flowerpeckers in *Prionochilus* and the Scarlet-backed and Scarlet-headed Flowerpeckers in *Dicaeum*, pectoral tufts, again white, have been recorded on males only. Since these tufts are sometimes rather difficult to detect, they may be found to be more widespread in occurrence among the Dicaeidae.

Iris colour sometimes differs between the sexes, and varies from white to various shades of yellow, orange, red, chestnut, brown or hazel; in one species, the Blood-breasted Flowerpecker, some individuals have a blue iris. Most flowerpeckers have a dark bill, brown, grey, black or blue in colour, sometimes with a pale base of the lower mandible, but the bill of the Pale-billed Flowerpecker is, as the species' vernacular name suggests, pale

Most flowerpecker calls are simple in form, comprising one or two notes. Some species' calls are loud and strident, others are thin and high-pitched, and yet others staccato or rasping. That of the **Buzzing Flowerpecker** is—as its name hints—a high-pitched buzz. This may be given as a single note, or in a short series. Either version may be the precursor to a rapid trill, interspersed with metallic notes. The Buzzing Flowerpecker is a rather drab species, its plumage tone varying among the five subspecies, although all share the broad pattern of dark upperparts and pale underparts.

[*Dicaeum hypoleucum pontifex*, Baracatan, Davao, Mindanao, Philippines. Photo: Doug Wechsler/VIREO]

horn, with the base of the lower mandible pinkish-flesh. The legs of dicaetids are generally dark, being various shades of horn, brown, grey, black or blackish-green. Those of the Cebu Flowerpecker are reported as changing from glossy black in the non-breeding season to pink when breeding.

Few data are available on moult. In the Mistletoebird, there is a partial post-juvenile moult into an adult-like first immature plumage, the extent varying individually. It is followed at about the age of one year by a moult into complete adult plumage.

Habitat

Flowerpeckers can be found in a wide variety of well-vegetated habitats, no members of the family being particularly specialized in this respect or being reliant upon any restricted habitat type. Flowers and fruits are the main, and in some species perhaps almost exclusive, food sources for these passerines, and any plants that can supply these needs may be utilized.

Five of the 44 species are recorded only from lowlands, with no specific altitudes documented. These are the Palawan, Cebu, Louisiade, Midget and Scarlet-headed Flowerpeckers. Eight species, among them the Olive-backed, Crimson-breasted and Brown-backed Flowerpeckers and the Mistletoebird, are found from sea-level to 1000 m or so, and a further three, the Scarlet-breasted, Black-belted and Scarlet-collared Flowerpeckers, are recorded at up to 1250 m. Seven dicaetids, of which the Yellow-breasted (*Prionochilus maculatus*), Orange-bellied and Buzzing Flowerpeckers are examples, occur at sea-level and upwards, and reach their maximum altitude between 1500 m and 1800 m. Ten others, including the Yellow-vented, Pygmy and Blood-breasted Flowerpeckers, extend from sea-level to between 2100 m and 2350 m. The Thick-billed Flowerpecker, however, breeds at all elevations from sea-level to 3000 m, although it is normally found below 975 m in the non-breeding season, while the Plain Flowerpecker has an even greater range, occurring from sea-level to 3700 m.

Only seven species of flowerpecker have not been recorded down to sea-level. The Crimson-crowned Flowerpecker lives at 600–2400 m, the Flame-crowned at 800 m to at least 2000 m, and the Black-sided at 460–2500 m, while the Whiskered

Flowerpecker is found only above 900 m, the Olive-capped from 900 m to at least 1600 m and the Fire-breasted at 600–4000 m; the Yellow-bellied Flowerpecker occurs at 1000–4000 m, but in winter is found down to 775 m.

Although flowerpeckers occupy a variety of vegetated habitats, the majority of the species have a fondness for mistletoes, which they utilize as a food source. In return, the birds are important to these parasitic plants for pollination and seed dispersal, both genera of flowerpeckers having the digestive tract adapted to deal with mistletoe berries (see Morphological Aspects).

A wide range of pristine habitats and also those influenced by man is utilized by the family as a whole. All species are known to exploit one or more different forest types, depending on their geographical and altitudinal distributions. Lowland dipterocarp forest harbours at least seven species, including Yellow-breasted and Plain Flowerpeckers. Lower montane forest is home to at least eight dicaetids, including the Blood-breasted and Grey-sided Flowerpeckers, and upper montane and moss forests provide habitat for a further six, among them the Crimson-crowned and Flame-crowned Flowerpeckers. Alluvial forest has five species, including Yellow-vented and Scarlet-backed Flowerpeckers. Peatswamp-forest has seven species, examples being the Yellow-breasted, Yellow-rumped and Thick-billed Flowerpeckers, and a further six are found in mangroves, among them the Thick-billed Flowerpecker and the Mistletoebird. Six members of the family occur in heath forest, two examples being the Yellow-rumped and Black-sided Flowerpeckers. Deciduous or semi-deciduous forests are likewise the recorded habitat of six species, including the Golden-rumped and Pale-billed Flowerpeckers. Some forest types would appear to be less suitable for flowerpeckers. Thus, paperbark (*Melaleuca*) forest harbours only one species, the Orange-bellied Flowerpecker; pine forest also has just one, the Yellow-bellied Flowerpecker; and upland forest on ultra-basic soil has only the Scarlet-breasted Flowerpecker. Ashy and Black-fronted Flowerpeckers are the only members of the family found in coastal forest other than mangroves.

Various types of woodland are occupied by six species, including the Golden-rumped and Red-chested Flowerpeckers. In Australia, the only flowerpecker present, the Mistletoebird, occurs in both mulga (*Acacia*) and mallee (*Eucalyptus*) woodlands, as well as in other habitats. Four dicaetids can be found in coconut

For such a wide-ranging family whose members are often relatively abundant, the biology of the Dicaetidae has been poorly studied. This generalization extends to the diet. Of the 44 species of flowerpecker, 27 have been observed to feed on fruit, particularly berries, but the others are simply conjectured to do so. The **Crimson-breasted Flowerpecker** falls into the first group. It commonly feeds on the purple berries of *Melastoma*, as here, crushing them before consumption. It also makes use of its strong bill to pierce figs (*Ficus*) and the fruit of *Eugenia* shrubs prior to sucking out and consuming their edible contents.

[*Prionochilus percussus*
ignicapilla,

Johor, Malaysia.
Photo: Ong Kiem Sian]

The large, curved bill of the **Yellow-vented Flowerpecker** enables it to feed on relatively larger fruits than many of its congeners. Like many dicaeids, this species feeds on the fruits of small figs (*Ficus*) and mistletoes (*Loranthaceae*). It also seeks out berries of *Muntingia calabura*, a Neotropical tree that has been naturalized in Asia because of its edible fruits. This flowerpecker is not entirely vegetarian, however, since it is also adept at catching and consuming small insects such as beetles (*Coleoptera*).

[*Dicaeum chrysorrheum chrysorrheum*,
Taman Negara, Malaysia.
Photo: Ong Kiem Sian]

groves; these are the Thick-billed, Red-striped, Black-belted and Scarlet-collared Flowerpeckers. Stands of bamboo are known to harbour one species, the Red-chested Flowerpecker, but no others. Savanna and similar rather open country is utilized by six species, examples being the Red-striped Flowerpecker and the Mistletoebird, but no member of the family is confined to open country.

More than 30 species are known to occur at forest edges and clearings, examples being the Olive-backed, Brown-backed, Whiskered, Red-striped, Black-belted, Scarlet-collared, Ashy and Mottled Flowerpeckers and the Mistletoebird. Secondary forest and other secondary habitats harbour 26 species, among which are the Palawan, Bicoloured, Plain, Pygmy and Scarlet-backed Flowerpeckers. Cultivation, including plantations and gardens, are exploited by some 25 members of the Dicaeidae, including the Yellow-sided, Red-capped, Black-fronted, Red-chested, Fire-breasted, Grey-sided, Blood-breasted, Scarlet-backed and Scarlet-headed Flowerpeckers.

Some habitats appear to be less attractive to this family, suitable evidently for only few of its species. Riverine vegetation away from forests is one such habitat, used by the Flame-breasted Flowerpecker. Beach vegetation and casuarina (*Casuarina*) groves attract the Scarlet-breasted Flowerpecker, and casuarina is a habitat also of the Blood-breasted Flowerpecker. Scrub hosts only Yellow-breasted, Flame-breasted and Crimson-breasted Flowerpeckers.

Little information has been documented with regard to the intraspecific and interspecific behaviour of flowerpeckers. There appears to be very little known about the ways in which flowerpeckers may partition the habitat in places where two or more species occur together.

General Habits

Although often common, flowerpeckers seem not to attract very much attention from ornithologists in the field. Many members of the family spend much time in the canopy. They are small and constantly on the move, as a result of which little has been recorded about the behaviour of most species.

Flowerpeckers are arboreal and diurnal, generally restless and active, ceaselessly flitting in or around foliage, and are rarely still for any period. Although often stated to prefer the canopy, almost all species for which relevant observations exist are known to forage also at other levels, even in low vegetation. The flight is high and rapid, frequently dipping in a rather erratic manner.

Dicaeids are encountered singly, in pairs or in small groups. Almost half of the family's species are frequently observed as pairs, but in two of these, the Fire-breasted Flowerpecker and the Mistletoebird, usually only during the breeding season. Of these, the Scarlet-backed is described as being aggressive, suggesting that it is territorial, but evidence of territoriality is absent for all others except the Pale-billed Flowerpecker, which defends a feeding territory. The latter species may form parties of up to ten or more individuals during the winter, and the Mistletoebird occasionally forms "large flocks", especially around food sources. The Yellow-bellied Flowerpecker, on the other hand, is described as being elusive and solitary, and is the only member of the family to fall in this category. Many of the flowerpeckers will join other species in loose mixed feeding groups (see Food and Feeding).

Non-breeding Mistletoebirds in Australia are highly nomadic, and solitary males may be encountered even during the breeding season. Furthermore, this species can become torpid in cold weather, a phenomenon that has so far not been recorded for any other species in this family.

Both the Yellow-vented Flowerpecker and the Scarlet-backed Flowerpecker are noted as being aggressive. In addition, interspecific competition is surmised as occurring among a few species. The Cebu Flowerpecker, a Critically Endangered species (see Status and Conservation), is thought to be threatened by competition from the much more aggressive Red-striped Flowerpecker. In Sulawesi, the Grey-sided Flowerpecker is aggressive towards the Yellow-sided Flowerpecker, and displaces it from foraging bushes in degraded habitats; the two species are mutually aggressive, and the former apparently has a less upright posture than does the latter. The Blood-breasted Flowerpecker is thought to be displaced by the Black-fronted and Red-chested Flowerpeckers in the lowlands of the Lesser Sunda.

Frugivores play an essential role in the ecosystem by dispersing plant seeds. The flowerpeckers' role is particularly important for at least twelve genera of mistletoe (Loranthaceae), since the intestinal tract of the birds is adapted to allow mistletoe seeds to pass quickly and unaltered through the digestive system. Studies of the relationship between the **Mistletoebird** of Australia and the grey mistletoe (*Amyema quandang*) have revealed that more than four-fifths of all seeds excreted by this species germinate successfully.

[*Dicaeum hirundinaceum*
hirundinaceum,
You Yangs,
Victoria, Australia.
Photo: Peter Fuller]

As a final point of interest, the Thick-billed Flowerpecker wags its tail from side to side when perched, a useful identification feature that appears not to have been observed for any other flowerpecker species.

Voice

As members of this family are not known for their vocal expertise, and because they are not skulking birds necessitating a knowledge of their vocalizations for identification or in order to draw them out from cover, little work seems to have been done on this aspect of their biology. Exceptions to this general statement include studies of the Mistletoebird's varied repertoire, carried out by N. Reid, and quantitative analyses of vocalizations of flowerpeckers, undertaken as part of a phylogenetic study by Iddi (see Systematics).

Most dicaeid calls that have been described are single or double notes, modified by such adjectives as loud, high-pitched, thin, sharp, rasping, strident, insect-like, buzzing, harsh, staccato and the like. Examples include a single buzzing note and a downslurred "bszzrt", given by the Red-capped Flowerpecker, a single "tzick" by the Red-banded Flowerpecker, a single loud "peeit" or "peeith" and a high "tsoot-eet" with rising second note, both uttered by the Olive-backed Flowerpecker, and a "swit" or "swit-szee", emitted by the Orange-bellied Flowerpecker.

Longer calls, or more continuous vocalizations, often interpreted as songs, have been noted for many species. The following are just some examples. The Yellow-rumped Flowerpecker produces seven to nine fast descending staccato notes, and the Golden-rumped Flowerpecker gives repeated, thin "see" notes all on the same pitch, the last three longer and more widely spaced. The song of the Whiskered Flowerpecker is described as consisting of rather buzzy high "swink" or "chenk" notes, which may be run together, some notes then rising and some falling. That of the White-throated Flowerpecker is said to be a series of two to four very high-pitched thin notes alternating in pitch, "tink-tuk-tink"; an ascending "keek-keek" ending with "tit-tiri-tit-tiri" and a rapid, irregular descending trill have also

been described for this species. The Olive-capped Flowerpecker delivers a rapid, rising and falling, high-pitched trill of about thirty notes, some rather sweet and described as being untypical for a flowerpecker. The song of the more familiar Orange-bellied Flowerpecker is a high-pitched rapid "sissipping", described also as an evenly rising series of rapid, very high

While berries and other small fruits probably form the bulk of most dicaeid diets, those with relatively hefty bills will tackle larger fruits, from figs (*Ficus*) upwards. The stronger the species' bill, the easier it is to penetrate the skin of large fruits, squeeze or suck out the contents, and discard the skin. The **Yellow-breasted Flowerpecker** is one of the stronger-billed species. It is adapted to feed on a wide variety of fruits, in addition to the nectar and pollen of mistletoes and probably the pollen of *Eugenia dyeriana* (*Myrtaceae*), a plant endemic to Malaysia.

[*Prionochilus maculatus*
oblitus,
Taman Negara, Malaysia.
Photo: Ong Kiem Sian]

The action seen here might easily be misinterpreted. At first glance, it may look as though this male **Black-sided Flowerpecker** has lost control of the berry it was about to eat. Instead, it is actually using its strong, slim bill to good effect with considerable skill. Having picked the berry, the flowerpecker manipulates it with its bill, turning it to extract the fleshy pulp within. Once all the nutritional benefit has been procured, the bird has no further use for the relatively indigestible skin, so it drops it. The **Black-sided Flowerpecker** is not solely a frugivore. It is one of just three members of the family that has been recorded consuming seeds. It forages mostly at lower levels in the forest, which has enabled researchers at ground level to record the animal elements of its calorie intake. Insects, such as aphids (*Aphidoidea*), flies (*Diptera*) and leafhoppers (*Homoptera*), have all been found to form part of this bird's diet.

[*Dicaeum monticolum*,
Kinabalu Park,
Sabah, Borneo.
Photos: Doug Wechsler/
VIREO]

The **Scarlet-backed Flowerpecker** is an adaptable forager. This male has just chanced upon a comparatively large fruit, but the species more commonly consumes smaller items such as berries of *Muntingia calabura*, *Melastoma malabathricum*, figs (*Ficus*) and mistletoes (*Loranthaceae*). It also flycatches for insects from a perch, and consumes seeds and nectar. It inhabits a range of forest types from mangroves to heath forest, as well as scrubby areas and even gardens. It will feed in all strata, and does so most frequently in pairs or family parties.

[*Dicaeum cruentatum ignitum*,
Bukit Timah
Nature Reserve,
Singapore.
Photo: Jimmy Chew]

upslurred "psee" notes followed by a sharp, high, metallic "ptit-ptit-ptit-ptit", and as a high, slightly descending "tsi-si-si-sew..."; other song types of this species include a slower version of the last, an evenly descending series of notes, and a three-note version with the middle note the lowest. The Black-fronted Flowerpecker has a song described as a very rapid, descending series of short, thin, dry notes, the series lasting for about 6 seconds. Many species in this family produce trills, or

rapidly repeated call notes in various combinations, that could be interpreted as songs.

Among species with an extensive geographical distribution, differences in song have been noted from one part of the range to another. The song of the Plain Flowerpecker, for example, is a high-pitched trill, but in Laos it is described as a very high, thin "tsit tsit tsit-si-si-si", repeated every few seconds; farther west in south-west India, it is reported as a very high, thin, short trill "tseep tsip-tsip-tsip", and a very short, strongly descending "tse'e'e'ep" trill, whereas the song of this species in the Andaman Islands is an extremely high musical "sit sew, sit sew, sit sew..." and very short, more buzzing notes mixed with calls.

The most intensively studied flowerpecker, the Mistletoebird, has a considerable range of vocalizations. This is, however, probably a reflection of the fact that it has received much greater attention than has been paid to any other member of the family, and it is quite possible that other dicaetids, when equally well studied, will prove to be as vocally variable and versatile as this Australian species. Along with a variety of single-note, double-note and triple-note calls, some given in flight, a number of different song types have been identified for the Mistletoebird. One, given by both sexes, is "wissweet... wissweet..." or "wit-wissweet... wit-wissweet...", usually repeated. The song by territorial males on high perches is a clear, penetrating "kinsey kinsey kinsey" or "wicky wicky wicky", or sometimes "swizit swizit, weet weet swizit" or "witsoo witsoo witsoo...", wiss wiss wiss". In addition, the Mistletoebird delivers a soft warbling song which incorporates much mimicry, including imitations of the Mulga Parrot (*Psephotus varius*) and of at least 28 species of passerine. Subsong, alarm calls and distress trills have also been recorded.

Food and Feeding

The Dicaetidae forage in vegetation at all levels, but in forest they are most frequently recorded in the canopy. Although occasionally seen alone, they are more often encountered in pairs or in small groups, but some, such as the Thick-billed Flowerpecker, are found in parties containing as many as 30 individuals, and a flock of 32 Orange-bellied Flowerpeckers, including nine depend-

Flowerpeckers feed extensively on fruit, but many are known to exploit other plant parts. Ten species have been recorded drinking nectar, and four are known to feed on pollen. These habits are recognized in the birds' common name, since the birds appear to peck at flowers. Endemic to the Philippine island of Mindanao, the **Olive-capped Flowerpecker** is among the poorly known members of its genus, and there is no solid information on its foraging preferences. Its diet is conjectured to include the nectar, pollen and fruits of mistletoes (*Loranthaceae*).

[*Dicaeum nigrilore*,
Mindanao, Philippines.

end first. After consuming three or four berries, the bird rests for a few minutes, with its feathers puffed out. The slimy, sticky seeds then pass out of the cloaca, again broad end first, on to a branch, to which they stick as the flowerpecker jerkily frees itself of the sticky mass. The Grey-sided Flowerpecker squeezes the seeds out of larger fruits, such as cherries (*Prunus*), before swallowing the pulp, whereas smaller fruits it swallows whole. It then wipes its bill on a branch.

Mistletoe fruits are swallowed whole by the Mistletoebird. They enter the intestine rapidly after bypassing the ventriculus, which is closed by means of a sphincter. The seeds of the grey mistletoe (*Amyema quandang*), a species which fruits continuously in South Australia, are excreted at a rapid rate, and many at first adhere to the cloacal region, before the Mistletoebird wipes its lower body on a branch. By making small sideways jumps, the bird detaches itself from the thread that sticks the seeds to a branch. Many seeds may be linked together by these gelatinous threads. The germination rate of seeds passed in this manner is very high, with an average of 85%, and 43% seedling survival, in various studies. In one study at Brookfield, in South Australia, germination rates of seeds thus expelled were 93–100% and 82% of the resultant seedlings survived for three months or longer. For comparison, it is worth mentioning that only 31% of *Amyema quandang* seeds eaten by the Spiny-cheeked Honeyeater (*Acanthagenys rufogularis*), the only other bird species known to eat them, produce seedlings.

Seven species of flowerpecker are associated with figs. Otherwise, recorded associations of dicaeids with particular genera or species of plants are relatively few. Twenty-seven members of the family are known to eat fruits, and all others are believed to do so, whereas seeds are known foods for only three species. The extremely rare Cebu Flowerpecker (see Status and Conservation) favours two kinds of vine, one a red-flowering species and the other producing greenish-white flowers, as food sources. Nectar is a confirmed food item for ten species, and pollen is consumed by four. Interestingly, only one dicaeid, the Pale-billed Flowerpecker, is known to defend a feeding territory.

Invertebrates presumably play an important part in the diet of the Dicaeidae. Twenty-three members of the family are known to take a variety of insects, including beetles (Coleoptera), bugs (Hemiptera) and flies (Diptera). The Thick-billed Flowerpecker

It is not only by acting as seed propagators that flowerpeckers contribute to the forest ecosystem. Those species that consume nectar also play a valuable role. A good example is the **Orange-bellied Flowerpecker**, which consumes the nectar of the durian (*Durio*), a tree at the same time both renowned and infamous for producing huge fruit with an extraordinarily pungent, distinctive odour. When the flowerpecker repeats the process of eating nectar at successive durian trees, it acts as a pollinator. This dicaeid also eats the flowers of rubber trees (*Euphorbiaceae*).

[*Dicaeum trigonostigma dayakanum*, Danum Valley, Sabah, Borneo. Photo: John & Jemi Holmes]

ent juveniles, was observed at a forest-edge banyan tree (*Ficus*) in Peninsular Malaysia.

Many members of the family can be found in mixed parties, usually with other flowerpeckers, sunbirds and white-eyes. Examples are the Scarlet-breasted and Palawan Flowerpeckers in the genus *Prionochilus* and the Thick-billed, Yellow-sided and Flame-crowned Flowerpeckers in *Dicaeum*, all of which may join other species in loose mixed foraging groups. One dicaeid, the Fire-breasted Flowerpecker, is known to associate with mixed parties only outside the breeding season.

Flowerpeckers feed on various plant materials, as well as invertebrates. In particular, more than 21 species of mistletoe in at least twelve genera, including *Viscum* (sometimes placed in a separate family, Viscaceae), have been recorded as food sources for flowerpeckers. All members of the Dicaeidae probably have an association with mistletoes, since all of them have a modified intestinal tract adapted to deal with mistletoe berries. The muscular part of the stomach, the ventriculus, can be closed off by a sphincter, and mistletoe berries pass rapidly from the glandular proventriculus to the duodenum. Seeds of mistletoes that are swallowed pass through the digestive tract unharmed.

Although few mistletoes utilized as food plants have been identified to the level of species or even to the genus level, six species of *Amyema* and at least two each of *Dendrophthoe*, *Loranthus*, *Lysaena* and *Taxillus* have been recorded as food sources. *Scurrula* and *Viscum* are each visited by four species of flowerpecker. The Thick-billed Flowerpecker has been observed to revolve mistletoe berries in its bill in order to remove the edible pericarp, which it swallows; it then wipes the viscous seed on to an adjoining branch, using side-to-side movements of the head. The Yellow-breasted Flowerpecker punctures large figs (*Ficus*) and extracts the contents. The Yellow-sided Flowerpecker, before swallowing large fruits, squeezes them, perhaps to remove seeds, and then wipes its bill on a branch. The Orange-bellied Flowerpecker's habit of wiping the cloaca on a branch after defecating is believed to help in the dispersal of mistletoe seeds. In captivity, this species seems to have difficulty in passing fruits other than mistletoe berries. More details are known about the feeding behaviour of the Pale-billed Flowerpecker. This species uses its bill to test the ripeness of berries, before consuming them. It swallows berries of *Loranthus* and *Viscum* whole, the broad

As with other aspects, our knowledge of the breeding biology of most flowerpeckers is extremely sketchy. Nests, for example, have been described for less than two-thirds of the species, among them the **Pale-billed Flowerpecker**. This species suspends its nest from a twig or branch, usually amidst foliage to provide concealment, a tactic seemingly shared by other flowerpeckers. However, such precautions are not universal, as is apparent here. The nest itself is a pear-shaped purse of grass, down and moss, lined with soft material.

[*Dicaeum erythrorhynchos ceylonense*, Sri Lanka. Photo: Rolf Kunz]

The breeding season of the **Yellow-breasted Flowerpecker** may be somewhat variable in timing, as males with enlarged gonads have been recorded in February in Sabah, with juveniles as late as October on the Malay Peninsula.

Alternatively, this may simply reflect slight seasonal differences across the species' range, which extends from southern Myanmar east to Sumatra and Borneo.

This species lays two eggs, which are white with dark spots. To date there is no information available on the duration of the incubation or nestling periods, or the roles of the sexes in processes such as the provisioning of nestlings.

[*Prionochilus maculatus oblitus*,

feeds on tiny caterpillars of the three-spot grass yellow butterfly (*Eurema blanda*) in *Albizia* plantations. At least 17 species take spiders (Araneae), and the Scarlet-breasted Flowerpecker removes them from webs. Unlike the situation with mistletoe berries, invertebrate food passes from the proventriculus through the open sphincter to the ventriculus, and does not bypass the latter.

Flowerpeckers can be rather acrobatic when feeding, and the Scarlet-breasted Flowerpecker sometimes climbs tree trunks in the manner of a nuthatch (*Sitta*) in order to take insects. Several members of the family will capture invertebrates in the air. The Yellow-bellied Flowerpecker, for instance, sometimes sallies from dead branches to catch insects, and the Scarlet-backed Flowerpecker hawks flying insects from a perch, as well as seizing them while hovering. The Mistletoebird flicks its wings when foraging for insects, which it catches by snatching and by aerial hawking.

Breeding

Much fieldwork needs to be carried out in order to add to the rather sparse knowledge of the breeding biology of this family.

Both sexes of the Scarlet-backed Flowerpecker are, it appears, involved in all aspects of breeding. In the case of the Mistletoebird, the female builds the nest and incubates alone, but the male helps in the feeding of the young and both parents remove the faecal sacs of the nestlings; the incubation of the eggs lasts for a period of about 10–12 days, and the chicks leave the nest after 15 days. Similarly, both sexes of the Midget Flowerpecker feed the nestlings and both remove the chicks' faecal sacs, but nothing else is known of the breeding biology of this species.

Apart from some information on courtship displays and on the nest and eggs, little else seems to have been recorded on the general breeding behaviour of the Dicaeidae. The courtship display of the Mistletoebird has been observed. The male, while singing from a small dead twig about 60 cm above the ground, was seen to bow his head and fan his tail, which he held above the level of the body; with each bow, he flicked the tail alternately to one side and then the other. During this time the cadence and tempo of the song were continuously increasing. The

male then flew to the female, which crouched while holding the body feathers ruffled, and the two copulated. What may have been a courtship display has been recorded for one other member of the family, the Thick-billed Flowerpecker. An individual of this species, possibly a male, was observed to flutter over another, possibly a female, the male revealing the white median stripe and white flecking on the crown, while twittering excitedly.

The nests of a third or more of the family's members appear not to have been described. Of those that are known, the majority are described as "pouches", for instance that of the Brown-backed Flowerpecker; "pockets", as in the Orange-bellied Flowerpecker; or "purses", like that of the Pale-billed Flowerpecker. They are spherical, oval or pear-shaped, and usually inconspicuous and well concealed, such as that of the Thick-billed Flowerpecker, with a side entrance, and they may resemble a leaf. The Midget Flowerpecker, however, is said to have a poorly concealed nest. Dicaeid nests often have a felted appearance, as demonstrated by that of the Flame-breasted Flowerpecker. Materials used in the construction of the nest are many, and include soft fibres, flower buds, cobweb, vegetable down, grass and grass-seed ends, moss, lichen, clubmoss (*Lycopodiaceae*), rootlets, feathers, caterpillar frass, ferns and so on. Some species, among them the Pale-billed and Black-sided Flowerpeckers, line their nests, whereas others, such as the Flame-breasted Flowerpecker, leave the nest unlined. External decoration is sometimes added to the nest. As examples, moss is recorded as being used by, among others, the Yellow-vented Flowerpecker; caterpillar frass by, for instance, the Orange-bellied Flowerpecker; berries and reptile skin by the Pale-billed Flowerpecker; flowers by the Mistletoebird and others; and lichen by a number of species, including the Pale-billed Flowerpecker.

Few details of nest dimensions are available. The nests of the Fire-breasted and Scarlet-backed Flowerpeckers measure 90 × 60 mm, that of the Flame-breasted Flowerpecker is more or less the same, at about 90 × 55 mm, and the Plain Flowerpecker's nest measures 70 × 50 mm. Mistletoebird nests have been recorded as being 75–114 mm long and 38–64 mm in diameter.

The nest-site, although normally well concealed, varies somewhat among the members of the family. A nest of the Scarlet-breasted Flowerpecker was found in a low bush, whereas two

The little information available for flowerpeckers regarding the division of tasks between parents suggests that both sexes seem to share responsibility for raising the brood. Information has been gathered for only six species, and from these data it emerges that both sexes probably carry out together some combination of nest-building, incubating, brooding, feeding and the removal of faecal sacs. In the **Mistletoebird**, the female seems to play the major role. She incubates the 3-4 eggs for 10-12 days, then broods the chicks for a further 15 days. As can be seen here, however, the male (above) assists the female (below) in provisioning the young. The nest is a pear-shaped purse that appears to be fairly typical of the family. Constructed by the female from plant down, lichen, feathers, wool and spider webs, the nest is often decorated with Acacia blossom and, less appealingly (to human eyes, at least), the excreta of insect larvae. The nestlings appear to be carnivorous, their parents returning to the nest with spiders and other small arthropods. Only later in life do birds develop the taste for the mistletoe berries which give rise to the species' English name.

 Photos: Michael Gore]

As with most other passerines, flowerpeckers' parental responsibilities do not cease once their young have fledged.

The fledglings are not immediately self-sufficient, and thus need regular provisioning at this critical stage in their lives before they become independent.

This female **Black-sided Flowerpecker** has found a good site for feeding berries to her offspring. Endemic to the highlands of Borneo, this species is relatively poorly known.

Young have been observed between November and February, and the clutch size appears to be three.

Elegem]

nests of the Black-bellied Flowerpecker were well above ground, one of them suspended from the end of a branch and the other in a tree-fern, 7–11 m above ground. Nests of the Thick-billed Flowerpecker are placed 2–9 m above ground and have been found in mango trees (*Mangifera indica*) and a lantana bush (*Lantana*). A nest of the rare Brown-backed Flowerpecker was suspended from the end of a branch 5–6 m above ground. That of the Yellow-vented Flowerpecker is usually below 8 m, whereas the well-

concealed nest of the Olive-capped Flowerpecker is suspended by fibres from small twigs 15 m above the ground, and the nest of the White-throated Flowerpecker is even higher, at 18–38 m in a dipterocarp tree. Several other species build pendent nests, that of the Orange-bellied Flowerpecker, for instance, hanging from a slender twig 2–13 m above the ground. Similarly, the Pale-billed Flowerpecker's nest is suspended from a twig among leaves 1.5–12 m up, and it may also be secured to a supporting branch at its back and is often well concealed by surrounding foliage, but it may be supported by twigs at each end, in hammock-like fashion. As further examples, Mistletoebird nests are suspended at 0.5–15.2 m from outer twigs, or from a frond of a tree-fern, and Scarlet-backed Flowerpecker nests from terminal twigs at 2–15 m but mostly 6–9 m. Nests of Red-banded, Midget and Grey-sided Flowerpeckers are low down, usually below 2 m, the first of these three often building in ferns, and the Midget Flowerpecker's nest poorly concealed on a horizontal branch. The Plain Flowerpecker places its nest 6–12 m above ground on trees or tall bushes, but sometimes it selects a much lower site among nettles and briars.

Those members of the family for which the clutch size is known lay from one egg, as in the Crimson-breasted Flowerpecker, to four eggs, as in the Thick-billed Flowerpecker and Mistletoebird. The commonest clutch size is of two or three eggs. The eggs of approximately half of the Dicaetidae have been described. They range in colour from pure white, or white with a greyish, pinkish, bluish or greenish tinge, to orange-pink, and are glossed or unglossed and, in some cases, clouded. Flowerpecker eggs may be unmarked, or speckled, blotched or spotted with various shades of red, brown, grey and purple. The egg colours and patterns are not necessarily constant within a species. For example, the Scarlet-headed Flowerpecker usually lays white eggs, described as glossed or unglossed, but some of this species' eggs have a few darker markings and one was distinctly red-brown at the pointed end. Although the eggs of the Pale-billed Flowerpecker are pure white in India, those laid by the Sri Lankan subspecies, *ceylonense*, are often speckled.

Measurements of eggs are available for, again, about half of the species in this family. They vary from 11.5–15.5 × 7.8–10.8 mm, as recorded for the Blood-breasted Flowerpecker, to 16.5–17 × 12–12.4 mm, the size of the Black-bellied Flowerpecker's

Of the 44 species of flowerpecker, some 19 (43%) are restricted-range species, each with a distribution of 50,000 km² or less. In part, this can be attributed to the mass of islands on which the family occurs. One such restricted-range species is the **Black-sided Flowerpecker**. Limited to the Bornean Mountains Endemic Bird Area, it occurs only at altitudes above 460 m. Persisting primarily in isolated patches of its favoured hill or montane forest habitat, this species is certainly uncommon, though not yet sufficiently rare to be of conservation concern.

[*Dicaeum monticulum*,
Kinabalu Park,
Sabah, Borneo.

VIREO]

eggs. The dimensional range of Mistletoebird eggs is 16.3–17.8 × 10.7–11.9 mm; the eggs in a two-egg clutch laid by this species measured, respectively, 17.9 × 11.2 mm and 16.8 × 11 mm.

Not surprisingly, there are very few data available on breeding success for this family. In various studies of Mistletoebirds in Australia, up to about 70% of nests were successful in producing at least one young. At least three species of cuckoo have been recorded as laying in the nests of this flowerpecker. Equally little is known of the longevity of the members of this family. A male Mistletoebird in Queensland was recaptured more than nine years after it had been ringed. Otherwise, ringing studies have revealed that Scarlet-backed Flowerpeckers can live for more than 3 years 9 months and Yellow-breasted Flowerpeckers for more than 2 years.

Clearly, there is scope for much further fieldwork and intensive study of the breeding behaviour of the flowerpeckers. In particular, there is a need for studies aimed at determining the duration of the incubation and nestling periods of these fascinating birds.

Movements

Little is recorded of the movements made by this family, and it has been assumed that the majority of the species are sedentary. This may, however, be due simply to a lack of knowledge, as some movements in response to the seasonality of mistletoes, so important in the dicaeid diet, is to be expected. For species associated with fairly intact lowland tropical forest, any such movements need not be over any great distance. Non-breeding Mistletoebirds are recorded as being highly nomadic in some parts of Australia in response to the fruiting of mistletoes. The Sundaic Scarlet-breasted Flowerpecker is likewise thought to be nomadic in some areas.

In the Sundas, the Blood-breasted Flowerpecker has been recorded in southern Sumatra, outside its normal range, which extends from Java eastwards to Timor. It is not clear whether this is the result of vagrancy or is part of regular nomadic behaviour, or whether it indicates that the species has been recently extirpated from parts of Sumatra that were once within its normal range.

Altitudinal movements in response to changing seasons are recorded for, or assumed to be made by, six species of

flowerpecker the ranges of which include higher-lying areas. The Thick-billed Flowerpecker exhibits such movements in the Himalayas, occurring in Nepal at 150–3000 m in summer, but only below 915 m in winter. Elevational movements made by the Yellow-bellied Flowerpecker are combined with lateral shifts that could be considered to represent migration, whereby the species occurs only in the non-breeding season in south-east Yunnan, in extreme south China, and from north Thailand east to north Tonkin, in extreme north Vietnam. The Pale-billed Flowerpecker, too, undertakes seasonal altitudinal movements in the Himalayas, and the Plain and Scarlet-backed Flowerpeckers are thought also to perform such movements in higher parts of their ranges. Altitudinal movements are well documented for the Fire-breasted

The species with perhaps the smallest range in the family is the **Louisiade Flowerpecker**. It occurs on the three main islands within the Louisiade Archipelago, an Endemic Bird Area of 1600 km² off the east coast of New Guinea. While habitat loss has only been moderate, about two-thirds of the largest island, Sudest, have been degraded. Nevertheless, the Louisiade Flowerpecker is sufficiently common in the remaining habitat for it not to be considered of global conservation concern yet.

[*Dicaeum nitidum nitidum*, Misima I, Louisiade Archipelago, off SE New Guinea. Photo: William S. Peckover]

Given the high levels of avian endemism in Indonesia, it is hardly surprising that six species of flowerpecker occur only there. Of these, three occur in the Northern Nusa Tenggara Endemic Bird Area, which comprises the northern chain of Lesser Sunda islands from Lombok to Alor. The most attractive of this trio is the **Black-fronted Flowerpecker**. Despite the extensive deforestation inflicted on the Lesser Sundas, this species is widespread and common, and not in danger of global extinction.

[*Dicaeum igniferum igniferum*, Flores, Indonesia. Photo: Morten Strange]

Flowerpecker. In the Himalayas of India and China, this species occurs at 900–3950 m in summer and below 300 m in winter, and in Nepal it is found above 1830 m in summer but down to 915 m in winter. In Taiwan, Fire-breasted Flowerpeckers are encountered at up to 2135 m in the nesting season, but descend to below 900 m in the non-breeding season.

Flowerpeckers are not particularly strong fliers. Nevertheless, both the Thick-billed Flowerpecker and the Yellow-vented Flowerpecker are known to cross water, as both of these species reach Singapore during dispersal from Peninsular Malaysia. The Johor Strait separating Singapore from the mainland is about 1.2 km at its narrowest and 4.8 km at its widest point.

Relationship with Man

This inconspicuous and poorly studied family seems to have had minimal impact on humans. Being rather small, and not noted for their vocal expertise, flowerpeckers have not suffered the depredations of the bird trade, nor are they trapped for any other purpose. A few of the species have been kept in captivity, perhaps the best-known of these being the Orange-bellied Flowerpecker, and in earlier times Mistletoebirds were very occasionally kept in aviaries, but the dicaeids are not widespread cagebirds. Furthermore, they appear not to figure significantly in literature or augury.

Flowerpeckers are very important in the dispersal of mistletoes, depositing the seeds up to 500 m or more from the parent tree, and they may yet be found to be important pollinators or dispersers of other plants. In general, are not seen as pests, but there are some instances in which the Mistletoebird has been so regarded for the very reason that it does play a significant role in seed dispersal. This is because mistletoe is considered a serious economic pest in some areas of Australia, as it parasitizes commercial fruit trees and other trees, including native ones, sometimes leading to the death of major limbs or even whole trees.

Few ornithologists have been inspired to study the flowerpeckers. An exception is those situations when habitat destruction by human beings has put the continued existence of a species in doubt, as is the case for the Critically Endangered Cebu Flowerpecker (see Status and Conservation).

Status and Conservation

Flowerpeckers are, on the whole, catholic in their choice of habitat. Most species are tolerant of areas modified by man, so long as flowering plants, and particularly mistletoes, abound. Hence, the same species may be met with in a range of habitats, from various types of pristine forest through secondary vegetation to cultivation and gardens. As a result, conservation problems exist for only eight species.

Of the 44 species in the family, 36, or 81.8%, are considered of Least Concern as regards their conservation. Of the remaining eight, one is classed as Critically Endangered, two are listed as Vulnerable, and five, 11.4% of the family total, are currently considered Near-threatened. Most dicaeids are regarded as uncommon to common over their distributional range. Some, such as those with a distribution covering a large geographical area, may be quite common in some areas but rare in others. The Orange-bellied Flowerpecker is one such example, being recorded as common and widespread over much of its range, and uncommon to rare in some areas, but in the Philippines the subspecies on Cebu, *pallidus*, is close to extinction. Some species, particularly those confined to higher altitudes, such as the Black-sided Flowerpecker, may exist in isolated "pockets" and are often considered to be local and uncommon. Extirpation from one or more pockets would probably be permanent, as most such species are apparently quite sedentary and, once an area has lost a species, it is unlikely to be recolonized from outside.

Although some flowerpeckers are brightly coloured, they are small and not considered great songsters. They have, therefore, to a large extent escaped the attentions of the cagebird trade. Furthermore, they are normally not regarded as pests, although they are instrumental in spreading mistletoes. It seems, however, that this was not always the case. In Australia, the sole member of the family, the Mistletoebird, was once shot because of its role in spreading mistletoes, plants which were perceived as pests. According to reports, one man claimed that, over a period of six years, he had killed more than 1200 Mistletoebirds.

Of the eight species about which there are some conservation concerns, one occurs in Sri Lanka, two are Sundaic, and five are restricted to the Philippines. Seven belong in the genus *Dicaeum*, and the eighth in *Prionochilus*. The latter, the Scar-

Of the six species of *Prionochilus*, only one is classified as restricted-range. As its English name suggests, the **Palawan Flowerpecker** occurs only in the Endemic Bird Area that covers the Philippine island of Palawan and adjacent small islands. Palawan is the most forested island in the Philippines, but human immigration from densely populated islands is increasingly resulting in habitat destruction through logging, mining and agriculture. Common in much of its range and present in Palawan's principal protected area, this smart bird is not considered to be globally threatened.

[*Prionochilus plateni*
plateni,
Buenavista,
north of Puerto Princesa,
Palawan, Philippines.
Photo: Ian Merrill]

While none of the six *Prionochilus* flowerpeckers is considered globally threatened, one is classified as Near-threatened. The **Scarlet-breasted Flowerpecker** occurs in Thailand and on the Malay Peninsula, Sumatra and Borneo. It once occurred in Vietnam, but there have been no records there since the nineteenth century. While widespread, it is generally considered uncommon or rare throughout its range. Lowland forest in this region is under severe threat, but this flowerpecker's use of montane and secondary forests gives conservationists hope for its future.

[*Prionochilus thoracicus*, Panti forest, Johor, Malaysia.
Photo: Teo Nam Siang]

let-breasted Flowerpecker, has a reasonably wide distribution, but it appears everywhere to be uncommon to rare. Habitat destruction, particularly of lowland forest, is implicated as a potential threat, but, as the species is known to utilize highland and secondary forests, too, it is considered to be only Near-threatened.

The four other Near-threatened members of the family are the Brown-backed, the Whiskered, the White-throated and the Flame-crowned Flowerpeckers. The first of these, the Brown-backed Flowerpecker, is found in the west part of Peninsular Malaysia, in west and north Borneo and in the Riau Archipelago and the Natuna Islands, and is uncommon to rare throughout its range. The disappearance of lowland forest is believed to be responsible for the presumed decline of this species, but its use of submontane and secondary forests, gardens and plantations places it at less risk than would otherwise be the case. Although confined to south-western Sri Lanka, the White-throated Flowerpecker is common or even locally abundant in some parts of its range, perhaps numbering several tens of thousands. Much of its forest habitat is evidently still under threat, but it does appear able to cross from one forest island to another. Nevertheless, because of its severely restricted range and fragmented habitat it is placed in the conservation category of Near-threatened. The final two dicaeids in this category are both confined to the Philippines. The Whiskered Flowerpecker, found only on Mindanao, is rare to uncommon throughout much of its range, but seems to be locally common in a few areas. It is, however, a low-density species. The Flame-crowned Flowerpecker, resident in northern Luzon and on Mindanao, is likewise a low-density species, generally considered uncommon, although it is common on Mount Pasian, in east Mindanao.

All three globally threatened members of the family are confined to the Philippines. The Black-belted Flowerpecker qualifies as Vulnerable because its restricted range is now severely fragmented owing to clearance of lowland forest and scrub. This has resulted in a severe population decline, and the apparent extinction of the species on Guimaras, one of the three Philippine islands on which it had occurred but where it could not be found in 1992. In the mid-1950s, this flowerpecker was reported as being common on Negros, and in 1991–1992 it was abundant on Mount Talinis in secondary forest and an agriculturally

prepared area on that island. Within the range of this species, Mt Canlaon National Park, on Negros, receives formal protection and other sites where it occurs fall within the proposed Central Panay Mountains National Park. The Mount Talinis and Twin Lakes area on Negros has been proposed for receipt of funding for protection. North Negros Forest Reserve and, on Panay, Sampunong Bolo National Park receive only nominal protection. In 1988, it was estimated that only 4% of Negros and 8% of Panay remained forested, mostly above 1000 m. The Black-belted Flowerpecker's ability to tolerate substantial habitat modification may help to make its future relatively secure. Its population is believed to lie in the range 10,000–19,999 indi-

One of 23 restricted-range species confined to the Sri Lanka Endemic Bird Area, the **White-throated Flowerpecker** occurs only in a small area on the south-west of the island. Locally common, it appears able to withstand a certain amount of habitat fragmentation, having been observed crossing large forest openings and gaps between forest patches. Nevertheless, its small and increasingly fragmented range justify its precautionary treatment as Near-threatened.

[*Dicaeum vincens*, Sinharaja Forest Reserve, Sri Lanka.
Photo: Andy & Gill Swash]

The Philippines have more globally threatened species than any country bar Indonesia and Brazil.

The Dicaeidae feature prominently on this Red List, with three species considered globally threatened, as well as two Near-threatened.

The **Flame-crowned Flowerpecker** falls into the latter group. This attractive bird is also a restricted-range species, occurring in the two Endemic Bird Areas centred on Luzon and Mindanao. It is generally uncommon, and only its preference for middle- and high-altitude forests saves it from entering the main threat categories.

viduals and to be decreasing, and the total area of its distribution is approximately 24,000 km².

Also listed as Vulnerable, the Scarlet-collared Flowerpecker has a small, rapidly declining population and a small, severely fragmented, diminishing range, as a result of the destruction of lowland forest in the Philippines. Its decreasing population is estimated at 10,000–19,999 individuals and its total range at 9900 km². It was thought to be endemic on the island of Mindoro, but has more recently been found farther south, on Panay and Negros. Considered common, even abundant, through much of the last century, and still common in a few areas now, this flowerpecker is said to be unable to survive in highly degraded land. It was estimated in the late 1980s that no more than about 120 km² of forest remained on Mindoro, little of that below 1000 m. The species is found within the Mount Iglit–Baco National Park, where scattered forest patches are present, and Lake Naujan National Park, where little forest remains. Smaller protected areas include the MUFRC Experimental Forest, covering 7853 ha of eastern Mindoro. Conservation funding has been proposed for two further areas in which the species has recently been recorded, namely the Baloy/Madja-as mountain range on Panay, forming part of the proposed Central Panay Mountains National Park, and the Mount Talinis and Twin Lakes area, on Negros. It is found also in the nominally protected North Negros Forest Reserve. On Mindoro, disturbance of undergrowth during harvesting of rattan palms (*Calamus*) has a detrimental effect, at least in Siburan, which, although it lies within the F. B. Harrison Game Reserve, is threatened also by logging and swidden agriculture. There are proposals to devise and implement a management plan for the forest at Siburan, to conserve remnant forest at Malpalon and Puerto Galera, and to extend the Mount Iglit–Baco National Park to encompass remaining tracts of lowland forest.

Without doubt, the most seriously threatened of all the Dicaeidae is the Cebu Flowerpecker, which is classed as Critical owing to its tiny, decreasing population and severely fragmented range, the result of extensive deforestation. This species is estimated as numbering 85–105 individuals, all within a global range of just 8 km² or so. It is confined to the island of Cebu, in the central Philippines, where it was considered to be not uncommon in the 1890s, although it was recorded only from Toledo

and near Cebu City; even then it was considered in danger of extinction, chiefly because of habitat destruction. What remains of its habitat today apparently supports very few individuals indeed. Logging, and the clearance of forest for agriculture, such as sugar-cane fields, are particularly implicated in this flowerpecker's decline. A single individual was found in 1906, after which the species was considered to be extinct until 1992, when it was rediscovered at Tabunan, in Central Cebu National Park. In 1998 it was found at Nug-as, in 1999 it was recorded at nearby Mount Lantoy, and more recently it has been observed at Dalaguete. The available habitat at Tabunan covers only 300 ha, of which only one tenth is considered ideal; the angle of slope on which the forest stands is such that, combined with the effects of landslides and logging, it is unable to support much closed-canopy forest, which is believed to be the optimal habitat for this species. Nug-as has secondary lowland forest and scrub at 200–500 m, and transitional mid-montane forest above 500 m, but few tall trees. Mount Lantoy offers low secondary forest and dense scrub, some old-growth trees at its peak, at 500 m, and some tall dipterocarps at 300 m.

In 2001, the island of Cebu was believed to retain only 0.03% of its original dipterocarp forest, amounting to, at most, just 15 km². The forest at Tabunan, being within the Central Cebu National Park, is technically protected by law, but by the early 1990s it was suffering the depredations of casual loggers and settlers. Part of Nug-as lies in the Watershed Reserve for Alcoy and Boljo-on municipalities, and Mount Lantoy is within the Argao–Dalaguete Watershed Forest Reserve.

Proposals for the rescue of the Cebu Flowerpecker from the brink of extinction include a number of main requirements. The Strict Protection Zone status of the forest areas concerned must be maintained, and effective implementation of such protection ensured. Adjacent areas must be replanted with native species, with the aim of doubling the area of forest. The reforestation of Mount Lantoy needs to be completed, and the proposal to designate this area as a national park supported. A conservation-based development and educational programme should be produced. Low-level tourism may be encouraged, and the local population be assisted in developing land and crops in a way that will not conflict with the conservation of this species.

Interspecific competition with the highly aggressive Red-striped Flowerpecker may have contributed to the decline of the species, but probably to a significant extent only where habitat modification favours the commoner species. More research needs to be undertaken in order to ascertain how important this threat is, and also to determine whether the Cebu Flowerpecker occurs in other, as yet unexplored, areas on the island.

Genus *PRIONOCHILUS* Strickland, 1841

1. Olive-backed Flowerpecker

Prionochilus olivaceus

French: Dicée olive **German:** Grünmantel-Mistelfresser **Spanish:** Picaflor Oliváceo

Taxonomy. *Prionochilus olivaceus* Tweeddale, 1877, Dinagat, Philippines. Three subspecies recognized.

Subspecies and Distribution.

P. o. parsonsi McGregor, 1927 – Luzon and Catanduanes, in N Philippines.
P. o. samarensis Steere, 1890 – Samar, Leyte and Bohol, in EC Philippines.
P. o. olivaceus Tweeddale, 1877 – Dinagat, Mindanao and Basilan, in S Philippines.

Descriptive notes. c. 9·1 cm; 8·4–10·7 g. Male nominate race has crown and upperparts golden-olive, tail and primaries blackish-brown, edged olive, lores grey to greyish-white; sides of face, throat and breast pale olive-grey, centre of chin to belly and undertail-coverts white, lower flanks olive with white streaking; iris brick-red or blood-red; upper mandible black, lower mandible blue-grey with black tip; legs black to blackish-horn. Female is paler than male, with sides of throat and breast greyer. Juvenile has chest olive-tinged grey, loreal spot greyish, central white band below has olive-grey tinge, yellowish on belly; bill pale brown. Race *parsonsi* differs from nominate in having lores and sides of throat and breast black; *samarensis* has breast side browner, tending to form streak at posterior end. VOICE. Repeated single, loud “peeit” or “peeith”; high “tsoo-eet”, with rising second note; high rattling trill.

Habitat. Forest, forest edge and secondary growth, especially around flowering and fruiting trees; sea-level to 1000 m.

Food and Feeding. No detailed data on diet, but probably includes fruit, pollen and nectar of mistletoes (Loranthaceae). Forages in understorey. Joins mixed-species flocks.

Breeding. Nesting recorded in Aug; birds with enlarged gonads in May. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Uncommon in all parts of range. Poorly known.

Bibliography. Cheke & Mann (2001), Dickinson *et al.* (1991), Kennedy *et al.* (2000), McGregor (1909, 1927), Parkes (1971), duPont (1971b), Salomonsen (1960a), Tweeddale (1877a), Worcester (1898).

2. Yellow-breasted Flowerpecker

Prionochilus maculatus

French: Dicée tacheté **German:** Goldbrust-Mistelfresser **Spanish:** Picaflor Moteado
Other common names: Yellow-throated Flowerpecker

Taxonomy. *Pardalotus maculatus* Temminck, 1836, Borneo.

Geographical variation not well marked. Race *septentrionalis* intergrades with *oblitus* in S Thailand. Proposed race *opistatus* (from Nias I) considered insufficiently distinct from nominate to warrant separation. Four subspecies recognized.

Subspecies and Distribution.

P. m. septentrionalis Robinson & Kloss, 1921 – extreme S Myanmar (S Tenasserim) and peninsular Thailand.
P. m. oblitus (Mayr, 1938) – extreme S Thailand and Peninsular Malaysia.
P. m. maculatus (Temminck, 1836) – Sumatra (including Nias I and Belitung) and Borneo.
P. m. natunensis (Chasen, 1935) – N Natuna Is (Bunguran).

Descriptive notes. 10 cm; male 7·5–11·8 g, female 7·8–7·9 g. Nominate race has dark olive-green head, orange patch on crown, pale lores; upperparts, including upperwing, olive-green, remiges with yellowish edgings, tail darker with black tip; malar stripe and ear-coverts greenish-olive, greyish-green or green, moustachial stripe and throat white; underparts yellow, broadly streaked greyish, green or olive-green, centre of abdomen with less streaking on brighter yellow ground; iris red; upper mandible black, lower mandible black or bluish-grey with paler base; legs grey. Sexes similar. Juvenile lacks orange on crown, is dull

greenish-olive above, dull greyish-olive below, with yellowish centre of belly, bill pale. Race *oblitus* has grey forehead, whitish upper throat; *septentrionalis* is more grey on head, is deeper yellow below than previous, has orange-chrome in centre of breast; *natunensis* has brighter and more yellow underparts than nominate, throat more washed with yellow, and dark markings more olive than grey. VOICE. High-pitched “tswik”; various harsh, metallic chattering calls; hoarse disyllabic, “tsweet-tsweet” or “chwit-chwit”.

Habitat. Dipterocarp, alluvial and secondary forests, peatswamp-forest, occasionally in montane forest, at forest edge, and in scrub, plantations and cultivation; to 1500 m.

Food and Feeding. Fruits, nectar and pollen of mistletoes (Loranthaceae); other fruits, including those of *Melastoma malabathricum* and figs (*Ficus*); also probably pollen of *Eugenia dyerana*. Large blue berries taken into bill, contents squeezed out and swallowed, skin discarded. Forages mostly in middle and upper storeys. Singly or in pairs.

Breeding. In Malay Peninsula, eggs mid-Aug, fledglings late Jul and late Oct, and juveniles early May to early Oct; laying in Mar on Belitung (Sumatra); in Borneo, juveniles May and Aug in

Kalimantan Tengah, and birds with enlarged gonads in Feb and Apr–Jul in Sabah. Nest pouch-shaped, with triangular entrance hole pointing upwards, constructed of fern rhizomes and tree cotton, reinforced at rim with spider webs, suspended 2·5 m up from twig of sapling, and surrounded by overhanging leaves, on forest path. Clutch 2 eggs, longish ovate, glossy white, with dense brown blotches and spots coalescing around broad end; no information on incubation and nestling periods; fledglings tended by both parents.

Movements. None recorded.

Status and Conservation. Not globally threatened. Locally common in S Myanmar; locally common to uncommon in S Thailand and common in Peninsular Malaysia; not uncommon in Sumatra and Borneo. Formerly occurred in Singapore, but now extinct there. Considered “near-threatened” in Malay Peninsula on account of possible future habitat loss. Occurs in several protected areas, e.g. Khao Pra Bang Wildlife Sanctuary, in Thailand, Way Kambas National Park, in Sumatra, and Danum Valley Conservation Area, in Borneo.

Bibliography. Cheke & Mann (2001), Danielsen & Heegaard (1995), King *et al.* (1975), Lekagul & Round (1991), MacKinnon & Phillips (1993), Mann (1996, 2008), van Marle & Voous (1988), Medway (1972), Medway & Wells (1976), Nash & Nash (1988), Pearson, D.C. (1975), Pieffer (1961), Robson (2000b), Salomonsen (1960a), Sheldon *et al.* (2001), Smythies (1957), Smythies & Cranbrook (1981), Smythies & Davison (1999), Verheugt *et al.* (1993), Wells (2007).

3. Crimson-breasted Flowerpecker

Prionochilus percussus

French: Dicée poignard **German:** Mennigbrust-Mistelfresser **Spanish:** Picaflor Carminoso

Taxonomy. *Pardalotus percussus* Temminck, 1826, Java.

Forms a superspecies with *P. plateni* and *P. xanthopygius*, although some range overlap with latter in Borneo. Three subspecies recognized.

Subspecies and Distribution.

P. p. ignicapilla (Eyton, 1839) – extreme S Myanmar (S Tenasserim) S through Malay Peninsula (including Penang and Tioman I) to Sumatra (including Bangka and Belitung), also N Natuna Is (Bunguran) and Borneo.

P. p. regulus (Meyer de Schauensee, 1940) – Batu Is, off W Sumatra.

P. p. percussus (Temminck, 1826) – W Java.

Descriptive notes. 10 cm; male 7–10 g, two females 6 g and 10 g. Male nominate race has black forehead, scarlet patch on crown, white malar stripe bordered below by blackish-blue line; otherwise slaty blue above, including upperwing and tail, remiges edged pale blue; throat and underparts deep yellow, with red patch of varying size in centre of breast, flanks dark grey, concealed pectoral tufts white, underwing-coverts white; iris red, brown or orange-brown; bill black, basal half of lower mandible pale blue-grey; legs black or bluish. Female is olive-green above, with dull orange crown patch, whitish malar stripe, throat pale

greyish, sometimes with yellowish tinge, underparts greyish-olive, yellow in centre, with whitish undertail-coverts. Juvenile is dull greenish-olive above, dull olive-grey below, whitish in centre of belly. Race *ignicapilla* has underparts less deep yellow than nominate; *regulus* has greenish-yellow underparts with breast patch deep orange. VOICE. “See-sik”, sometimes fast; monosyllabic “weg”.

Habitat. Lowland dipterocarp forest, peatswamp-forest, alluvial forest, lower montane forest, mangrove and secondary forest, at forest edge, in scrub and old plantations; sea-level to 1065 m, once at 1200 m.

Food and Feeding. Crushes berries of *Melastoma*; uses bill to puncture figs (*Ficus*) and *Eugenia* and “sucks” out contents, or bites out pieces; diet presumably includes also nectar, pollen and fruits of mistletoes (Loranthaceae). Found at all levels, but mostly in middle and lower storeys.

Breeding. In Malay Peninsula, oviduct egg in late May, nestlings May, fledglings Jun, and juveniles Apr, May and Aug–Oct; in Sumatra, juveniles in NW (Aceh) late Aug and in NC & SE (Sumatra Utara and Lampung) late Apr to Jun; in Borneo, laying in Apr (Sarawak) and dependent young in Jul (Kalimantan Tengah). Nest a pear-shaped bag, circular entrance 2·5 cm in diameter, protruding rim around entrance (but no porch), constructed from reddish vegetable down (not so compacted as nest of *Dicaeum*), lined with fine roots, and decorated with caterpillar excreta, lichen, moss, roots etc., external measurements 101 × 70 mm, internally 50 × 50 mm, upper end of structure drawn out and fastened to pendent twig 1·8 m above ground. Clutch 1 egg, pure white, or white with cap of purple-brown spots. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Uncommon to fairly common in S Myanmar and S Thailand; common in Peninsular Malaysia, but less common in N; rare in Sumatra and Java; rare generally in Borneo, but less so at higher altitudes. Occurs in several protected areas, e.g. Khao Pra Bang Wildlife Sanctuary, in Thailand, and Way Kambas National Park, in Sumatra.

Bibliography. Bennett & Bishop (1991), Cheke & Mann (2001), David & Gosselin (2002a), Hellebrekers & Hoogerwerf (1967), Holmes (1996), King *et al.* (1975), MacKinnon & Phillips (1993), Mann (1996, 2008), van Marle & Voous (1988), Medway & Wells (1976), Mees (1986), Meyer de Schauensee (1940), Nash & Nash (1988), Robson (2000b), Salomonsen (1960a), Sheldon *et al.* (2001), Smythies (1957, 1960), Smythies & Cranbrook (1981), Smythies & Davison (1999), Stuart Baker (1934), Verheugt *et al.* (1993), Wells (2007), Wilkinson *et al.* (1991).

4. Palawan Flowerpecker

Prionochilus plateni

French: Dicée de Palawan **German:** Palawanmistelfresser **Spanish:** Picaflor de Palawan
Other common names: Platen’s/Palawan Yellow-rumped Flowerpecker

Taxonomy. *Prionochilus Plateni* A. W. H. Blasius, 1888, Puerto Princesa, Palawan, west Philippines. Forms a superspecies with *P. percussus* and *P. xanthopygius*, although some range overlap between these two species in Borneo; present species (in both sexes) is intermediate between these two in plumage characters. Described form *johannae* considered indistinguishable from nominate. Two subspecies recognized.

Subspecies and Distribution.

P. p. culionensis (Rand, 1948) – Calamian Group (Calauit, Busuanga, Culion), in W Philippines.
P. p. plateni A. W. H. Blasius, 1888 – Palawan and Balabac, in W Philippines.

Descriptive notes. 9 cm; 8–9 g. Male nominate race is dark greyish-blue above, except for orange-red centre of crown and yellow rump; chin and malar stripe white, separated by greyish-blue line; throat and underparts yellow, red patch in middle of breast; iris dark red to dark brown; bill black, base of lower mandible grey; legs black. Female is olive-green to olive-grey above, with centre of crown and rump yellowish, whitish malar stripe separated from whitish chin and throat by grey line, side of neck and flanks grey, rest of underparts yellowish. Juvenile is similar to female but without white malar stripe, much greyer below, with almost no yellow, and has pale base of bill. Race *culionensis* male has orange-yellow rump, throat and breast to belly, female is deep yellow (instead of yellowish) below, with orange pectoral spot. VOICE. Repeated high-pitched metallic “seep-seep”.

Habitat. Forest, secondary growth, scrub and gardens, particularly around fruiting and flowering trees.
Food and Feeding. No information on diet, but probably includes fruit, nectar and pollen of mistletoes (Loranthaceae). Occurs in all storeys of forest. Usually forages singly; sometimes joins mixed-species flocks.

Breeding. Fledged young observed in Mar, and birds with active gonads in Apr, May and Aug. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Restricted-range species: present in Palawan EBA. Common in much of its range. Occurs in St Paul Subterranean River National Park.

Bibliography. Cheke & Mann (2001), Delacour & Mayr (1945), Dickinson *et al.* (1991), Hartley & McGowan (1991), Kennedy *et al.* (2000), McGregor (1909), duPont (1971b), Robson & Davidson (1996), Salomonsen (1960a), Sharpe (1888), Worcester (1898), Worcester & Bourns (1898).

5. Yellow-rumped Flowerpecker

Prionochilus xanthopygius

French: Dicée à croupion jaune **German:** Gelbbürzel-Mistelfresser **Spanish:** Picaflor Culigualdo

Other common names: Borneo (Yellow-rumped)/Bornean Flowerpecker

Taxonomy. *Prionochilus xanthopygius* Salvadori, 1868, Sarawak, Borneo.

Forms a superspecies with *P. percutus* and *P. plateni*, although distribution overlaps with that of former in parts of Borneo. Monotypic.

Distribution. Borneo; also N Natuna Is (one record).

Descriptive notes. 9 cm; male 6.5–8.6 g, female 6.9–8.6 g, unsexed juveniles 6.5–8.2 g. Male has slate-blue head, back, upperwing and tail, red patch on crown, yellow rump; yellow below, orange patch on upper breast, white pectoral tufts (concealed), flanks olive and grey, undertail-coverts yellowish-white, underwing-coverts white; iris brown; bill and legs black. Female is duller than male, has blue-grey crown with very small dull orange-red patch, greenish-olive back, yellow rump; throat whitish, side of face grey, flanks olive-grey, undertail-coverts whitish, rest of underparts yellow, some orange on upper breast. Juvenile

is similar to female, but more bluish-tinged grey above, uppertail-coverts olive, yellow of rump less distinct, upperwing and tail blackish-brown, wing feathers edged blue-grey; much greyer below, with almost no yellow; bill pale. VOICE. High-pitched chattering in flight; other calls are “tsee-oo”, first note rising and second one level, “ship-ship” or “ship-ship-ship”, “tsik-tsik”, which may be repeated rapidly, and 7–9 fast descending staccato notes.

Habitat. Dipterocarp forest, peatswamp-forest, heath and secondary forests, at forest edge, in plantations and clearings; sea-level to 1760 m.

Food and Feeding. Flowers, pollen, nectar, ripe fruit pulp, buds, also insects and spiders (Araneae). Frequently forages at low levels, but found in all storeys.

Breeding. Nesting in Apr in Kalimantan Barat and Jul and Aug in Kalimantan Tengah; in Sabah, nest-building in Feb, birds with enlarged gonads in Feb–Apr, Jun, Jul and Sept, and juveniles in Aug; fledgling in Oct in Sarawak. Nest a loosely felted pouch measuring c. 100 × 50 mm, lateral opening near top 35 × 18 mm, constructed from lichens and plant materials, including moss, attached to leaf stalk c. 1 m above ground. Eggs reddish-white with red, grey and purple markings. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Common and widespread throughout Borneo. Status in N Natunas uncertain; only one confirmed record. Occurs in several protected areas, e.g. Danum Valley Conservation Area, in Borneo.

Bibliography. Cheke & Mann (2001), Coomans de Ruiter (1936), Hartert (1895), MacKinnon & Phillips (1993), Mann (1996, 2008), Nash & Nash (1988), Salomonsen (1960a), Schönwetter & Meise (1980), Sheldon *et al.* (2001), Smythies (1957, 1960), Smythies & Cranbrook (1981), Smythies & Davison (1999).

6. Scarlet-breasted Flowerpecker

Prionochilus thoracicus

French: Dicée à poitrine écarlate **German:** Rubinkehl-Mistelfresser **Spanish:** Picaflor Pechiescarlata

Taxonomy. *Pardalotus thoracicus* Temminck, 1836, Borneo.

An undescribed race may exist in Riau Archipelago. Monotypic.

Distribution. S Thailand, Peninsular Malaysia, N & SE Sumatra (Aceh, Sumatera Utara, Lampung), Lingga Archipelago, Belitung and Borneo.

Descriptive notes. 9.5–10 cm; male 8.9–13 g. Male has black head, small red patch on crown, yellowish-green mantle and back, lesser and outer upperwing-coverts narrowly tipped yellow, rump and uppertail-coverts, rest of upperwing and tail black; throat and breast red, enclosed by broad black border, remainder of underparts yellow becoming whitish towards rear belly and more ashy olive on flanks; iris brown; bill dark brown to black; legs dark slate. Female is duller than male, has greyish head, with or without dull olive-yellow patch on crown, olive-green upperparts, yellowish uppertail-coverts, black tail; side of face grey,

throat paler grey, orange-yellow breast patch, rest of underparts greyish-olive, extensive area of yellow on belly and undertail-coverts. Juvenile is similar to female but greyer below, with base of bill pale; young male has some yellow and red on breast, and occasionally a tiny amount of red on crown.

VOICE. Metallic clicking twitter; c. 6 very high-pitched, insect-like “seek” notes; harsh “chink”.

Habitat. Peatswamp-forest, heath forest and secondary growth, at forest edge, in coastal vegetation, casuarina (*Casuarina*) groves, rubber plantations and in fire-cleared heath forest; lowlands to 1280 m.

Food and Feeding. Insects, spiders (Araneae), also fruits, including those of mistletoes (Loranthaceae), perhaps also pollen and nectar. Generally found at low levels. Sometimes climbs on tree trunks in manner of a nuthatch (*Sitta*). Picks invertebrates from spider webs.

Breeding. Juveniles recorded in Jan, May and Aug–Oct in Malay Peninsula; young in nest in Jan on Belitung; in Borneo, birds with enlarged testes in Mar (Sabah) and fledged young Jul–Sept (Kalimantan Tengah). Nest placed in low bush. No other information.

Movements. Thought to be nomadic in some areas.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Uncommon in Thailand and uncommon in Peninsular Malaysia; rare in Sumatra; uncommon in Borneo. Formerly occurred in extreme S Vietnam, but no records since 19th-century. This species could be at risk as a result of habitat destruction. In Malay Peninsula considered to be “vulnerable”, possibly “endangered”.

Bibliography. Anon. (2007e), Butchart & Stattersfield (2004), Cheke & Mann (2001), Collar *et al.* (2001), Holmes (1996), King *et al.* (1975), MacKinnon & Phillips (1993), Mann (1996, 2008), van Marle & Voous (1988), Medway & Wells (1976), Nash & Nash (1988), Parrott & Andrew (1996), Rajathurai (1996), Robson (2000b), Salomonsen (1960a), Sheldon *et al.* (2001), Smythies (1957, 1960), Smythies & Cranbrook (1981), Smythies & Davison (1999), Stattersfield & Capper (2000), Wells (2007), Wilkinson *et al.* (1991).

Genus DICAENUM Cuvier, 1816

7. Golden-rumped Flowerpecker

Dicaeum annae

French: Dicée de la Sonde **German:** Bartmistelfresser **Spanish:** Picaflor Culidorado

Other common names: Anna’s/Flores/Sunda Flowerpecker

Taxonomy. *Acmonorhynchus annae* Büttikofer, 1894, Flores, Lesser Sunda Islands.

Races not well differentiated. Two subspecies recognized.

Subspecies and Distribution.

D. a. sumbavense (Rensch, 1931) – Sumbawa.

D. a. annae (Büttikofer, 1894) – Flores.

Descriptive notes. 9.4–10 cm; female 10.3 g, unsexed 9.7 g. Male nominate race has crown and upperparts olive-green, rump yellow; throat and malar stripe white, underparts pale yellowish centrally, duller towards sides, and streaked olive-grey, with concealed white pectoral tufts; iris light brown; bill and legs blackish. Female differs from male in lacking yellow on rump. Juvenile is similar to female, but throat and belly greyer, malar stripe less distinct, bill paler, especially on lower mandible. Race *sumbavense* is slightly smaller than nominate, a little more olive above, with tips of flight-feathers duller and less green. VOICE. Re-

peated thin “see” notes on same pitch, terminal 3 notes longer and more widely spaced.

Habitat. Deciduous, semi-evergreen and secondary forest, woodland and cultivation; sea-level to 1530 m on Sumbawa, and to 1800 m on Flores.

Food and Feeding. No detailed information recorded; diet thought to include fruit, pollen and nectar of mistletoes (Loranthaceae). Forages singly, in pairs or in small groups.

Breeding. Laying in Jan and Mar–Oct (peak May) on Flores. Nest a thick oval pouch c. 130 × 65 mm, entrance hole in middle, constructed from felted plant material, spider webs and lichen, decorated with leaf fragments; one was attached at top directly to horizontal twig, another attached over a broad area directly to a twig at angle of 45 degrees. Clutch 2 eggs. No further information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Nusa Tenggara EBA. Locally common to rare.

Bibliography. Butchart *et al.* (1996), Cheke & Mann (2001), Coates & Bishop (1997), Mees (2006), Rensch (1931a), Salomonsen (1960b), Verhoye & Holmes (1999), White & Bruce (1986).

8. Thick-billed Flowerpecker

Dicaeum agile

French: Dicée à bec épais **German:** Dickschnabel-Mistelfresser **Spanish:** Picaflor Picogrueso

Other common names: Streaky-breasted Flowerpecker; Ceylon Thick-billed Flowerpecker (*zeylonicum*); Striped/Fairy Flowerpecker (Philippine races)

Taxonomy. *Fringilla Agilis* Tickell, 1833, Borabhum and Dolbhum, Bengal, east India. Shares tongue morphology with *D. aureolimbatum*, *D. bicolor* and *D. celebicum*. Poorly known N Natuna race *bungurensis* of *D. everetti* (known only from the type specimen) possibly belongs with present species. Geographical variation complex, involving bill shape and various plumage characters (particularly colour of dorsal surface, pale spots on rectrices and ventral streaking), and with mosaic pattern of distribution among races. Philippine races (*striatissimum*, *affine* and *aeruginosum*) sometimes considered to represent a separate species; other races fall into two further groups, one in W (nominate and *zeylonicum*) and the other from NE India and SE Asia S to Sundas (remaining races), these groups possibly representing two additional species; moreover, *finschi* is perhaps sufficiently distinctive to be considered a separate species. Other proposed races are *degnani* (described from Kohima, in Assam) and *separabile* (from Dalat, in C Vietnam), both synonymized with *pallascens*, and *remotum* (from Negri Sembilan, in Peninsular Malaysia), considered indistinguishable from *modestum*. Eleven subspecies currently recognized.

Subspecies and Distribution.

D. a. agile (Tickell, 1833) – NE Pakistan E to W Bangladesh and S through peninsular India.
D. a. zeylonicum (Whistler, 1944) – Sri Lanka.
D. a. pallascens (Riley, 1935) – NE India (S Assam, Meghalaya), E Bangladesh, and Myanmar (except N, W & SW), Thailand (except S & E), Laos, Cambodia and Vietnam (except Tonkin); probably also S China (S Yunnan).
D. a. modestum (Hume, 1875) – S peninsular Thailand, Peninsular Malaysia and Borneo.
D. a. atjehense Delacour, 1946 – NE & S Sumatra.
D. a. finschi M. Bartels, 1914 – W Java.
D. a. tinctum (Mayr, 1944) – Lesser Sundas (Sumba, Flores and Alor).
D. a. obsoletum (S. Müller, 1843) – Timor.
D. a. striatissimum Parkes, 1962 – Luzon, Lubang, Romblon, Sibuyan and Catanduanes (N Philippines).
D. a. affine (J. T. Zimmer, 1918) – Palawan (W Philippines).
D. a. aeruginosum (Bourne & Worcester, 1894) – Mindoro, Negros, Cebu and Mindanao (S Philippines).

Descriptive notes. c. 9–10.4 cm; 7.5–11 g. A relatively dull flowerpecker with bill of variable thickness; has distinctive habit of jerking tail from side to side. Nominate race is grey-brown with variably intense olive or green tinge above, more olive tinge on rump (presumed male in display shows distinct white mesial stripe down crown and nape, and white flecking on centre of crown); tail and remiges brown, tail edged olive-green; white submoustachial streak, thin brown malar stripe; throat buffy white with faint brown streaking at sides, underparts buffy with obscure brown streaking, browner on flanks; concealed whitish pectoral tufts present;

undertail with large white tips on outer feathers, narrow white tips on adjacent pair; iris light brick red, sometimes dull orange or brown; bill bluish-black; legs slaty brown. Sexes similar. Juvenile is much less streaked than adult, and has yellowish wash on underparts, pale lower mandible. Races differ mainly in plumage coloration and markings and in bill shape, also races other than nominate have bill usually brownish with yellowish area on lower mandible (sometimes all black) and legs often black or grey; *zeylonicum* is smaller and darker than nominate, more olive-grey above, with more olive rump, and more heavily streaked below; *pallascens* is much greyer above, more heavily streaked below, with bill less deep than that of nominate; *modestum* is olive above, moderately streaked below, with tail spots faint; *finschi* is more olive above than nominate, greyish-white below, with more grey breast streaking, thin bill; *atjehense* is similar to previous in general coloration, but with slightly more prominent whitish tail tips, thicker bill; *tinctum* is brownish-olive above, greener-looking than nominate, has creamy underparts with less obvious streaking, faint spots on undertail; *obsoletum* is less olive above than nominate, browner on rump, almost pure unstreaked white below, has faint tail spots; *aeruginosum* is olive-green above, more greenish on lower back to uppertail-coverts, with whitish underparts heavily streaked brown, particularly on breast, has faint whitish patches on underside of outer rectrices, juvenile greyer and unstreaked; *affine* is smaller and more greyish-tinged olive than previous, has paler underparts with narrow more obscure streaking, white terminal spots on rectrices brighter, smaller and more sharply defined, has shorter and broader bill; *striatissimum* has darker, sootier (less greenish) upperparts than *aeruginosum*, underparts more heavily and extensively streaked, white spot on inner web of outer rectrix larger but fainter. **VOICE.** Loud “chik-chik-chik-chik”, rattling “titiititit”, and very high-pitched “chit-chit”; twittering call during display; sharp, cracked chirp “spick!”, likened to sound made by a small woodpecker (Picidae). Song of 6–8 notes at different pitches; described also as “spick!” call notes with short, dry, titting trills.

Habitat. Range of forest types, at forest edge, in secondary growth, plantations, coconut groves, orchards and gardens; particularly around flowering and fruiting trees and shrubs, and mistletoes (Loranthaceae). Lowlands to 3000 m.

Food and Feeding. Feeds on fruits, including those of mistletoes, lantana (*Lantana*) and figs (*Ficus*), also flowers; also takes insects, including caterpillars (Lepidoptera), and spiders (Araneae). Forages mainly in canopy and middle stratum; sometimes lower down in shrubs. Singly, in pairs or in small groups; joins mixed parties.

Breeding. Laying in Dec–Aug in India and Apr and May in Sri Lanka; nestlings found Jan in S Thailand; males with enlarged testes in Mar in Vietnam (S Annam). Nest a pear-shaped felted pouch with side entrance (apparently looking like a leaf), constructed of soft felted fibres, flower buds, cobweb and vegetable down, inconspicuously suspended 2–9 m above ground from twig of tree or bush; mango trees (*Mangifera indica*) and *Lantana* bushes recorded as used. Clutch 2–4 eggs, pale pinkish-white, blotched and speckled pale or deep brick red. No other information.

Movements. Resident in much of range. Seasonal altitudinal movement in Himalayas; in Nepal, found at 150–3000 m in summer, below 915 m in winter. Rare visitor in Singapore, where two records.

Status and Conservation. Not globally threatened. Generally fairly common throughout most of range; rare and local in Pakistan; widespread but not uncommon in India, widespread in Nepal, scarce in Sri Lanka, and local in Bangladesh; rare in Myanmar, but not uncommon in Thailand and locally common in S Laos; uncommon in Peninsular Malaysia, where assessed as being at best “near-threatened”; rare in Sumatra, Borneo, Java and Alor, and uncommon or rare on Sumba, Flores and Timor; uncommon in Philippines. Race *aeruginosum* possibly extinct on Cebu (Philippines), where no confirmed records since 1950s. Very local in Sumatra, where currently known from just four sites: Pendeng and Ketambe (in Aceh province, in N), Mt Sibayak (in Utara province, in N), and Padang-Sugihan Reserve (in Selatan province, in S). Occurs also in several other protected areas, e.g. Kaeng Krachan National Park and Khao Pra Bang Wildlife Sanctuary, in Thailand, and rare in Danum Valley Conservation Area, in Borneo.

9. Brown-backed Flowerpecker

Dicaeum everetti

French: Dicée d'Everett **German:** Braunrücken-Mistelfresser **Spanish:** Picaflor de Dorsipardo
Other common names: Everett's Flowerpecker

Taxonomy. *Prionochilus everetti* Sharpe, 1877, Bintulu, Sarawak, western Borneo. Race *bungurensis* possibly belongs in *D. agile*. Described race *sordidum*, from Rawang, in C Selangor (W Peninsular Malaysia), is considered inseparable from nominate and therefore synonymized with it. Two subspecies recognized.

Subspecies and Distribution.

D. e. everetti (Sharpe, 1877) – Peninsular Malaysia (Selangor), Riau Archipelago (Bintan I) and N & W Borneo.
D. e. bungurensis (Chasen, 1935) – Bungan, in N Natuna Is.

Descriptive notes. 10 cm. A rather dull, pale-eyed flowerpecker with thick bill. Nominate race has most of head and all upperparts olive-brown, darker tail, edges of secondaries greenish; throat white, underparts grey-brown, with centre of breast and belly white; iris whitish to pale yellow or orange; bill grey or dark brown, or upper mandible grey and lower mandible brown with yellowish patch; legs grey or dark brown. Sexes similar. Juvenile undescribed. Race *bungurensis* differs from nominate in having underparts markedly streaked. **VOICE.** A sharp metallic “chip-chip” recorded.

Habitat. Heath forest, swamp-forest, secondary forest, mangroves, plantations and gardens, and at forest edge; sea-level to 1100 m.

Food and Feeding. Spiders (Araneae), insects and flowers taken; probably also nectar, pollen and fruits of mistletoes (Loranthaceae). Often forages at lower levels.

Breeding. In Borneo, laying in Feb and birds with active testes in Mar in Sabah. Nest a small, whitish felted pouch, probably made from grass and vegetable down such as kapok, suspended 5–6 m above ground from end of branch. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. May be at risk because of relatively small, fragmented known range, within which it is generally uncommon to rare. Thought to be possibly “endangered” in Peninsular Malaysia.

Bibliography. Anon. (2007e), Butchart & Stattersfield (2004), Chasen (1931), Cheke & Mann (2001), Collar *et al.* (2001), MacKinnon & Phillips (1993), Mann (2002, 2008), van Marle & Voous (1988), Pfeiffer (1961), Salomonsen (1960b), Sheldon (1985), Sheldon *et al.* (2001), Smythies (1957, 1960), Smythies & Cranbrook (1981), Smythies & Davison (1999), Stattersfield & Capper (2000), Wells (2007).

10. Whiskered Flowerpecker

Dicaeum proprium

French: Dicée à poitrine grise **German:** Graubrust-Mistelfresser **Spanish:** Picaflor Bigotudo
Other common names: Grey-breasted Flowerpecker

Taxonomy. *Dicaeum proprium* Ripley and Rabor, 1966, Mount Mayo, Limot, Mati, Davao Province, Mindanao, Philippines.

Relationships within genus uncertain. Monotypic.

Distribution. Mindanao, in S Philippines.

Descriptive notes. 9 cm; male 10.2 g. Male has crown and upperparts blue-black, glossed green, primaries dark brown; submoustachial stripe and chin greyish-white, separated by blue-black malar stripe; rest of underparts pale sepia-brown, darker and greyer on flanks, paler and greyer on undertail-coverts, pectoral tufts white; iris brown or reddish-brown; bill blackish or dark horn; legs black or dark brown. Female has crown and upperparts dark blackish-brown with slight gloss, throat whitish with pale brownish wash, and underparts darker, slightly reddish on breast, contrasting with paler belly and flanks. Juvenile undescribed. **VOICE.** Various raspy and snappy notes, e.g. “zaak”, and insect-like sounds; occasionally series of notes, as “zaach-zee-peew”.

Also, 4 or 5 high-pitched notes, first two higher; low “zenk”; high “swink” or “chenk” notes, rather buzzy, sometimes run into a song in which some notes rising and some falling.

Habitat. Forest, at forest edge and in secondary growth, particularly around flowering and fruiting trees; above 900 m.

Food and Feeding. No documented information; diet probably includes fruit, nectar and pollen of mistletoes (Loranthaceae).

Breeding. Carrying nest material to top of 20-m tree on 30th Apr–2nd May. No other information. **Movements.** No information.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species; present in Mindanao and the Eastern Visayas EBA. Generally uncommon to rare, but apparently locally common in a few areas. Sites where this species is known to occur include Mt Apo, Mt Matutum, Mt Mayo, Mt Piapayungan, Mt Kitanglad, Mt Sugarloaf, mountains of Lanao del Norte Province, and at Mainit, Manticao, Misamis Oriental, and L. Sebu.

Bibliography. Anon. (2007e), Butchart & Stattersfield (2004), Cheke & Mann (2001), Collar, Andreev *et al.* (2001), Collar, Crosby & Stattersfield (1994), Collar, Mallari & Tabaranza (1999), Dickinson *et al.* (1991), Kennedy *et al.* (2000), duPont (1971b), Ripley & Rabor (1966), Robson (1994a), Robson & Davidson (1996), Stattersfield & Capper (2000).

11. Yellow-vented Flowerpecker

Dicaeum chrysorrheum

French: Dicée cul-d'or **German:** Gelbsteiß-Mistelfresser **Spanish:** Picaflres Pechiestradi

Taxonomy. *Dicaeum chrysorrheum* Temminck, 1829, Java. Proposed race *intensum* (from Sikkim, in N India) considered a synonym of *chrysochlore*. Two subspecies recognized.

Subspecies and Distribution.

D. c. chrysochlore Blyth, 1843 – Himalayan foothills from C Nepal E to NE India (Assam, S to Mizo Hills), E Bangladesh (Chittagong Hills), Myanmar, S China (W & SE Yunnan) and Indochina, and S to C peninsular Thailand (Isthmus of Kra).

D. c. chrysorrheum Temminck, 1829 – S Thailand (S of Isthmus of Kra) S to Peninsular Malaysia, Singapore, Sumatra, Borneo, Java (including Madura I) and Bali.

Descriptive notes. 9–10 cm; male 9.1–10.1 g, female 9 g. Greenish flowerpecker with striped underparts, large curved bill. Male nominate race has lores white, crown, side of neck and upperparts bright olive-green, upperwing and tail black; submoustachial stripe and throat white, greyish-black malar streak; breast and belly creamy white, streaked blackish, undertail-coverts yellow or orange; iris orange or orange-red; bill dark grey or blackish; legs dark grey. Sexes similar, female generally with less bright undertail-coverts. Juvenile differs from adult in having upperparts duller, underparts more greyish and with finer, less well-defined,

greyish-brown streaks, bill pale with black tip. Race *chrysochlore* has breast and belly yellowish-white and more heavily streaked greyish-black, and undertail-coverts bright golden-yellow. **VOICE.** A single “zeet”; flight call a repeated “zit-zit-zit”; also a repeated “chip-a-chip-tree”, and soft squeaks; contact notes loud, deep and hoarse.

Habitat. Lowland and hill dipterocarp forest, lower montane forest and secondary forest, moist deciduous and alluvial forests, peat swamp-forest, and highland heath forest, in open jungle, woodland, *Albizia* and old rubber plantations, gardens and orchards, and at forest edge; occurs particularly where mistletoes (Loranthaceae) present. To 245 m in Nepal, but to over 2000 m in Bhutan; to 1500 m in Myanmar, to 1300 m in Laos and to 870 m in Malay Peninsula; sea-level to 700 m in Sumatra and to 1700 m in Borneo.

Food and Feeding. Feeds on fruits of mistletoes and small figs (*Ficus*), berries of *Muntingia calabura*, nectar; also insects, including small beetles (Coleoptera). Forages at all levels of vegetation.

Breeding. Laying Apr–Aug in India, fledglings in Jan in S Thailand, and juveniles in May and Sept in Peninsular Malaysia. Nest built by both sexes, taking c. 4–5 days, a well-concealed pouch of moss, grass, fibre, cotton down (including of tree genus *Bombax*), fine grass-seed ends and spider webs, suspended usually below 8 m from bush or tree branch. Clutch 2–3 eggs, white; incubation by both sexes; no information on nestling period.

Movements. Sometimes makes dispersal movements. Apparently crosses to Singapore from Peninsular Malaysia more or less annually.

Status and Conservation. Not globally threatened. Common in India, but rare in Nepal, Bhutan and Bangladesh; uncommon in Myanmar and in Borneo; uncommon to common in Malay Peninsula; rare in Sumatra, Java and Bali. Only one confirmed record for Bali, from Bali Barat National Park. Occurs in several other protected areas, e.g. Kaziranga National Park, in India, Khao Yai National Park, in Thailand, and Cat Tien National Park, in Vietnam; rare in Danum Valley Conservation Area, in Borneo.

Bibliography. Ali & Ripley (1974), Cheke & Mann (2001), Cheng Tsohsin (1987), Fleming *et al.* (1976), Green (1991), Gretton (1990), Grimmett *et al.* (1998), Hellebrekers & Hoogerwerf (1967), Inskipp & Inskipp (1991), King *et al.* (1975), MacKinnon & Philipps (1993), Mann (1996, 2008), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Pfeffer (1961), Rasmussen & Anderton (2005b), Rheindt (2004a), Ripley (1982), Robson (2000b), Salomonsen (1960b), Sheldon *et al.* (2001), Smythies (1957, 1986), Smythies & Cranbrook (1981), Smythies & Davison (1999), Stressemann & Heinrich (1940a), Wells (2007).

12. Yellow-bellied Flowerpecker

Dicaeum melanoxanthum

French: Dicée à ventre jaune **Spanish:** Picaflres Ventrigualdo **German:** Gelbbauch-Mistelfresser

Taxonomy. *Pachyglossa melanozantha* [error for *melanoxantha*] Blyth, 1843, Nepal.

The only member of its genus possessing a visible outermost primary, which is the character state in *Prionochilus*, but was placed in present genus owing to superficial resemblance to *D. vincens*; in tongue morphology, however, resembles *D. australe* and *D. hypoleucum*, and not *Prionochilus*. Monotypic.

Distribution. Himalayas from N India (E Uttaranchal) and N Nepal E discontinuously to Arunachal Pradesh, Nagaland and Manipur, NE Bangladesh, W & E Myanmar and S China (W & SW Sichuan S to W & NW Yunnan). Non-breeding also S to N Thailand, N Laos and extreme N Vietnam.

Descriptive notes. 11.5–13 cm. Male has head and upperparts slaty blue-black with slight gloss, upperwing and tail black, two outer pairs of tail feathers with large white patch on inner web (sometimes reduced or absent on penultimate feather); outermost primary (P10) not vestigial but short (as in *Prionochilus*); centre of throat and upper breast white, sides of neck and of breast dull greyish-black, rest of underparts bright yellow; iris red or chestnut; upper mandible black, lower mandible grey; legs black. Female is duller than male, has head, side of neck and upperparts, olive-grey, centre of throat and breast white, centre of belly and undertail-coverts pale yellow, flanks olive-yellow, less white on tail. Juvenile is mostly dull brown, with hint of white on throat and yellow on belly; immature male duller than adult, with brownish-grey upperparts. **VOICE.** Agitated “zit-zit-zit-zit”.

Habitat. Found in pine (*Pinus*) forest, in tall trees of open forest, clearings in rainforest and also at forest edge. Present at altitudes of 1400–3915 m in summer, and usually 775–1550 m (though has been recorded up to 2450 m) in winter.

Food and Feeding. Insects; probably also fruit, nectar and pollen, and in winter perhaps also leaves, of mistletoes (Loranthaceae). Solitary, elusive, generally more sluggish than smaller congeners. Sits upright on exposed perch often for lengthy periods. Sometimes flycatches by sallying.

Breeding. Nesting in Apr in Myanmar; juvenile in Jun in India, and males with enlarged testes in Jul in Nepal. Clutch 3 eggs, white. No other information.

Movements. Seasonal altitudinal movements recorded. Non-breeding visitor in winter months to N Thailand, SE Yunnan (S China) and N Indochina.

Status and Conservation. Not globally threatened. Scarce and local in India, local in Nepal and rare in Bhutan; only two records from Bangladesh, where possibly only a vagrant; in Myanmar, not uncommon in S Shan States. Rare non-breeding visitor in N Thailand. Occurs in several protected areas, e.g. rare in Namdapha National Park, in NE India, and scarce non-breeding visitor in Doi Inthanon National Park, in NW Thailand.

Bibliography. Ali & Ripley (1974), Cheke & Mann (2001), Cheng Tsohsin (1987), David-Beaulieu (1948), Davidson (1998), Dickinson (1970), Dickinson & Chaiyaphun (1973), Fleming (1968), Fleming *et al.* (1976), Fuchs *et al.* (2007), Grimmett *et al.* (1998), Inskipp & Inskipp (1991), Martens & Eck (1995), Meyer de Schauensee (1984), Rasmussen & Anderton (2005b), Ripley (1982), Robson (2000b), Robson *et al.* (1998), Salomonsen (1960b), Smythies (1986), Thompson & Johnson (2003).

13. White-throated Flowerpecker

Dicaeum vincens

French: Dicée de Ceylan **German:** Weißkeh-Mistelfresser **Spanish:** Picaflres Cingalés **Other common names:** Legge’s Flowerpecker

Taxonomy. *Prionochilus vincens* P. L. Slater, 1872, Sri Lanka. Monotypic.

Distribution. SW Sri Lanka.

Descriptive notes. 9–10 cm. Male has slaty-blue head and upperparts, paler on rump, black upperwing with narrow slaty-blue margins, black tail with large white terminal spots; throat to upper breast white, slaty-blue patches on sides of breast, lower breast and belly bright yellow, undertail-coverts white; iris brown or reddish-brown; bill black, blue-grey at base of lower mandible; legs black. Female is duller than male, has head grey, back dull olive, wing and tail brownish-black, outer rectrices with large white spots, throat whitish, belly pale yellow, flanks olive, undertail-coverts whitish, underwing-coverts white. Juvenile resembles

female, but with yellow wash on throat; pale lower mandible. **VOICE.** Calls include “tchip, tchip-two-see-see, tzee, tzee, tzee”, repeated high-pitched “tee-too”, weak “tze-tze-tze”, also “tsit; tsee-tsit(-tsit)” and “wheep-wheep-wheep”. Song said to be a series of 4–5 very high-pitched thin notes alternating in pitch, as “tink-tuk-tink”; ascending “keek-keek” ending with “tit-tiri-tit-tiri” and a rapid, irregular descending trill also described.

Habitat. Among tall trees and creepers in rainforest, at up to 1000 m. Has been recorded in drier forests and at higher altitudes; occasionally visits gardens and plantations near forest.

Food and Feeding. Fruits, probably including mistletoes (Loranthaceae), also nectar, spiders (Araneae) and small insects. Forages mostly at high levels, occasionally lower. Found singly, in pairs or in small family parties. Often joins mixed feeding flocks.

Breeding. Laying in Jan–Aug. Nest said to be typical of family, placed 18–38 m up in dipterocarp tree. Clutch 2 eggs, pinkish-white, speckled with pinkish-brown, more heavily at broad end. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Sri Lanka EBA. In some areas considered common, or even locally abundant, below 900 m. Potentially at risk because of its small range and highly fragmented habitat.

Bibliography. Ali & Ripley (1974), Anon. (2007e), Banks & Banks (1986), Butchart & Stattersfield (2004), Cheke & Mann (2001), Collar, Andreev *et al.* (2001), Collar, Crosby & Stattersfield (1994), Grimmett *et al.* (1998), Harrison (1999), Kazmierczak (2000), Kotagama & Goodale (2004), Rasmussen & Anderton (2005b), Ripley (1982), Stattersfield & Capper (2000).

14. Yellow-sided Flowerpecker

Dicaeum aureolimbatus

French: Dicée à flancs jaunes **Spanish:** Picaflres Flanquigualdo **German:** Gelbflanken-Mistelfresser

Other common names: Golden-edged/Golden-flanked/Minahassa/Sulawesi/Celebes Flowerpecker

Taxonomy. *Prionochilus aureolimbatus* Wallace, 1865, mountains of Minahassa, northern Sulawesi. Has been thought perhaps to form a superspecies with *D. nigrilore*, with which it shares some plumage resemblances, but differs markedly in bill shape and tongue structure. Tongue morphol-

On following pages: 15. Olive-capped Flowerpecker (*Dicaeum nigrilore*); 16. Flame-crowned Flowerpecker (*Dicaeum anthonyi*); 17. Bicoloured Flowerpecker (*Dicaeum bicolor*); 18. Cebu Flowerpecker (*Dicaeum quadricolor*); 19. Red-striped Flowerpecker (*Dicaeum australe*); 20. Black-belted Flowerpecker (*Dicaeum haematostictum*); 21. Scarlet-collared Flowerpecker (*Dicaeum retrocinctum*).

ogy of present species resembles that of *D. agile*, *D. bicolor* and *D. celebicum*. Races rather poorly differentiated. Two subspecies recognized.

Subspecies and Distribution.

D. a. aureolimbatum (Wallace, 1865) – Sulawesi and adjacent islands (including Bangka, Lembah, Togian Is, Kabaena, Muna, Butung).

D. a. laterale Salomonsen, 1960 – Sangihe I, N of Sulawesi.

Descriptive notes. 8.5 cm. Nominate race is bright olive-green above, duller on crown, brighter green on rump, with upperwing and tail blackish-brown; auriculars blackish-grey, cheek dark grey, moustachial stripe greyish-white; greyish-white below, tinged ashy on foreneck, with side of breast, flanks and undertail-coverts bright yellow; underwing-coverts white; iris reddish-brown to brown; bill and legs blackish. Sexes similar. Juvenile has side of chest yellow, less bright than adult, flanks grey, undertail-coverts whitish, bare parts pinkish-brown. Race *laterale* has flanks greyish-olive. Voice. Call “s-uit”, less high-pitched and less strident than that of *D. celebicum*, and given less frequently; also 5–6 “tuk” notes, rapid and staccato; sharp and clear “zit-zit-zit”, sometimes run together 5–6 times.

Habitat. Occurs in primary forest and tall secondary forest; also found at forest edge, in woodland, cultivation, plantations, scrub, *Lantana camara* thickets and gardens. Recorded from sea-level up to 2000 m.

Food and Feeding. Spiders (Araneae), insects, fruits of mistletoes (Loranthaceae), small figs (*Ficus*) and wild cherries (*Prunus*); possibly also nectar and pollen of mistletoes. Larger fruits squeezed before being swallowed, and bill wiped on a branch afterwards. Forages mostly in middle storey or in medium-sized trees. Displaced from feeding sites by *D. celebicum*. Occurs singly, in pairs or in small groups.

Breeding. Active nests Togian Is in Jun and Aug, and fledglings in Nov; immatures late Aug to early Sept on Kabaena. Nest pear-shaped, mainly of woven dry leaves and/oralang grasses, c. 15 cm above ground. Eggs white, spotted violet or red, or grey with dense purple-brown flecks. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Widespread and common in Sulawesi, including on Kabaena; rare on Sumpu (off SW Butung). Race *laterale* common on Sangihe I. Occurs in Lore Lindu National Park, in C Sulawesi.

Bibliography. van Bemmelen & Voous (1951), Blasius (1897), Cheke & Mann (2001), Coates & Bishop (1997), Coomans de Ruiter (1950, 1951), Holmes & Wood (1980), Indrawan *et al.* (2006), Meyer & Wigglesworth (1898a, 1898b), Riley, J. 15. Olive-capped Flowerpecker

Dicaeum nigrilore

French: Dicée à calotte olive

German: Olivkopf-Mistelfresser

Spanish: Picaflres de Mindanao

Taxonomy. *Dicaeum nigrilore* E. J. O. Hartert, 1904, Mount Apo, 3000 feet [c. 915 m], Mindanao, Philippines.

Has been thought perhaps to form a superspecies with *D. aureolimbatum*, with which it exhibits some plumage resemblances, but differs markedly in bill shape and tongue structure; indeed, tongue morphology of present species is unlike that of any other species examined. Two subspecies recognized.

Subspecies and Distribution.

D. n. nigrilore E. J. O. Hartert, 1904 – mountains of W, C & S Mindanao, in S Philippines.

D. n. diutae Salomonsen, 1953 – E Mindanao (Mt Hilong-Hilong, Mt Pasian and Mt Puting Bato).

Descriptive notes. c. 9.8 cm; 9.5–12.4 g. Fairly modest-looking flowerpecker with long, slender, curved bill. Nominate race has top of head light olive, mantle brown, back brownish, rump olive-green; upperwing and tail dark brown, wing feathers edged green; lores and patch under eye black, chin white, throat, breast and belly grey, flanks and undertail-coverts dull yellow, abdomen white; iris brown or blood-red; bill black; feet greyish-black. Sexes similar. Immature is duller than adult. Race *diutae* is distinctive, has top of head dark, dull green, mantle blackish-brown, back, flanks and undertail-coverts olive-green, abdomen suffused yellow. Voice. High-pitched, scratchy “zuti-zuti-zuti-zuti...” repeated 10–15 times; high (tseep-tseep...); also rapid rising and falling high-pitched trill of c. 30 notes, some rather sweet and atypical of a flowerpecker.

Habitat. Submontane and montane forests above 900 m; found particularly around flowering and fruiting trees.

Food and Feeding. No information; diet thought to include fruits, pollen and nectar of mistletoes (Loranthaceae).

Breeding. Nest-building observed in May; birds with active gonads in Jan, Apr and May. Nest, under construction, spherical, 15–18 cm in diameter, made of fibres and other dried plant material, woven together with moss; well-concealed at 15 m above ground, suspended by fibres from small twigs. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Restricted-range species; present in Mindanao and the Eastern Visayas EBA. Common. Nominate race occurs on Mt Malindang, Mt Kitanglad, Mt Apo, Mt McKinley, Mt Busa, Mt Matutum, Mt Mayo, and mountains in Misamis Oriental province. E race *diutae* is found on Mt Hilong-Hilong, Mt Pasian and Mt Puting Bato, where it appears not to be at any immediate risk.

Bibliography. Cheke & Mann (2001), Dickinson *et al.* (1991), Kennedy *et al.* (2000), McGregor (1909), duPont (1971b), Rand & Rabor (1960), Salomonsen (1953b, 1960b).

16. Flame-crowned Flowerpecker

Dicaeum anthonyi

French: Dicée couronné

German: Goldkronen-Mistelfresser

Spanish: Picaflres Coronado

Other common names: Anthony's Flowerpecker; Yellow-crowned Flowerpecker (nominate)

Taxonomy. *Prionochilus anthonyi* McGregor, 1914, Mount Polis, Ifugao Subprovince, 2000 m, Luzon, Philippines.

Nominate race particularly distinctive, possibly represents a separate species; study required. Three subspecies recognized.

Subspecies and Distribution.

D. a. anthonyi (McGregor, 1914) – N Luzon (Mt Polis, Mt Puguig, Mt Tabuan and Mt Dipalayag), in N Philippines.

D. a. masawani Rand & Rabor, 1957 – W Mindanao (Mt Malindang), in S Philippines.

D. a. kampilili Manuel & Gilliard, 1953 – N, C & SE Mindanao (Mt Kitanglad, Daggayan near Mt Balatukan, Mt Pasian, Mt Kampilili, Mt McKinley and Mt Apo).

Descriptive notes. 9.6 cm; male 9.6–13 g, female 11.7 g. Male nominate race has forehead and lores black, crown orange-yellow; hind-neck and upperparts black, glossed blue; chin and throat white, breast and belly pale yellowish, undertail-coverts yellow to orange-yellow; iris chestnut; bill black; legs black or blackish-slate, soles pale yellow. Female much duller; crown, side of head, side of neck and upperparts olive; lores and forehead grey, chin, throat and submoustachial area whitish, malar area and most of abdomen pale olivaceous buff mixed with some yellow, and a yellow stripe running down central abdomen to undertail-coverts; iris dark brown. Juvenile undescribed; immature paler and less glossy than adult of corresponding sex. Race *kampilili* male has crown glossy orange-red, breast and belly greyish-white and undertail-coverts orange, female brown below with buff undertail-coverts; *masawani* resembles previous, but male has much more yellow breast and belly. Voice. High-pitched, sharp “srreep”; no further details.

Habitat. Forest, particularly mossy forest, and at forest edge, around flowering and fruiting trees; usually above 800 m and to at least 2000 m.

Food and Feeding. No detailed information; diet presumably includes fruits, pollen and nectar of mistletoes (Loranthaceae). Occurs in all storeys; may feed close to ground. Forages singly and in pairs; may join mixed-species flocks.

Breeding. Birds with active gonads in May; fledged young seen in Mar on Mindanao.

Movements. No information.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species; present in Luzon EBA and in Mindanao and the Eastern Visayas EBA. Generally uncommon, occurring at low density; common on Mt Pasian, in E Mindanao.

Bibliography. Anon. (2007e), Butchart & Stattersfield (2004), Cheke & Mann (2001), Collar, Andreev *et al.* (2001), Collar, Crosby & Stattersfield (1994), Dickinson *et al.* (1991), Kennedy *et al.* (2000), Manuel & Gilliard (1952), McGregor (1927), duPont (1971b), Rand & Rabor (1957), Ripley & Rabor (1961), Robson & Davidson (1996), Salomonsen (1960b), Stattersfield & Capper (2000).

17. Bicoloured Flowerpecker

Dicaeum bicolor

French: Dicée bicolor

German: Zweifarben-Mistelfresser

Spanish: Picaflres Bicolor

Taxonomy. *Prionochilus bicolor* Bourns and Worcester, 1894, hills at back of Ayala, Zamboanga, Mindanao, Philippines.

Forms a superspecies with *D. quadricolor*. Tongue morphology similar to that of *D. agile*, *D. aureolimbatum* and *D. celebicum*. Recent records on Panay probably refer to race *viridissimum*. Three subspecies recognized.

Subspecies and Distribution.

D. b. inexpectatum (E. J. O. Hartert, 1895) – Luzon, Mindoro and Catanduanes, in N Philippines.

D. b. viridissimum Parkes, 1971 – Guimaras, Negros and (probably this race) Panay, in C Philippines.

D. b. bicolor (Bourns & Worcester, 1894) – Samar, Leyte, Bohol, Dinagat and Mindanao, in EC & S Philippines.

Descriptive notes. c. 9 cm; male 7.8–8.5 g, female 8.6–10 g. Male nominate race has top of head (to below eye), upperparts, upperwing and tail black, glossed purple; mostly grey below, whitish on throat, submoustachial area and centre of belly and undertail-coverts; iris red; bill and legs black. Female is duller than male, dark glossy green above, browner on crown, greener on lower back, rump and upperpart-coverts, with black tail, grey underparts have olive-green wash and lighter streak down middle, whitish submoustachial area and whitish undertail-coverts, underwing-coverts white; iris chestnut, bill dark brown with pale

yellowish-brown or orange-flesh base of lower mandible, legs dark brownish-grey. Juvenile undescribed; immature as female, but greyer above. Race *inexpectatum* is slightly bigger than nominate, male has blue (not purple) gloss on upperparts, female is greyish-olive above, wing-coverts and remiges dark brown with olive-brown edging, tail blackish-brown, grey below with olive wash and lighter central streak; *viridissimum* also is slightly bigger than nominate, male has green gloss above, female has greyish-olive upperparts and olive-green wash below. Voice. “Swip-swip...” notes developing into rapid trill, becoming slower and lower-pitched towards end.

Habitat. Forest, at forest edge and in secondary growth, around flowering and fruiting trees; usually below 1000 m, but recorded to above 2250 m.

Food and Feeding. No detailed information; diet probably includes fruit, pollen and nectar of mistletoes (Loranthaceae). Spends most of time in canopy. Forages singly or in small groups; joins mixed-species flocks.

Breeding. Young fledglings observed in Mar and May on Luzon and in Apr on Mindanao; female with oviduct egg in Apr in S Luzon. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Uncommon in all parts of range. As a canopy-dweller, this species is possibly more numerous than it appears to be.

Bibliography. Cheke & Mann (2001), Dickinson *et al.* (1991), Goodman & Gonzales (1990), Kennedy *et al.* (2000), McGregor (1909), Parkes (1971), duPont (1971b), duPont & Rabor (1973b), Ripley & Rabor (1958), Robson & Davidson (1996), Salomonsen (1960b), Whitehead (1899), Worcester (1898).

18. Cebu Flowerpecker

Dicaeum quadricolor

French: Dicée quadricolore **German:** Vierfarben-Mistelfresser **Spanish:** Picaflor de Cebú
Other common names: Orange-backed/Four-coloured Flowerpecker

Taxonomy. *Prionochilus quadricolor* Tweeddale, 1878, Cebu, Philippines.

Forms a superspecies with *D. bicolor*. Monotypic.

Distribution. Cebu, in C Philippines.

Descriptive notes. 9 cm. Male has top and side of head and hindneck black, mantle and back black, feathers with extensively bright orange-red tips, lower back and rump greenish-yellow, upperwing and tail black; whitish submoustachial area, throat and centre of breast, rest of underparts grey; iris dark brown; bill and legs glossy black (legs bright pink in breeding season). Female has upperparts brownish olive-green, underparts greyish white. Juvenile is very similar to female, but is paler above, and has a pinkish lower mandible. **Voice.** Gives "seep-seep-seep tik-tik-tik-tik", the "tik" notes like sound made by striking

together two pebbles; also "tseep-tseep-tseep". Series of "tisp-tisp" or "trik-trik" notes, sometimes developing into trill; very high-pitched, sometimes repeated, insect-like "see-ip"; high-pitched "sit-sit-sit".

Habitat. Occurs around flowering and fruiting vines and trees in forest; found in both open-canopy and closed-canopy forests.

Food and Feeding. Small fruits of forest trees, and presumably also fruit, nectar and pollen of mistletoes (Loranthaceae). Attracted to red-flowered vines and also to vines with greenish-white flowers. Spends most of its time in forest canopy. Forages singly or in small groups.

Breeding. Nesting in Jun, juveniles observed in Jun, Jul and Dec; singing male in Mar. Nest observed but details not yet documented. No other information.

Movements. Presumed sedentary.

Status and Conservation. **CRITICALLY ENDANGERED.** Restricted-range species: present in Cebu EBA. Has tiny population, and equally tiny and fragmented range in danger from deforestation. Global population estimated at 85–105 individuals, and total range c. 8 km². Occurs at four localities: Tabunan, in Central Cebu National Park; Nug-as, part of which lies in the Watershed Reserve for Alcoy and Boljo-on municipalities; Mt Lantoy, within the Argao–Dalaguete Watershed Forest Reserve; and Dalaguete. Previously recorded from Toledo and near Cebu City, but believed now extinct there. Was considered to be not uncommon in 1890s; after a single individual was collected in 1906, however, the species was for long considered extinct, until its rediscovery in 1992, at Tabunan. In addition to extensive habitat loss, interspecific competition with the more aggressive *D. australe* may be a significant problem in areas where habitat modification favours latter species.

Bibliography. Anon. (2007c), Bourns & Worcester (1894), Butchart & Stattersfield (2004), Cheke & Mann (2001), Collar (1998b), Collar, Andreev *et al.* (2001), Collar, Crosby & Stattersfield (1994), Collar, Mallari & Tabaranza (1999), Delacour & Mayr (1945), Dickinson *et al.* (1991), Dutton (1993, 1997b), Dutton *et al.* (1993), Evans *et al.* (1993), Kennedy *et al.* (2000), Magsalay (1993, 1995), Magsalay *et al.* (1995), McGregor (1909), duPont (1971b), Salomonsen (1960b), Stattersfield & Capper (2000), Timmins (1992), Worcester (1898).

19. Red-striped Flowerpecker

Dicaeum australe

French: Dicée des Philippines **German:** Rostbauch-Mistelfresser **Spanish:** Picaflor Filipino
Other common names: Red-keeled/Austral/Philippine Flowerpecker

Taxonomy. *Pipra australis* Hermann, 1783, New Guinea; error = Luzon, Philippines.

Forms a superspecies with *D. haematostictum*, and sometimes considered conspecific; *D. retrocinctum* possibly part of same superspecies, but differs in several characters. Tongue morphology of present species similar to that of *D. melanoxanthum* and *D. hypoleucum*. Geographical variation minor; birds from Cebu described as race *flaviventer*, but considered insufficiently distinct from those in rest of range to warrant recognition. Monotypic.

Distribution. Philippines (except islands from Mindoro S to Palawan, and E to Sibuyan, Panay and Negros).

Descriptive notes. 10 cm; male 9–11 g, unsexed 7.9–10.5 g. Mostly black-and-white flowerpecker with longish, stout, curved bill. Has top and side of head and upperparts black, glossed blue; chin and throat white, breast and belly grey, with scarlet stripe down middle; underwing and concealed pectoral tufts white; iris dark chestnut to dark brown; bill dark brown to black; legs greyish-brown or black. Sexes similar. Juvenile is unglossed blackish brown above to below cheek, underparts brownish olive-grey below, paler on side of throat, slightly buffy on centre of abdomen, axillaries whitish; base of upper mandible and

basal two thirds of lower mandible orange-red or brownish yellow, legs pale brown. **Voice.** Utters a high-pitched insect-like trilling "suit-sui...", and also a high-pitched rising and falling "tik-tik", becoming a trill.

Habitat. Forest and forest edge, secondary growth, coconut groves and in open country, generally around flowering and fruiting trees; below 1000 m.

Food and Feeding. No information on diet; probably includes fruit, nectar and pollen of mistletoes (Loranthaceae). Mostly in canopy. Forages singly, in pairs or in small groups; joins mixed-species flocks.

Breeding. Laying recorded in Jun and Aug, juveniles observed in Aug and birds with active gonads in Aug; fledged young observed in Apr on Mindanao and in May on Luzon. No other information available.

Movements. None recorded.

Status and Conservation. Not globally threatened. Common throughout most of range. Ability to adapt well to secondary habitats favours this species. In view of its relative abundance, this flowerpecker's ecology and biology are surprisingly poorly known.

Bibliography. Cheke & Mann (2001), Delacour & Mayr (1945), Dickinson *et al.* (1991), Eritzee (1995), Gilliard (1950a), Kennedy *et al.* (2000), Kraus (1986b), Mann (2002), McGregor (1909), duPont (1971b), duPont & Rabor (1973b), Robson & Davidson (1996), Salomonsen (1960b), Whitehead (1899), Worcester (1898).

20. Black-belted Flowerpecker

Dicaeum haematostictum

French: Dicée à poitrine noire **Spanish:** Picaflor Pechinegro

German: Schwarzgürtel-Mistelfresser

Other common names: Visayan/Guimaras/Red-keeled Flowerpecker

Taxonomy. *Dicaeum haematostictum* Sharpe, 1876, Guimaras, Philippines.

Forms a superspecies with *D. australe*, and sometimes considered conspecific; *D. retrocinctum* possibly part of same superspecies, but differs in several characters. Proposed race *whiteheadi* (described from Mt Canlaon, on Negros) considered not distinguishable from birds elsewhere in range. Monotypic.

Distribution. Panay, Guimaras and Negros, in WC Philippines.

Descriptive notes. 10 cm. Plumage above is black, glossed blue; chin and throat white, black band across upper breast, rest of breast and belly grey with broad scarlet stripe down middle; underwing and concealed pectoral tufts white; iris dark brown or black; bill dark brown to black; legs greyish-brown or black. Sexes similar. Juvenile is dark greyish-brown above and on sides of neck and cheek, grey below, with iris hazel, and proximal half of lower mandible and base of upper mandible cream; transitional plumage is blackish-brown above and down to cheek and malar region, unglossed (except for shoulder), with much less red and

black than adult on underparts, which chiefly grey, becoming slightly buffy on centre of abdomen, and with yellow base of lower mandible. **Voice.** Call "seet-seet", sometimes becoming a trill; also "chip", and rapid tinkling notes; also "chip-seet-seet" followed by short trill.

Habitat. Occurs in forest and at forest edge, also in open country, secondary growth, cultivation, coconut groves and gardens, usually around fruiting and flowering trees. Present from sea-level up to 1250 m.

Food and Feeding. Insects, spiders (Araneae); figs (*Ficus*); also fruits, flowers and possibly nectar and pollen from mistletoes (Loranthaceae). Forages singly, in pairs or in small groups; joins mixed-species flocks.

Breeding. Nests found in Mar, Aug and Sept, and juveniles observed in Aug; males with enlarged testes in Dec–Mar and May. Nest 7–11 m above ground suspended from end of branch, or in tree-fern. Clutch 1 egg, very pale greenish-white, heavily clouded lilac, profusely spotted at broader end, and with olive-brown speckles all over. No other information.

Movements. None recorded.

Status and Conservation. **VULNERABLE.** Restricted-range species: present in Negros and Panay EBA. Has small, extremely fragmented range, severely affected by clearance of lowland forest and scrub, resulting in rapid decline of population. Estimated global population 10,000–19,999 individuals and decreasing, and total range c. 24,000 km². Probably extinct on Guimaras as a result of almost complete clearance of forest. Was previously considered common in some areas, e.g. on Negros; on latter island, was abundant on Mt Talinis in secondary forest in early 1990s. On Negros, occurs in Mt Canlaon National Park, North Negros Forest Reserve (only nominally protected) and Mt Talinis and Twin Lakes area (proposed for receipt of funding for protection). On Panay, found at various sites within proposed Central Panay Mountains National Park, also in Sampunong Bolo National Park (protection only nominal).

Bibliography. Anon. (2007c), Brooks *et al.* (1992), Butchart & Stattersfield (2004), Cheke & Mann (2001), Collar, Andreev *et al.* (2001), Collar, Crosby & Stattersfield (1994), Collar, Mallari & Tabaranza (1999), Dickinson *et al.* (1991), Kennedy *et al.* (2000), Mann (2002), McGregor (1909), Ogilvie-Grant & Whitehead (1898), duPont (1971b), Salomonsen (1960b), Schönwetter & Meise (1980), Stattersfield & Capper (2000), Whitehead (1899).

21. Scarlet-collared Flowerpecker

Dicaeum retrocinctum

French: Dicée de Mindoro **German:** Mindoromistelfresser **Spanish:** Picaflor de Mindoro
Other common names: Red-collared/Mindoro Flowerpecker

Taxonomy. *Dicaeum retrocinctum* Gould, 1872, Manila and Mindanao; error = Mindoro, Philippines.

Possibly part of the superspecies formed by *D. australe* and *D. haematostictum*, but differs from those in several characters. Monotypic.

Distribution. Mindoro, Panay and Negros, in WC Philippines.

Descriptive notes. 10 cm. Black, white and red flowerpecker with rather slender and decurved bill. Most of head and upperparts, including tail, are blue-black, with scarlet collar (sometimes incomplete) on hindneck; remiges blackish-brown; chin and throat to upper breast black, red patch in centre of throat, scarlet stripe on centre of breast and belly, rest of underparts (lower breast, belly and undertail-coverts) grey-white, underwing-coverts white; iris dark red-brown; bill and legs black. Sexes similar. Juvenile undescribed; immature dark grey above, greyish-white with yellow wash below. **Voice.** Continuous sharp "tipk-tipk-tipk-tipk", like sound produced when two pebbles struck together; occasionally "tip-chik, zeet-zeet-zeet".

Habitat. Closed-canopy forest, forest edge, secondary growth, including on limestone, open country, in coconut groves and cultivation, usually around flowering or fruiting trees; sea-level to 1000 m, and once recorded in montane forest at 1200 m.

Food and Feeding. Feeds on fruit, and presumably berries, nectar and pollen of mistletoes (Loranthaceae). Visits epiphytes, figs (*Ficus*) and *Muntingia* trees. Generally found in higher storeys, often in canopy, but occasionally close to ground. Forages singly, in pairs or in small groups; joins mixed-species flocks.

Breeding. Nesting recorded in Apr; males with enlarged testes in Feb and Apr–Jun and females with active ovaries Apr–May; family parties with immatures in Sept.

Movements. None recorded.

Status and Conservation. **VULNERABLE.** Restricted-range species: present in Mindoro EBA and in Negros and Panay EBA. Small population rapidly declining, and small, severely fragmented range being reduced by forest clearance. Its decreasing population is estimated at 10,000–19,999 individuals and its total range at 9900 km². Was thought to be confined to Mindoro, but recently found farther S, on Panay and Negros. Considered common, even abundant, through much of 20th century, and still common in a few areas, but unable to persist in highly degraded habitat. On Mindoro, occurs within Mount Iglit–Baco National Park, where scattered forest patches present, and in Lake Naujan National Park, where little forest remains; smaller protected areas include the MUFRC Experimental Forest (7853 ha), in E Mindoro. Conservation funding proposed also for the Baloy/Madja-as mountain range (forming part of proposed Central Panay Mountains National Park), on Panay, and Mount Talinis and Twin Lakes area, on Negros; the species occurs also in nominally protected North Negros Forest Reserve.

Bibliography. Anon. (2007e), Butchart & Stattersfield (2004), Catibog-Sinha (1982), Cheke & Mann (2001), Collar, Andreev *et al.* (2001), Collar, Crosby & Stattersfield (1994), Collar, Mallari & Tabaranza (1999), Curio (1994), Curio *et al.* (1996), Dickinson *et al.* (1991), Dutson *et al.* (1992), Evans *et al.* (1993), Kennedy *et al.* (2000), Mann (2002), McGregor (1909), duPont (1971b), Ripley & Rabor (1958), Salomonsen (1960b), Stattersfield & Capper (2000), Whitehead (1899), Worcester (1898).

22. Orange-bellied Flowerpecker

Dicaeum trigonostigma

French: Dicée à ventre orange **Spanish:** Picaflores Ventrinaranja
German: Orangebauch-Mistelfresser

Other common names: Orange-breasted Flowerpecker (“*dorsale* subgroup”); Sulu Flowerpecker (“*sibutuense* subgroup”)

Taxonomy. *Certhia trigonostigma* Scopoli, 1786, China [i.e. Malaysia] = Malacca, Peninsular Malaysia.

Tongue morphology similar to that of *D. erythrothorax*, *D. pygmaeum*, *D. aeneum*, *D. sanguinolentum* and *D. cruentatum*, although one specimen exhibits a unique variation. Geographical variation considerable, some of it well marked. Races fall into two groups, “*dorsale* group” in Philippines and “*nominate* group” in rest of range; former can be divided into four subgroups, namely “*dorsale* subgroup” (from Luzon to W Visayan Is, excluding islands in Sibuyan Sea), “*sibuyanica* subgroup” (islands in Sibuyan Sea), “*cinereigulare* subgroup” (E Visayan Is S to Mindanao), and “*sibutuense* subgroup” (Sulu Archipelago). *Nominate* race intergrades with *rubropygium* in S peninsular Thailand. Race *cnecolaemum* doubtfully distinct from *intermedium*, and *antiopectum* possibly better subsumed in *nominate*. Other proposed races are *croceiventre* (described from Sumatra), *melanthe* (Lasia I, off NW Sumatra), *lyprum* (Nias I, off W Sumatra), *tanamassae* (Tanahmasa, in Batu Is, off W Sumatra), *pagense* (South Pagai I, off W Sumatra) and *hypochlous* (Siantan, in Anamba Is, E of Peninsular Malaysia), all synonymized with *nominate*, and *hanadori* (Siasi, in Sulu Archipelago), merged with *assimile*. Seventeen subspecies currently recognized.

Subspecies and Distribution.

D. t. rubropygium Stuart Baker, 1921 – NE India (E Assam), Bangladesh (including Sundarbans), SW, SE & S Myanmar S to S peninsular Thailand.

D. t. trigonostigma (Scopoli, 1786) – S peninsular Thailand (S from Trang) and Peninsular Malaysia, Anamba Is, Riau Archipelago, Lingga Archipelago, Sumatra and satellites (except Simeulue) and Karimata I (off SW Borneo).

D. t. antiopectum Oberholser, 1912 – Simeulue I, off NW Sumatra.

D. t. dayakanum Chasen & Kloss, 1929 – Borneo (including islands off N coast).

D. t. megastoma E. J. O. Hartert, 1918 – Natuna Is.

D. t. flaviplum E. J. O. Hartert, 1918 – Java, Bali and Krakatau.

D. t. xanthopygium Tweeddale, 1877 – Luzon, Polillo Is, Mindoro and Marinduque, in N Philippines.

D. t. dorsale Sharpe, 1876 – Panay, Masbate and Negros, in WC Philippines.

D. t. cnecolaemum Parkes, 1989 – Tablas (NC Philippines).

D. t. intermedium Bourns & Worcester, 1894 – Romblon (NC Philippines).

D. t. sibuyanica Bourns & Worcester, 1894 – Sibuyan (NC Philippines).

D. t. pallidus Bourns & Worcester, 1894 – Cebu (Nug-as), in EC Philippines.

D. t. cinereigulare Tweeddale, 1878 – Samar, Calicoan, Biliran, Leyte, Bohol and Mindanao, in E & S Philippines.

D. t. besti Steere, 1890 – Siquijor (S of Bohol).

D. t. isidroi Rand & Rabor, 1969 – Camiguin Sur (N of Mindanao).

D. t. assimile Bourns & Worcester, 1894 – C Sulu Archipelago (Jolo, Siasi, Tawi-Tawi).

D. t. sibutuense Sharpe, 1893 – SW Sulu Archipelago (Sipangkot, Omapoy, Sibutu).

Descriptive notes. 8–9 cm; male 5–7.9 g, female 5–8.7 g, unsexed 5.9–8.4 g. Male *nominate* race has head to below eye, neck, upper mantle, upperwing and tail dark slate-blue, somewhat glossed, with triangular orange patch on upper back, orange lower back and rump; lores and side of head blue-grey or slaty; throat to upper breast pale grey, rest of underparts bright orange, becoming more yellow on belly; iris chestnut or brown; bill blackish, paler on lower mandible; legs dark grey, indigo or blackish. Female is greyish to olive-brown above, with rump olive-yellow, throat, breast and flanks grey-brown, belly yellow,

becoming orange on lower belly and undertail-coverts; iris pale to dark brown. Juvenile is similar to female, but throat, breast and flanks greyish-olive, usually lacking all yellow or orange, upperparts olive-green, wings and tail black, remiges edged blue, tertials edged green, and light olive below, washed greenish on chin, centre of breast and abdomen; iris dark brown, bill bright yellow with light brown tip, legs pale slate-blue. Races differ mainly in plumage coloration and pattern, all members of “*nominate* group” having rump patch continuous in colour with back, whereas those in “*dorsale* group” have rump patch separated from back or sometimes (*besti* and *cinereigulare*) absent: *antiopectum* is very like *nominate*, but female more greenish, with less olive rump and less olive underparts; *dayakanum* is blacker above than *nominate*, with more extensive orange on back, darker grey on throat to breast, female has more greenish-tinged orange rump, yellowish-white throat, grey breast with some orange, yellow abdomen; *flaviplum* male has purer yellow rump than *nominate*, female has brighter yellow rump, is more yellow below, becoming orange on centre of breast, juvenile is browner, lacking all yellow and orange; *megastoma* differs from *nominate* in having much larger bill; *rubropygium* male is more orange below, has blackish tail, female more orange on uppertail-coverts than *nominate* and with whitish throat; *dorsale* male is less orange above than *nominate*, has dark blue rump, is more orange on breast and belly, female is yellow below, more orange on centre of breast; *pallidus* male is paler blue above than previous and uniform yellow below, with only trace of orange on breast; *xanthopygium* male has top of head and upperparts dark slaty blue, bright orange-red patch on middle of back, yellow uppertail-coverts and rump, blue-black tail, black lower face, yellow underparts, orange on centre of breast and belly, female differs from *nominate* in being olive (not grey) below; *cinereigulare* male differs from *nominate* in having small triangular orange patch on back, no yellow on rump, has greyish band across centre of yellow throat, orange breast and belly, female has yellow throat and more orange in centre of breast; *besti* male is larger than previous, and has less yellow on throat; *isidroi* male is larger than last, with chin and throat much paler yellow, lacks yellowish wash on greyish-white side of throat; *assimile* male differs from *cinereigulare* in having yellow rump, dark grey chin and throat, paler orange breast and belly; *sibutuense* male has less orange on back than *nominate*, little yellow on rump, rest of upperparts more bluish, very

dark blue-grey throat, female is much greener than *nominate*, tending to greenish-yellow on rump, with throat to breast greyer, some orange on upper breast; *sibuyanica* male differs from *nominate* in having very dark olive-green rump with no yellow, grey chin and throat, underparts more greenish-yellow (less orange), female lacks yellow on rump; *intermedium* male differs from previous in much paler grey chin and throat washed pale yellow, olive-green rump patch very small or absent, female is duller below; *cnecolaemum* male differs from last in having yellow wash on throat, deeper orange-yellow on breast, and being less blackish-blue above (but variable, differences may not be constant). Voice. Continuous shrill chirp, also “swit” or “swit-zee”, long drawn-out “zeeee”, and series 5–6 seconds long of twittering and wheezy notes; repeated rapid “chit-it-chit-it-chit”; repeated “zit-zit-zit” by male in flight or perched; prolonged buzzing “brrr-brrr”; high-pitched “zeeeeep zeeeep” with notes well spaced. Song a high-pitched rapid “sissip” series, also described as evenly rising series of rapid, very high upslurred notes, “psee-psee-psee-psee-psee...”, followed by sharp, high, metallic “ptit-ptit-ptit-ptit-ptit” and high, slightly descending “tsi-si-si-si-sew...”; other song types include slower version of last, an evenly descending series, and a 3-note version with middle note lowest.

Habitat. Various forest types, including dipterocarp, lower montane, lowland and highland heath, peat-swamp-forest, alluvial forest, paperbark (*Melaleuca*) forest and mangroves, more frequent at forest edge than in interior; also in scrub, plantations, secondary growth, cultivation and gardens; usually around flowering and fruiting trees. From sea-level to 1800 m; below 1500 m in Philippines.

Food and Feeding. Recorded foods include fruits of *Eugenia*, *Dillenia suffruticosa*, *Melastoma malabathricum*, *Muntingia calabura*, *Breynia*, mistletoes (*Loranthaceae*), figs (*Ficus*), plantains (*Musa*), mangrove trees, rubber trees and coffee bushes; also seeds of sedges (*Cyperaceae*), flowers of rubber trees, nectar, pollen; also spiders (*Araneae*) and small insects. Takes nectar from, and pollinates, a species of durian tree (*Durio*) in Borneo. Spends much time in tops of trees.

Breeding. At least Apr–May in Bangladesh, Jan–May and Jul in Peninsular Malaysia, Jul and Sept–Dec (and enlarged gonads Feb–Apr, Jun and Aug) in N Borneo (Sabah), Feb–May, Oct and Dec in W Java, and Feb, Apr and Jun–Aug in Philippines; laying in Jul in Sumatra and in Mar in NW Borneo (Sarawak); juveniles in Jan, Mar and May–Sept in Peninsular Malaysia and in Aug in Riau Archipelago; fledglings in May in Philippines. Nest the size and shape of a goose (*Anser*) egg, or pocket-shaped and felt-like, with side entrance, made from lichen, fine green moss, clubmoss (*Lycopodiaceae*), ferns, *Imperata* pappus, plant fibres, rootlets and spider webs, lined with white fibres, down from fern fronds and small feathers, decorated on outside with caterpillar frass and plant material, and suspended by small end 1.5–13 m above ground from slender twig. Clutch 2–3 eggs, bluish-white, finely speckled brown, with larger dark brown spots at broader end, or pure white; no information on incubation and nestling periods.

Movements. Few data. Ringing recoveries at Gombak Valley (Selangor), in Peninsular Malaysia, imply some mobility.

Status and Conservation. Not globally threatened. Locally common in Bangladesh; rare in Myanmar outside S Tenasserim; common and widespread in Malay Peninsula; common in Borneo; generally common in Philippines, except on Cebu and Tawi-Tawi. Possibly present in NE India, where one report from Arunachal Pradesh. Previously occurred in extreme S Vietnam. Race *pallidus*, confined to Cebu (Philippines), was thought extinct, but recently rediscovered; nevertheless, is probably close to extinction. Race *assimile* probably now extinct on Tawi-Tawi, but survives on two other small islands in C Sulu Archipelago. Species occurs in many protected areas, e.g. Khao Pra Bang Wildlife Sanctuary, in Thailand, Way Kambas National Park, in Sumatra, Kinabalu Park, in Borneo, and Rajah Sikatuna National Park, in Philippines.

Bibliography. 23. Buzzing Flowerpecker

Dicaeum hypoleucum

French: Dicée à ventre blanc **German:** Weißbauch-Mistelfresser **Spanish:** Picaflores Zumbador
Other common names: White-bellied Flowerpecker

Taxonomy. *Dicaeum hypoleucum* Sharpe, 1876, Basilan, Philippines.

Tongue morphology similar to that of *D. melanoxanthum* and *D. australe*. Variation between some races quite well marked, and this species could perhaps be split into two or even three species. Proposed race *lagunae*, from Pangil (Laguna Province), in SC Luzon, insufficiently distinct from *obscurum* to warrant recognition. Five subspecies recognized.

Subspecies and Distribution.

D. h. obscurum Ogilvie-Grant, 1894 – NW, C & S Luzon and Catanduanes, in N Philippines.

D. h. cagayanense Rand & Rabor, 1967 – Sierra Madre Mts (including Mt Cagua), in NE Luzon.

D. h. pontifex Mayr, 1946 – Samar, Biliran, Leyte, Panaon, Bohol, Dinagat, and Mindanao (except Zamboanga Peninsula), in EC & S Philippines.

D. h. mindanense Tweeddale, 1877 – Zamboanga Peninsula, in W Mindanao.

D. h. hypoleucum Sharpe, 1876 – Sulu Archipelago (Malamaui, Basilan, Jolo, Siasi, Tawi-Tawi, Bongao, Sanga Sanga and Manuk Manka).

Descriptive notes. 8–9 cm; 6.9–9.6 g. A simple-patterned flowerpecker with long, thin, slightly decurved bill. Male *nominate* race has top and side of head, upperparts, including tail and primaries, blackish-brown, throat white, underparts greyish-white; axillaries and underwing-coverts white; iris brown to reddish-brown; bill dark horn to black, sometimes paler at base; legs dark brown, greyish or black. Female is generally dark olivaceous above. Juvenile is dark olive-grey above, grey with greenish-yellow tinge below, bill paler. Races differ mainly in tone of plumage above: *obscurum* has olive-brown upperparts, with tail and primaries dark brown edged olive, underparts grey washed olive, with paler, yellow line down centre of abdomen and on undertail-coverts, sexes alike; *cagayanense* is similar to previous, but underparts more yellow; *pontifex* is dark greenish brown above, sexes alike; *mindanense* is fuliginous olive-green above, with olive-green edging on tail and primaries, greyish-white below, brightest on breast, sexes alike. Voice. High-pitched buzzing “bzeeeppp”, singly or as long series, and sometimes followed by rapid trilled “cheenjet”; very metallic “chimp chimp”, finally running into a trill.

Habitat. Forest, forest edge, cultivation and scrub, around flowering and fruiting trees, particularly figs (*Ficus*); from sea-level up to 1500 m, but up to 1800 m in NC Mindanao (Kitanglad range).

Food and Feeding. Known to eat fig fruits; probably also fruit, nectar and pollen of mistletoes (Loranthaceae), and probably also insects. Occurs in all storeys; hovers at flowers on outer branches. Forages singly, in pairs or in small groups; joins mixed-species flocks.

Breeding. Birds with active gonads in Jan, Mar–Jun, Aug and Sept. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Common throughout most of range.

Bibliography. Cheke & Mann (2001), Delacour & Mayr (1945), Dickinson *et al.* (1991), Kennedy *et al.* (2000), McGregor (1909), Mendoza (1987), Ogilvie-Grant (1894), Parkes (1962, 1971), duPont (1971b), Salomonsen (1960c), Worcester (1898).

24. Pale-billed Flowerpecker

Dicaeum erythrorhynchos

French: Dicée à bec rouge

German: Lachsschnabel-Mistelfresser

Spanish: Picaflor Piquirrojo

Other common name: Tickell's/Small Flowerpecker; Ceylon Small Flowerpecker (*ceylonense*)

Taxonomy. *Certhia erythrorhynchos* Latham, 1790, Bombay, India.

Two subspecies recognized.

Subspecies and Distribution.

D. e. erythrorhynchos (Latham, 1790) – India, S Nepal, W Bhutan, Bangladesh and W & C Myanmar.

D. e. ceylonense Babault, 1920 – Sri Lanka.

Descriptive notes. 8 cm; 4–8 g. Plain-looking flowerpecker with markedly downcurved pale bill. Nominative race is plain greyish-brown or olive-brown above, remiges dark brown with pale edging, rectrices dark brown with pale tips; lores and side of face paler; sandy grey to greyish-white below, sometimes tinged greyish-brown on sides of breast, and often more buffy on belly and flanks, whitish underwing-coverts; iris hazel-brown; bill pale horn-brown, pinkish-flesh at gape and on lower mandible except tip, mouth pale pink; legs dark slate-coloured. Sexes similar. Juvenile is greyer above and below than adult, with shorter bill

orange-yellow at gape and on lower mandible (except tip). Race *ceylonense* is smaller, darker, more olive above and below, than nominate, with bill plumbeous-brown, or silvery or pinkish with dark culmen, lower mandible dark brown, and iris yellowish-brown. Voice. High-pitched, repeated “pit”, and incessant sharp “chik-chik-chik”. Two songs recorded: one a series of twittering notes; the other an orthopteran-like reel said to be either a rather slow even-tempo reel or starting much faster but abruptly becoming a slow trill at mid-point.

Habitat. Deciduous forest, mangroves, cultivation, plantations and orchards, and fig trees (*Ficus*) in open country; particularly near mistletoes (Loranthaceae) in canopy. To 1400 m in Nepal (in summer), and to 2100 m in Sri Lanka.

Food and Feeding. Mainly fruits of mistletoes; also nectar, spiders (Araneae) and small insects. Forages mostly in canopy. Forages singly and in pairs; also in groups in non-breeding season. May join mixed-species feeding flocks in Sri Lanka.

Breeding. Egg-laying in Jan–Jun in N India and Nepal and Feb–May, Aug and Sept in S India; Jan–Jul (peak in Mar), Sept and Nov in Sri Lanka. Nest-building, care of young, and probably incubation, by both sexes. Nest a small pinkish-brown, felted, oval purse of fine grass, vegetable down, bark, moss, cocoons and caterpillar frass, lined with soft, silky down and fibres, decorated with berries, lichen and flat white material resembling shed reptile skin, suspended from twig among leaves 1.5–12 m above ground, sometimes secured to supporting branch at back and often well concealed by surrounding foliage, or may be supported at each end by twigs in hammock-like fashion. Clutch 1–3 eggs, usually unmarked white, but in Sri Lanka may be spotted; no information on duration of incubation and nestling periods.

Movements. Seasonal altitudinal movements in Himalayas.

Status and Conservation. Not globally threatened. Widespread and locally abundant in India; widespread and frequent in Nepal; common in Bangladesh; common at all altitudes in Sri Lanka; not uncommon in Myanmar. Occurs in several protected areas, e.g. Nagarhole National Park, in India, and Chitwan National Park, in Nepal.

Bibliography. Ali (1932, 1969), Ali & Ripley (1974), Cheke & Mann (2001), Fleming *et al.* (1976), Grimmett *et al.* (1998), Inskipp & Inskipp (1991), Kotagama & Goodale (2004), Rasmussen & Anderton (2005b), Ripley (1982), Robson (2000b), Salomonsen (1960c), Smythies (1986), Stuart Baker (1926), Wait (1931), Whistler & Kinnear (1949).

25. Plain Flowerpecker

Dicaeum concolor

French: Dicée concolore

German: Einfarb-Mistelfresser

Spanish: Picaflor Sencillo

Other common names: Plain-coloured Flowerpecker; Olivaceous Flowerpecker (“*minullum* group”); Nilgiri Flowerpecker (*concolor*); Andaman Flowerpecker (*virescens*)

Taxonomy. *Dicaeum concolor* Jerdon, 1840, Malabar Coast, India.

Nominative race and *virescens* sometimes treated as two distinct species, with remaining races (“*minullum* group”) as a third species, on basis of markedly distinct morphological and, apparently, vocal differences. Geographical variation, however, generally rather subtle; *uchidai* could perhaps be included in *olivaceum*. Other proposed races are *subflavum* (described from Karnataka, in SW India) and *unicolor* (Palni Hills, in S India), both treated as synonyms of nominate, and *inornatum* (Nepal) and *sinense* (foothills of Omei Shan, Sichuan, in S China), both subsumed within *olivaceum*. Seven subspecies currently recognized.

Subspecies and Distribution.

D. c. concolor Jerdon, 1840 – SW India (in Western Ghats).

D. c. olivaceum Walden, 1875 – Himalayan foothills from C Nepal E to NE India (Arunachal Pradesh, S to Assam, Nagaland and Manipur), E Bangladesh (Chittagongs), Myanmar, S China (Sichuan S to SE Xizang, Yunnan and Guangdong), Thailand and Indochina.

D. c. virescens Hume, 1873 – Andaman Is (Middle and South).

D. c. borneanum Lönnerberg, 1925 – Peninsula Malaysia (S from N Perlis and Penang), Sumatra, N Natuna Is and Borneo.

D. c. minullum Swinhoe, 1870 – Hainan Is.

D. c. uchidai Nagamichi Kuroda, 1920 – Taiwan.

D. c. sollicitans E. J. O. Hartert, 1901 – Java (including Madura) and Bali.

Descriptive notes. 7.5–9 cm; 4–8 g. Nominative race is greyish olive-brown above, more olive on rump, with dark centres of crown feathers, pale forehead, lores and supercilium; wings and tail darker; yellowish-white below, axillaries white; iris brown to dark brown; bill black-tipped bluish-grey or black, dark horn-brown on culmen; legs brownish-black or plumbeous. Sexes similar. Juvenile is browner, duller and less olive than adult, with underparts more ashy, also lacks dark feather centres on crown; part of lower mandible yellowish, or bases of both mandibles pale. Races vary mainly in tone of plumage: *olivaceum* is

slightly more olive-green above than nominate, has duller, ashier underparts with buffy yellow tinge; *uchidai* is similar to previous but slightly darker, and tail shorter; *minullum* is slightly smaller and smaller-billed than nominate, also slightly greener above, with less white on supercilium, brownish on head, back and scapulars, yellow on rump, tail tipped white, throat and belly dusky yellow, vent yellow; *borneanum* is green above, brighter on rump, with throat to breast grey, centre of belly buffish-white, flanks yellowish-green; *sollicitans* is similar to nominate but greener above, brighter on rump, and differs from *olivaceum* in having larger, more distinct buff patch on lores; *virescens* is much greener above than others, has speckled crown, pale lores but no white on forehead, almost no supercilium, and has glossy black tail, yellow belly and vent. Voice. Calls “tik-tik-tik” or “chirp-chirp-chirp”, sharp “chek”, very short staccato ticking “chrik”, various twittering calls; also short, piercing high-pitched “zink!” and shrill, hard, emphatic “tzit!, tzit!...”. Song a high-pitched trill; other songs described as very high, thin “tsit-tsit-tsit-si-si-si-si” repeated every few seconds (Laos), very high, thin, short “tseep-tsip-tsip-tsip” trill, and very short, strongly descending “tse-e’e’ep” trill (SW India), extremely high musical “sit-sew, sit-sew, sit-sew...”, and buzzier, very short notes mixed with calls (Andamans).

Habitat. Various forest types, including evergreen, moist deciduous, submontane heath and montane forests, chiefly at edge; also secondary growth, plantations and other cultivation, groves of trees in open country, and trees around habitation; appears to be dependent on mistletoes (Loranthaceae), and often around flowering and fruiting vines. From sea-level to 3660 m.

Food and Feeding. Insects, spiders (Araneae), figs (*Ficus*); in particular, fruits and nectar of mistletoes, especially those of small-flowered *Scurrula* species (e.g. *Scurrula rhododendricolus*). Forages in all storeys, but most frequently in canopy. Occurs singly, sometimes in pairs or in small groups.

Breeding. Egg-laying in Mar–Sept in Nepal and NE India, Jan–May and Sept in S India, and chiefly May–Jun in Andamans (breeding condition in Mar); laying in Mar and males with enlarged testes Jun and Jul in N Borneo (Sabah); nestlings in late Mar and fledglings early Aug in Malay Peninsula, and juveniles in Jun in Taiwan. Both sexes build nest, incubate eggs, tend nestlings and care for young. Nest a very small hanging purse, 70 × 50 mm, made chiefly of floss of *Bombax malabarica*, and other fibres and vegetable down, 6–12 m above ground in tree or tall bush, sometimes much lower among nettles and briars. Clutch 2–3 eggs, usually unmarked white, but those from Sabah (Borneo) pale orange-pink, thickly flecked with burnt sienna at broad end, and finely and sparsely spotted chestnut; food delivered to chicks by adults every 2–5 minutes; no information on duration of incubation and nestling periods.

Movements. Probably seasonal altitudinal movements in higher parts of range. Vagrant in Hong Kong (SE China).

Status and Conservation. Not globally threatened. Local to common in Indian Subcontinent; widely but sparsely distributed in Myanmar, but common on coastal islands of Arakan; common in many parts of Thailand; uncommon to common in Malay Peninsula; very uncommon on Borneo; not rare on Java. Considered to be, at best, “near-threatened” in Peninsular Malaysia. Occurs in several protected areas, e.g. Mudumalai National Park, in SW India, Dibru-Saikhowa National Park, in NE India, Khao Yai National Park, in Thailand, and Cuc Phuong National Park, in Vietnam.

Bibliography. Ali (1969), Ali & Ripley (1974), Atyeo (1971), Cheke & Mann (2001), Cooper (1991), Davidar (1985a), Grimmett *et al.* (1998), Hellebrekers & Hoogerwerf (1967), Hoogerwerf (1949), Inskipp & Inskipp (1991), King *et al.* (1975), Lim Hsing-yu (1995), MacKinnon & Phillips (1993), Mann (2008), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Pfeiffer (1961), Rasmussen & Anderton (2005b), Ripley (1982), Robson (2000b), Salomonsen (1960c), Sheldon *et al.* (2001), Smythies (1957, 1960), Smythies & Cranbrook (1981), Smythies & Davison (1999), Wells (2007).

26. Pygmy Flowerpecker

Dicaeum pygmaeum

French: Dicée pygmée

German: Zwergmistelfresser

Spanish: Picaflor Pigmeo

Other common names: Palawan Flowerpecker

Taxonomy. *Nectarinia pygmaea* Kittlitz, 1835, Manila, Luzon, Philippines.

Tongue morphology similar to that of *D. trigonostigma*, *D. erythrorhox*, *D. aeneum*, *D. sanguinolentum* and *D. cruentatum*. Original description contained spellings “*pygmaea*” and “*pygmea*”; former adopted by same author acting as First Reviser in 1858. Five subspecies recognized.

Subspecies and Distribution.

D. p. fugaense Parkes, 1988 – Calayan and Fuga (N of Luzon), in extreme N Philippines.

D. p. salomonseni Parkes, 1962 – NW Luzon, in N Philippines.

D. p. pygmaeum (Kittlitz, 1835) – NC & C Philippines (C and S Luzon, Corregidor, Lubang, Poilolo Is, Mindoro, Marinduque, Maestre de Campo, Semirara, Sibay, Boracay, Romblon, Sibuyan, Ticao, Masbate, Samar, Gigantes, Calagna-an, Sicogon, Guimaras, Negros, Cebu, Bohol, Siquijor, Leyte).

D. p. palawanorum Hachisuka, 1926 – Calauit, Culion, Palawan and Balabac, in W Philippines.
D. p. davao Mearns, 1905 – Camiguin Sur and Mindanao, in S Philippines.

Descriptive notes. 8.4 cm; 4.5–5.6 g. Rather plain-looking flowerpecker with relatively short, thin bill. Male nominate race has top of head, back, upperwing and tail olive-black, glossed green, rump dull olive-yellow, upper-tail-coverts dull olive-green; chin, centre of throat and pectoral tufts white, face, side of throat and flanks grey becoming olive-yellow towards rear, rest of underparts buffy white, mottled grey; iris dark brown; bill black to dark horn; legs brownish-black. Female has head grey, often tinged olive, mantle and back olive, lores, anterior supercilium and narrow eyering pale olive to buff-white, face drab grey; underparts drab grey variably tinged olive-yellow, most markedly so on flanks, white pectoral tufts, whitish chin, throat and median line down centre of abdomen to undertail-coverts. Juvenile is greyer than female, and has greenish rump. Races vary mostly in colour of dorsal gloss, and rump colour of male: *palawanorum* male has gloss more blue-green and confined to shoulders, is generally slightly

lighter above than nominate and with duller olive-yellow rump and paler underparts; *davao* differs from nominate in having greenish-blue gloss above, darker face and sides of throat and breast, more yellow belly and undertail-coverts; *fugaense* is much blacker above, with more restricted greenish rump, greyish flanks, female and immature male have greyer flanks and much smaller greenish rump patch than nominate; *salomonseni* is larger and slightly paler than nominate, and has duller olive-yellow rump. Voice. Loud, sharp, almost continuous, irregularly spaced “tip tip...” during foraging; also high “schenk-schenk...”; and double notes “zip-zip...zip-zip...zip-zip”.

Habitat. Forest, forest edge and secondary growth, around flowering and fruiting trees, and *Loranthus* mistletoes; usually below 1000 m, but to over 2000 m on Luzon.

Food and Feeding. *Loranthus* mistletoes, and probably eats fruit, nectar and pollen of other mistletoes. Forages in canopy, or high in understorey. Forages singly or in small groups; joins mixed-species flocks.

Breeding. Dependent fledgling in May, and birds with active gonads in Feb, Apr, Jul and Dec. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Common through most of its range, which covers most islands of Philippines.

Bibliography. Allen *et al.* (2006), Cheke & Mann (2001), Delacour & Mayr (1945), Dickinson *et al.* (1991), Gilliard (1950a), Kennedy *et al.* (2000), McGregor (1909), Ogilvie-Grant (1894), Parkes (1962), duPont (1971b), Salomonsen (1960c), Worcester (1898), Worcester & Bourns (1898).

27. Crimson-crowned Flowerpecker

Dicaeum nehrkorni

French: Dicée à tête rouge **German:** Nehrkorntistelfresser **Spanish:** Picaflor de Nehrkor
Other common names: Celebes/Crimson-crested/Nehrkor's/Red-headed Flowerpecker

Taxonomy. *Dicaeum nehrkorni* A. W. H. Blasius, 1886, Rurukan, northern Sulawesi.
Forms a superspecies with *D. erythrothorax*, *D. vulneratum*, *D. pectorale*, *D. geelvinkianum*, *D. nitidum*, *D. eximium* and *D. aeneum*. Monotypic.
Distribution. Mountains of Sulawesi.

Descriptive notes. 8.5 cm. Male has crown and rump bright crimson, forehead and supercilium to hindneck and rest of upperparts glossy blue-black; throat, breast and flanks grey, small crimson spot on breast, white pectoral tufts, abdomen white with blackish-brown median line; iris dark; bill dark brown to black; legs blackish. Female is duller than male, with little or no red on crown; also lacks the breast spot and the abdominal stripe. Juvenile is similar to female, but has no red on rump. Voice. A short, sharp double note, "zit-zit", and a repeated hard "tit"; also a high-pitched insect-like trill.

Habitat. Hill and montane forest, and forest edge; 200–2400 m.

Food and Feeding. Wild cherries (*Prunus*) and other fruits, including berries and perhaps also nectar and pollen of mistletoes (Loranthaceae). Occurs mostly in canopy. Forages singly or in pairs; joins mixed-species flocks.

Breeding. No information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Restricted-range species: present in Sulawesi EBA. Widespread but generally uncommon; commoner at higher altitudes. Occurs in several protected areas, including Lore Lindu National Park.

Bibliography. Blasius (1897), Bostock & Sujatika (1993), Cheke & Mann (2001), Coates & Bishop (1997), Coomans de Ruiter (1950), Holmes & Philipps (1996), Meyer & Wigglesworth (1989a, 1989b), Riley (1924), Rozendaal & Dekker (1989), Salomonsen (1960c), Stresemann & Heinrich (1940b), Watling (1983), White & Bruce (1986).

28. Flame-breasted Flowerpecker

Dicaeum erythrothorax

French: Dicée à gorge blanche **German:** Burumistelfresser **Spanish:** Picaflor Pechirrojo
Other common names: Flame-chested/White-throated/Buru/Indonesian Flowerpecker

Taxonomy. *Dicaeum erythrothorax* Lesson and Garnot, 1828, Buru, southern Moluccas.
Forms a superspecies with *D. nehrkorni*, *D. vulneratum*, *D. pectorale*, *D. geelvinkianum*, *D. nitidum*, *D. eximium* and *D. aeneum*. Tongue morphology similar to that of *D. trigonostigma*, *D. pygmaeum*, *D. aeneum*, *D. sanguinolentum* and *D. cruentatum*. Two subspecies recognized.

Subspecies and Distribution.

D. e. schistaceiceps G. R. Gray, 1861 – Morotai, Halmahera, Bacan, Bisa and Obi.

D. e. erythrothorax Lesson & Garnot, 1828 – Buru.

Descriptive notes. 9 cm. Male nominate race has head grey, glossed green, throat white; upperparts olive, rump yellowish-green, upperwing-coverts and remiges dark brown with broad olive edging; breast grey, orange-red patch in centre, flanks olive-yellow, middle of abdomen whitish-yellow; iris brown; bill and legs black. Female is similar to male but lacks red. Juvenile is similar to female, but less green on rump, greyer below, less olive on flanks. Race *schistaceiceps* has a more golden rump than nominate, lacks olive edging on wing-coverts, has grey throat and olive-green flanks. Voice. Single, repeated, high note,

"tcheep tcheep tcheep".

Habitat. Inhabits forest, scrub and riverine areas; in lowlands, generally up to 800 m, but to 950 m on Bacan.

Food and Feeding. No information; diet probably includes fruit, and perhaps also nectar and pollen of mistletoes (Loranthaceae). Forages in canopy. Occurs in pairs or in small groups; joins mixed-species flocks.

Breeding. Laying: Oct or Nov, and nestling found in Nov. Nest an unlined oval pouch, 90 × 55 mm, entrance just above centre, made of plant fibres and dried grass, giving felted appearance, suspended by broad attachment from twig, partly concealed by large leaves. Clutch 2 eggs. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Restricted-range species: present in Buru EBA and in Northern Maluku EBA. Common to uncommon on Halmahera; common on Buru.

Bibliography. Bishop (1992), Cheke & Mann (2001), Coates & Bishop (1997), Jepson (1993a), Salomonsen (1960c), Schönwetter & Meise (1980), Siebers (1930), White & Bruce (1986).

29. Ashy Flowerpecker

Dicaeum vulneratum

French: Dicée cendré **German:** Seranmistelfresser **Spanish:** Picaflor Cenizo
Other common names: Ashy-fronted/Ceram/Moluccan Flowerpecker

Taxonomy. *Dicaeum vulneratum* Wallace, 1863, Seram, Moluccas.

Forms a superspecies with *D. nehrkorni*, *D. erythrothorax*, *D. pectorale*, *D. geelvinkianum*, *D. nitidum*, *D. eximium* and *D. aeneum*. Monotypic.

Distribution. Seram, Ambon, Saparua and Seram Laut (Gorong and Manawoka).

Descriptive notes. 8–8.5 cm. Male is dark brownish-grey above, with scarlet rump; face ashy brown, underparts ashy grey with large scarlet patch in centre of upper breast, white vent and undertail-coverts; iris brown; bill and legs black. Female is similar to male but lacks red on chest, has white throat and centre of breast and abdomen. Juvenile resembles female, but rump yellowish-green, not red. Voice. A hard, staccato "tst", given while perched and also in flight. Song consists of 3 high-pitched metallic, disyllabic notes (Seram), or thin, very high-pitched trisyllabic notes (Ambon).

Habitat. Hill and coastal forest, old gardens, and at forest and plantation edges; sea-level to 2100 m, mainly below 1000 m.

Food and Feeding. Only nectar recorded, but diet thought also to include fruits and pollen of mistletoes (Loranthaceae). Forages in tops of trees and lower, in shrubs. Occurs singly and in pairs; joins mixed-species flocks.

Breeding. Nest globular, 100 × 55 mm, entrance hole closer to top and 50 mm from bottom, made from plant fibres and decorated with a few leaves, attached by suspensor of same material. No further information.

Movements. Nothing recorded.

Status and Conservation. Not globally threatened. Restricted-range species: present in Banda Sea Islands EBA and in Seram EBA. Common; more abundant in hills.

Bibliography. Bowler & Taylor (1989a), Cheke & Mann (2001), Coates & Bishop (1997), Robson (1988), Salomonsen (1960c), White & Bruce (1986).

30. Olive-crowned Flowerpecker

Dicaeum pectorale

French: Dicée à plastron **German:** Papuamistelfresser **Spanish:** Picaflor Pectoral
Other common names: Pectoral/Shining/Papuan Flowerpecker

Taxonomy. *Dicaeum pectorale* S. Müller, 1843, Lobo, Triton Bay, New Guinea.
Forms a superspecies with *D. nehrkorni*, *D. erythrothorax*, *D. vulneratum*, *D. geelvinkianum*, *D. nitidum*, *D. eximium* and *D. aeneum*. Could perhaps be considered conspecific with *D. geelvinkianum* and/or *D. nitidum*. Race *ignotum*, although geographically situated between nominate race and *D. erythrothorax*, is not intermediate in plumage, suggesting that treatment of latter and present species as two distinct species is appropriate. Two subspecies recognized.

Subspecies and Distribution.

D. p. ignotum Mees, 1964 – Gebe I, between Halmahera and NW New Guinea.

D. p. pectorale S. Müller, 1843 – West Papuan Is (Waigeo, Batanta, Salawati, Misool) and NW New Guinea (E to neck of Vogelkop).

Descriptive notes. 9 cm; 7–7.8 g. Male nominate race has crown and upperparts olive, yellowish on rump; side of head greyer, throat white; large scarlet patch on breast, yellowish or whitish centre of abdomen and undertail-coverts, rest of underparts grey; iris brown; bill and legs dark brown or black. Female differs from male in having no red on breast, centre of abdomen and undertail-coverts yellowish. Juvenile is similar to adult female, but more olive, less grey, below. Race *ignotum* is more olive above than nominate, paler, less yellowish, on centre of belly and undertail-coverts, and has slightly larger wing and bill. Voice.

Short, dry, insect-like, buzzing note; single high, upslurred note; also single drawn-out "chew", repeated at short intervals.

Habitat. Occurs in forest canopy, and in secondary growth; sea-level to 1500 m, rarely to 2350 m.

Food and Feeding. Unprotected fruits, including figs (*Ficus*) and presumably those of mistletoes (Loranthaceae); also spiders (Araneae). Forages in canopy, singly or in pairs.

Breeding. No information.

Movements. No information.

Status and Conservation. Not globally threatened. Restricted-range species: present in West Papuan Lowlands EBA. Not uncommon. Very poorly known species.

Bibliography. Bechler *et al.* (1986), Brown & Hopkins (2002), Cheke & Mann (2001), Diamond (1972a), Greenway (1966), Iredale (1956), LeCroy (2000), Mees (1964a), Mitchell (1996), Rand & Gilliard (1967), Salomonsen (1960c).

31. Red-capped Flowerpecker

Dicaeum geelvinkianum

French: Dicée de Geelvink **German:** Rotkappen-Mistelfresser **Spanish:** Picaflor Capirrojo
Other common names: Geelvink/Papuan Flowerpecker

Taxonomy. *Dicaeum geelvinkianum* A. B. Meyer, 1874, Yapen Island, Geelvink Bay, New Guinea.
Forms a superspecies with *D. nehrkorni*, *D. erythrothorax*, *D. vulneratum*, *D. pectorale*, *D. nitidum*, *D. eximium* and *D. aeneum*. Could perhaps be treated as conspecific with *D. pectorale* and/or *D. nitidum*. Other proposed races include *simillimum* (described from Hollandia, on N New Guinea coast) included in *diversum*, *jobiense* (Yapen I) merged into nominate, and *pulchrum* (Astrolabe Mts, in SE), merged with *rubrocoronatum*. Eleven subspecies recognized.

Subspecies and Distribution.

D. g. majorensis Salvadori, 1876 – Numfor I (Geelvink Bay), in NW New Guinea.
D. g. misoriensis Salvadori, 1876 – Biak I (Geelvink Bay).
D. g. geelvinkianum A. B. Meyer, 1874 – Yapen I and Kurudu I (Geelvink Bay).
D. g. diversum Rothschild & E. J. O. Hartert, 1903 – N New Guinea (Mamberano R to Humboldt Bay).
D. g. setekwa Rand, 1941 – SW New Guinea (S slopes of Snow Mts E to Noord R).
D. g. obscurifrons Junge, 1952 – WC New Guinea (Wissel L. to NE of Etna Bay).
D. g. centrale Rand, 1941 – WC New Guinea (Balim R Valley in Nassau Mts and Oranje Mts).
D. g. rubrigularis D'Alberty & Salvadori, 1879 – S New Guinea (Palmer Junction to mouth of Fly R).
D. g. albobunctatum D'Alberty & Salvadori, 1879 – lowlands of SC New Guinea (Merauke and Dagul R E to Daru I and Orioma R).
D. g. rubrocoronatum Sharpe, 1876 – SE New Guinea (W to upper Sepik R and Purari R, including Karkar I and Manam I).
D. g. violaceum Mayr, 1936 – D'Entrecasteaux Archipelago (Fergusson, Goodenough, Dobu), off SE New Guinea.

Descriptive notes. 9 cm; 5.3–7.5 g. Male nominate race has bright red crown, rump and uppertail-coverts, rest of upperparts very dark greenish, upperwing and tail dark brown, shoulder darker with slight bluish gloss; throat white; red patch on chest, rest of underparts olive-grey, pectoral tufts white, centre of belly yellowish-buff, vent and undertail-coverts yellowish; iris brown; bill and legs blackish. Female is similar to male, but lacks red on chest, is paler on belly. Juvenile is similar to female, but little or no red above, bill mostly pale. Races differ mainly in shade of red on dorsal surface, and extent of red below on male (following details refer to male unless otherwise stated): *rubrocoronatum* has vermilion crown and rump, rest of upperparts blackish, glossed purple and blue, with dark olive lower back, is more yellow below than nominate, has very small red pectoral patch, female slightly glossed blue on dark greenish-brown upperparts; *rubrigularis* differs from previous in having foreneck entirely red; *albobunctatum* differs from last in having white areas between red tip and dusky base of feathers of head, rump and uppertail-coverts, and red pectoral patch extends over chin, throat and side of breast; *setekwa* is very dark olive-green above, with vent and undertail-coverts white or pink; *majorensis* differs from previous in having dull dark red crown, rump and uppertail-coverts, and yellowish vent and undertail-coverts; *misoriensis* has much less red on breast than previous, and is duller above, with bright carmine rump; *diversum* has lighter, more scarlet, crown and uppertail-coverts than *rubrocoronatum*, is more steel-blue on upper surface (which has more of an olive tinge); *centrale* is larger than preceding race, slightly darker above, has more greyish breast and lighter flanks; *obscurifrons* is similar in size to last, but is greener on upperparts, darker below, and red on head and uppertail-coverts duller, more brownish-tinged; *violaceum* is similar to *rubrocoronatum*, but duller and lighter above, with purple-violet gloss, and red of crown, rump and breast darker, underparts more grey, with greyish-olive abdomen. Voice. Single buzzing note, a downslurred “bszzt”.

Habitat. Forest canopy and edge, particularly around flowering and fruiting trees, also secondary growth, dense savanna, plantations and gardens. From sea-level to 1500 m, rarely to 2350 m; race *centrale* above 1600 m.

Food and Feeding. Fruits, and possibly nectar and pollen, of mistletoes (Loranthaceae), and probably of other plants; large seeds also taken; also spiders (Araneae). Forages in canopy and upper levels.

Breeding. Laying recorded in Mar, Nov and Dec. Nest pear-shaped, c. 100 mm long and 45 mm across, with side entrance 17 mm wide near top, made from grey animal silk and reddish-brown strips from ferns, felted and well camouflaged; one recorded as suspended from short, slender *Croton* tree. Clutch 2–3 eggs, white. No other information.

Movements. Few data; mainly resident. Recorded several times from islands of Saibai and Boigu, in N Torres Strait, suggesting possible regular dispersal from New Guinea mainland or a resident population on islands.

Status and Conservation. Not globally threatened. Common at lower altitudes in much of New Guinea. Possibly a small resident population on Saibai I, in N Torres Strait; adult female with recently fledged juvenile recorded on island in Feb 2002.

Bibliography. Beehler (1978a), Beehler *et al.* (1986), Cheke & Mann (2001), Diamond (1972a), Gilliard & LeCroy (1967a, 1968), Lansley (2004), Mayr (1936), Mayr & Gilliard (1954), Higgins *et al.* (2006), Rand (1936b, 1938, 1941), Rand & Gilliard (1967), Rothschild & Hartert (1896b), Salomonsen (1960c), Schönwetter & Meise (1980), Sharpe (1885).

32. Louisiade Flowerpecker*Dicaeum nitidum*

French: Dicée des Louisiade **Spanish:** Picaflores de las Luisiade

German: Louisiadenmistelfresser

Other common names: Papuan Flowerpecker

Taxonomy. *Dicaeum nitidum* Tristram, 1889, Sudest (= Tagula) Island, Louisiade Archipelago, New Guinea.

Forms a superspecies with *D. nehrkorni*, *D. erythrothorax*, *D. vulneratum*, *D. pectorale*, *D. geelvinkianum*, *D. eximium* and *D. aeneum*. Could perhaps be considered conspecific with *D. pectorale* and/or *D. geelvinkianum*. Two subspecies recognized.

**Subspecies and Distribution.**

D. n. nitidum Tristram, 1889 – Louisiade Archipelago (Misima I, Tagula I), off SE New Guinea.

D. n. rosseli Rothschild & E. J. O. Hartert, 1914 – Rossel I, in E Louisiades.

Descriptive notes. 9 cm. Male nominate race has dull red cap, brighter red rump, rest of upperparts dark brownish-grey, glossed blue and green (particularly on mantle and upperwing-coverts); remiges blackish-brown, edged greenish, tail glossy blackish; side of head greyish; chin and throat whitish, bright red patch on breast, rest of underparts yellowish-

olive, paler on central belly and undertail-coverts, pectoral tufts white; iris brown; bill black, base of lower mandible whitish; legs black. Female differs from male in lacking red breast patch. Juvenile differs from adult female in lacking red on upperparts. Race *rosseli* male has shoulders glossed blue-green, and is more dark olive-green, less blackish-looking, above than nominate. Voice. Short, dry, buzzing insect-like note; single high-pitched upslurred note.

Habitat. Forest and secondary growth.

Food and Feeding. Fruits, presumably including those of mistletoes (Loranthaceae), and spiders (Araneae). Forages in canopy, singly or in pairs.

Breeding. No information.

Movements. No information.

Status and Conservation. Not globally threatened. Restricted-range species: present in Louisiade Archipelago EBA. Very poorly known species. Appears not to be at any risk.

Bibliography. Beehler *et al.* (1986), Cheke & Mann (2001), Iredale (1956), Rand & Gilliard (1967).

33. Red-banded Flowerpecker*Dicaeum eximium*

French: Dicée des Bismarck

Spanish: Picaflores de las Bismarck

German: Bismarckmistelfresser

Other common names: Beautiful/New Ireland/Bismarck Flowerpecker

Taxonomy. *Dicaeum eximium* P. L. Sclater, 1877, New Ireland, Bismarck Archipelago.

Forms a superspecies with *D. nehrkorni*, *D. erythrothorax*, *D. vulneratum*, *D. pectorale*, *D. geelvinkianum*, *D. nitidum* and *D. aeneum*. Three subspecies recognized.

Subspecies and Distribution.

D. e. eximium P. L. Sclater, 1877 – New Hanover and New Ireland (including Selapiu and Lihir Group), in N Bismarck Archipelago.

D. e. phaeopygium Salomonsen, 1964 – Dyaul I (off W New Ireland).

D. e. layardorum Salvadori, 1880 – New Britain (including islands of Lolobau and Watom), in S Bismarck Archipelago.

Descriptive notes. 8–9.5 cm; 7–9.5 g. Male nominate race has brownish crown and side of head, contrasting olive-brown and bronze-green upperparts, rump scarlet, tail blackish, glossed blue; white below, narrow scarlet breastband, dark grey sides of breast also forming irregular band, flanks greenish-tinged olive-brown and abdomen whitish with darkish slate central line; iris dark brown; bill black; legs blackish-slate. Female is dark grey above, rump crimson, throat, chest, centre of belly and vent isabelline-white, flanks yellowish-olive. Juvenile is similar to female, but greyer below, and white on throat slightly narrower.

Race *phaeopygium* male has head, back and rump dark brown; *layardorum* male is blackish above, with grey head, red spot on breast, below this grey, then yellowish-green, with thin blackish stripe down centre of abdomen, iris brownish-red or reddish-brown. Voice. A single “tzick”; various single high-pitched squeaky notes.

Habitat. Forest, including degraded forest and forest edge, but rarely coastal or montane forest; also tall bushes and isolated trees on edges of native gardens. To 1000 m, rarely to 1500 m.

Food and Feeding. Insects recorded as taken. Few other data, but recorded as foraging for fruits and around flowers in canopy.

Breeding. Birds with enlarged ovaries in Jul and Aug; thought to be possibly double-brooded. Nest with overhanging roof, but no porch, usually below 2 m, often in ferns. Eggs elongated, white. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Restricted-range species: present in New Britain and New Ireland EBA. Poorly known. Although large areas of lowland forest have been or are being cleared for oil-palm (*Elaeis guineensis*) plantation and logged, this species is secure in logged forest and hill forest. Common in canopy in C New Britain; noted as being locally abundant on that island in 1960s.

Bibliography. Cheke & Mann (2001), Gilliard & LeCroy (1967b), Gould (1878), Hartert (1924b, 1926b), Heinroth (1903), Mayr (1955), Mayr & Diamond (2001), Meyer (1933), Orenstein (1976), Salomonsen (1960c, 1964, 1965), Schönwetter & Meise (1980).

34. Midget Flowerpecker*Dicaeum aeneum*

French: Dicée des Salomon **German:** Bronzemistelfresser **Spanish:** Picaflores de las Salomón

Other common names: Solomon (Islands) Flowerpecker

Taxonomy. *Dicaeum aeneum* Pucheran, 1853, San Jorge, near Santa Isabel, Solomon Islands.

Forms a superspecies with *D. nehrkorni*, *D. erythrothorax*, *D. vulneratum*, *D. pectorale*, *D. geelvinkianum*, *D. nitidum* and *D. eximium*. Up to 8% difference found between subspecies using mtDNA markers. Three subspecies recognized.

Subspecies and Distribution.

D. a. aeneum Pucheran, 1853 – N & C Solomons (Buka, Bougainville, Fauro, Shortland, Choiseul, Santa Isabel, New Georgia Is, Buena Vista, Florida Is).

D. a. becki E. J. O. Hartert, 1929 – Guadalcanal, in SW Solomons.

D. a. malaitae Salomonsen, 1960 – Malaita I, in E Solomons.

Descriptive notes. 8 cm; male 7.1–8.8 g, one female 8.5 g. Male nominate race has crown and upperparts, including upperwing, slaty grey with metallic blue gloss, side of head grey, tail black; middle of upper throat whitish, sides of throat and breast grey, bright scarlet patch on breast, flanks citrine-olive, middle of upper abdomen dark grey, middle of lower abdomen and undertail-coverts buffy white; iris brown or dark brown; bill and feet black. Female differs from male in lacking red below and having olive flanks; supraloral and submoustachial stripes white, middle of throat, breast and abdomen buffy white. Juvenile lacks metallic blue gloss above, and is more greyish on throat than female. Races differ mainly in colour of gloss on dorsal surface: *becki* male has greenish gloss above, rather than the blue of nominate; *malaitae* male has gloss reduced to faint blue tinge, slate on underparts slightly paler, and both sexes have bill much thinner and longer than other two. Voice. Rapid “tik-tik-tik-tik”, short, high-pitched squeaks, and very high-

pitched "sweet sweet"; a brief trisyllabic call; and a very high-pitched chipping which develops into a trill. Also twittering notes resembling sound of snapping twigs; weak spitting note, sometimes rapidly repeated, and a sibilant note.

Habitat. Recorded in all available forest and scrub habitats, usually in canopy but also frequently in undergrowth and lower parts of the forest; from coast to highest mountains.

Food and Feeding. Insects and fruits. Forages usually in canopy, but frequently also in undergrowth and lower parts of forest. Often hovers to feed. Generally seen in pairs or family groups.

Breeding. Laying in Nov, and females with enlarged ovaries in Jul. Nest oval in shape, with side entrance, constructed of grass and fine vegetable material, suspended from twig or poorly concealed on horizontal branch 1–2 m above ground in bush. Both sexes feed nestlings and remove faecal sacs. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Common.

Bibliography. Cain & Galbraith (1956), Cheke & Mann (2001), Diamond (1975a), Donaghy (1950), Doughty *et al.* (1999), Hadden (1981, 2004), Kratter, Steadman, Smith & Filardi (2001), Mayr (1945a, 1945b, 1955), Mayr & Diamond (2001), Pucheran (1853), Salomonsen (1960c), Schodde (1977), Smith & Filardi (2007).

35. Mottled Flowerpecker

Dicaeum tristrami

French: Dicée de San Cristobal

German: Tristrammistelfresser

Spanish: Picaflres de San Cristóbal

Other common names: San Cristobal (Midget)/Tristram's Flowerpecker

Taxonomy. *Dicaeum tristrami* Sharpe, 1884, San Cristobal Island [Makira], Solomon Islands.

A very distinctive species, with no obvious close relatives. Monotypic.

Distribution. San Cristobal, in SE Solomons.

Descriptive notes. 8–9 cm; male 11–13 g, female 10–12.5 g. Male has top of head and upperparts brown, paler on mantle, head mottled profusely blackish and irregularly whitish, especially on forehead and ear-coverts; upperwing brown, tail blackish; throat to upper breast brown with pale edges of feathers (giving mottled or scaled effect), rest of underparts pale brownish-white; iris dark brown; bill black, may have paler base of lower mandible (especially in some females); legs dark slate or black. Female differs from male in having most of face whitish, blackish-brown area around base of bill; whitish below, some brown

on throat. Juvenile differs from adult in having pale bill and less well-marked scaling below. **VOICE.** High-pitched, emphatic, metallic "tsch-p-tsch-p".

Habitat. Primary forest, and more commonly in secondary growth and at forest edge; in highlands and lowlands, chiefly in former.

Food and Feeding. Insects and spiders (Araneae); food probably includes also fruits, and nectar and pollen of ant-plants (*Myrmecodia* and *Hydnophytum*), and perhaps gingers (*Alpinia*). Forages chiefly by hovering in front of dense foliage, especially tree-ferns; picks small invertebrates from spider webs.

Breeding. Females with enlarged ovaries in Oct–Dec. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Abundant in mountains, uncommon in lowlands. Occurs in Hauta Conservation Area.

Bibliography. Cain & Galbraith (1956), Cheke & Mann (2001), Doughty *et al.* (1999), Mayr (1945a, 1945b, 1955), Mayr & Diamond (2001), Salomonsen (1960c).

36. Black-fronted Flowerpecker

Dicaeum igniferum

French: Dicée porte-flamme

German: Rotkehl-Mistelfresser

Spanish: Picaflres Encendido

Other common names: Black-banded/Fire-tailed/Rusty Flowerpecker, Lesser Sunda Flowerpecker

Taxonomy. *Dicaeum igniferum* Wallace, 1864, Flores, Lesser Sunda Islands.

Forms a superspecies with *D. maugei*. Races poorly differentiated; species perhaps better considered monotypic. Two subspecies tentatively recognized.

Subspecies and Distribution.

D. i. igniferum Wallace, 1864 – Sumbawa, Komodo and Flores, in W Lesser Sundas.

D. i. cretum Rensch, 1929 – Pantar and Alor, in EC Lesser Sundas.

Descriptive notes. 9 cm. Male has whole upperside from crown to rump dull scarlet, glossed violet on back; forehead, face, side of neck, scapulars, upperwing and tail purplish-black; chin white,

throat and uppermost breast scarlet, pectoral band purplish-black, rest of underparts white, black central band down abdomen; iris dark; bill blackish; legs black. Female is duller above than male, with less gloss, forehead greyish-brown, crown to upper back, and rump, scarlet, rest of upperparts brown; greyish-brown side of face, lower throat and pectoral band, rest of underparts whitish. Juvenile is similar to female, but red above confined to rump, bill entirely pale, darkening towards tip. Race *cretum* is slightly larger than nominate, and male has broader black line below. **VOICE.** Rapidly repeated, thin, high-pitched "see-saw".

Song a very rapid, descending series, c. 6 seconds long, consisting of short, thin, dry notes.

Habitat. Semi-deciduous, degraded or secondary forest, coastal monsoon scrub-forest, lightly wooded cultivation and clearings; sea-level to 1730 m, usually below 800 m.

Food and Feeding. No information; diet probably includes fruit, pollen and nectar of mistletoes (Loranthaceae). Forages singly, in pairs or in small groups; joins mixed-species flocks.

Breeding. No information.

Movements. No information.

Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Nusa Tenggara EBA. Widespread and generally common.

Bibliography. Cheke & Mann (2001), Coates & Bishop (1997), Mees (2006), Rensch (1931a), Salomonsen (1961a), White & Bruce (1986).

37. Red-chested Flowerpecker

Dicaeum maugei

French: Dicée de Mauge

German: Blauwangen-Mistelfresser

Spanish: Picaflres de Mauge

Other common names: Blue-checked/Mauge's/Timor Flowerpecker, Lesser Sunda Flowerpecker

Taxonomy. *Dicaeum maugei* Lesson, 1830, Timor.

Forms a superspecies with *D. igniferum*. Proposed race *mariae* (from Nusa Penida, off SE Bali) synonymized with *neglectum*; *romae* (from Roma I) considered indistinguishable from nominate. Four subspecies recognized.

Subspecies and Distribution.

D. m. splendidum Büttikofer, 1893 – Salayar and Tanahjampea, S of Sulawesi.

D. m. neglectum E. J. O Hartert, 1897 – Nusa Penida (off SE Bali) and Lombok, in W Lesser Sundas.

D. m. maugei Lesson, 1830 – Romang, Damar, Timor, Sawu, Roti, Semau and perhaps Wetar, in E Lesser Sundas.

D. m. salvadorii A. B. Meyer, 1884 – Moa and Babar, in extreme E Lesser Sundas.

Descriptive notes. 8–9.5 cm. Male nominate race is glossy dark purplish-blue above, face blackish, rump scarlet; chin whitish, scarlet patch on throat and uppermost breast bordered blackish at side and below, rest of underparts creamy, blackish central stripe on abdomen; iris dark; bill and legs black. Female has scarlet rump and uppertail-coverts, rest of upperparts grey-brown, black tail, side of neck, face and partial pectoral band greyish-brown, rest of underparts white. Juvenile is similar to female but with paler bill. Race *neglectum* has slightly longer and more slender bill than nominate, male darker red below, with slightly

broader black band; *salvadorii* male has more extensive red below, with much narrower black border; *splendidum* has slightly smaller bill than last, male with lighter red below and black breastband almost absent, female with some reddish on upper back. **VOICE.** A high-pitched "tsit"; high-pitched whistle of 2–3 notes.

Habitat. Usually around mistletoes; occurs in primary forest, secondary forest and degraded forest, woodland, plantations, wooded cultivation and bamboos; generally below 1200 m, but up to 2000 m on Lombok.

Food and Feeding. Feeds on figs (*Ficus*) as well as flowering tamarind (*Tamarindus*); diet thought also to include the fruits, pollen and nectar of mistletoes (Loranthaceae). Forages singly and in pairs.

Breeding. Laying in May on Lombok; on Timor, laying in Mar, Apr and Nov, chicks being fed in early Dec, juveniles recorded in Apr–May. Nest a compact oval purse-like structure with large entrance hole near apex and a short "tail", consisting of thick layer of pappus with loose covering of fine vegetable fibre, dead leaves and lichen, attached to palm frond. Clutch 2 eggs; white. No other information.

Movements. Nothing recorded.

Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Nusa Tenggara EBA, in Timor and Wetar EBA and in Banda Sea Islands EBA. Generally common throughout range.

Bibliography. Cheke & Mann (2001), Bruce (1987), Coates & Bishop (1997), Hartert (1904), Hellmayr (1914), MacKinnon & Phillips (1993), Mason (1997), Mayr (1944a), Meyer & Wigglesworth (1898a, 1898b), Noske (2003), Rensch (1931a), Salomonsen (1961a), Trainor (2007a, 2007b), Trainor & Soares (2004), White & Bruce (1986).

38. Fire-breasted Flowerpecker

Dicaeum ignipectus

French: Dicée à gorge feu **German:** Feuerbrust-Mistelfresser **Spanish:** Picaflor de Pechofuego
Other common names: Buff-bellied Flowerpecker, Fire-throated/Scarlet-breasted/Green-backed/Bronze-backed Flowerpecker; Cambodian Flowerpecker (*cambodianum*); Sumatran Flowerpecker (*beccarii*); Luzon Flowerpecker (*luzoniense*)

Taxonomy. *Myzanthus ignipectus* Blyth, 1843, Nepal and Bhutan.

Forms a superspecies with *D. monticulum*, *D. celebicum*, *D. sanguinolentum* and *D. hirundinaceum*; all sometimes treated as conspecific. Has hybridized with *D. cruentatum* in SE China (Fujian). Some races, e.g. *beccarii*, distinctive and possibly approaching species level, but linked to other races through intermediate forms. Race *formosum* somewhat variable, not well differentiated from nominate and possibly better merged with it. Other proposed races are *pulchellum* (described from Lushan Hills, in Assam) and *cyanonotum* (from Ichang, in Hubei, China), both subsumed in nominate, and *vanheysti* (from Brastagi, in N Sumatra), merged with *beccarii*; *umbratile* (from Kao Kuap, in SE Thailand) is a synonym of *cambodianum*. Birds on Panay (Mt Madja-as), in Philippines, apparently belong to an as yet undescribed race. Eight subspecies currently recognized.

Subspecies and Distribution.

D. i. ignipectus (Blyth, 1843) – Himalayas from Kashmir E to NE India (Arunachal Pradesh, Assam S to Mizo Hills), SE Bangladesh, and S & SE China (S Shaanxi S to SE Xizang, Yunnan, Hainan, Guangdong and Fujian) S to Myanmar, N Thailand, Laos, Vietnam (except C Annam and Cochinchina) and E Cambodia (Phumi Dak area).

D. i. formosum Ogilvie-Grant, 1912 – Taiwan.

D. i. dolichorhynchum Deignan, 1938 – Malay Peninsula.

D. i. cambodianum Delacour & Jabouille, 1928 – SE Thailand and Cambodia.

D. i. beccarii Robinson & Kloss, 1916 – N to WC Sumatra.

D. i. luzoniense Ogilvie-Grant, 1894 – N & C Luzon (N Philippines).

D. i. bonga E. J. O. Hartert, 1904 – Samar (EC Philippines).

D. i. apo E. J. O. Hartert, 1904 – Negros and Mindanao (Mt Malindang, Mt Kitanglad, Mt Hilong-Hilong, Mt Apo, Mt Puting Bato), in S Philippines.

Also present (race as yet undetermined) on Panay, in C Philippines.

Descriptive notes. 7–9 cm; male 4–8 g, female 5.5–6.1 g. Male nominate race has crown and upperparts metallic greenish blue-black; face black; throat buffy white (sometimes with red feather tips), side of breast black, scarlet patch on breast, rest of underparts rich buff, black stripe in centre of belly, flanks olive, lower belly and undertail-coverts yellow; iris brown or black; bill black, sometimes whitish patch at base of lower mandible; legs dark horn-coloured or black. Female has crown greyish-olive, upperparts olive-green, more yellow on rump and uppertail-coverts, lores buffy white, narrow pale eyering; underparts

pale buff to cinnamon-buff, with olive wash on flanks; bill black, yellow to orange patch at base of lower mandible. Juvenile is similar to female but greyer above, chin and throat white, buff on underparts paler and duller. Races differ mainly in extent of red and black below on male, also in tone of gloss above: *formosum* is hardly distinguishable from nominate, male bluish-tinged bottle-green above, red below extending variably onto chin; *dolichorhynchum* male has narrower red chestband than nominate, female is greyer above and browner below than nominate; *cambodianum* male is distinctive, metallic blue-green or green above, lacks scarlet below, has throat, breast and centre of belly rich buff; *beccarii* male is distinctive, glossy blue-green above, darker rusty-buff and lacking red below, with cinnamon breastband and narrow black stripe down centre of belly; *luzoniense* male is dark glossy green above, dull blackish on sides of head and neck, has more extensive red on breast than nominate (extending to throat, but not chin), olivaceous-grey flanks, female differs from nominate in darker upperparts with slight greenish gloss, greyish-white underparts washed olive on flanks, orange-yellow undertail-coverts; *apo* male differs from previous in having slightly glossy green sides of head and neck, darker olive-green flanks, lighter and brighter yellow undertail-coverts; *bonga* is smaller than preceding two, male has side of head as dark as or darker than last race, and upperparts more steel-blue. **VOICE.** Calls include high-pitched buzzing “zeep” or “bzeep”, sharp metallic “chip” (which may be repeated), repeated high-pitched “tsik” or “tsit”, repeated high-pitched “see”, twittering trill, also a rising, rattling trill, “dit di-di-di-di-di-di...”. Song, from perch or in flight, high-pitched, strident “see-bit, see-bit, see-bit, see-bit”, followed by long series of clicks; another song is a shrill “titty-titty-titty” or “tissit-tissit-tissit”, rather like sound made by rapid opening and closing of scissors.

Habitat. Montane forest, hill forest, subtropical evergreen and deciduous oak (*Quercus*) forests, disturbed forest, forest edge, and in rhododendrons (*Rhododendron*), secondary growth, orchards, plantations and other cultivations, around flowering and fruiting trees, and particularly around mistletoes (Loranthaceae). In Himalayas of China and India, 900–3950 m in summer and down to 300 m in winter; in Nepal, 1830–2700 m in summer and 915–2285 m in winter; in Taiwan, to 2135 m in summer and down to 900 m in winter; in Myanmar, to 2600 m; in Malay Peninsula and Sumatra, 800–2200 m; and in Philippines, above 1000 m.

Food and Feeding. Fruits and nectar, particularly of mistletoes (including *Scurrula rhododendricolus*), figs (*Ficus*); also spiders (Araneae) and insects. Forages generally in canopy or middle storey. Forages singly and in pairs; outside breeding season sometimes in small groups and in mixed-species flocks.

Breeding. Laying Mar–Jun in India, Mar–Apr and possibly May in Nepal (where also fledgling in May), Feb and Apr–Jun in Myanmar, and mostly Oct–Mar in Hong Kong (SE China); nest in Mar in Sumatra (Batak Highlands); nestlings mid-Aug in Peninsular Malaysia; birds with active gonads in Jan and May in Philippines. Nest an oval purse, 90 × 60 mm, entrance hole on side near top, with or without porch, constructed from soft vegetable down held together with rootlets, spider webs and grass, sometimes decorated with moss, suspended 3–9 m above ground from branch of small tree. Clutch 2–3 eggs, white. No other information.

Movements. Seasonal altitudinal movements; post-breeding descent in Himalayas, China and Taiwan, possibly also elsewhere in range.

Status and Conservation. Not globally threatened. Generally common throughout much of its range; considered uncommon in Philippines. Occurs in many protected areas in all parts of range.

39. Black-sided Flowerpecker

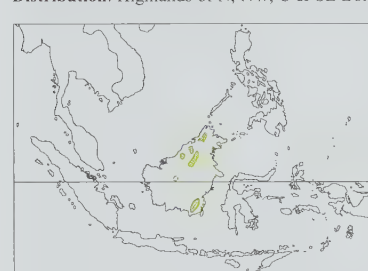

Dicaeum monticulum

French: Dicée de Bornéo **German:** Borneomistelfresser **Spanish:** Picaflor de Borneo
Other common names: Bornean (Fire-breasted)/Mountain Flowerpecker

Taxonomy. *Dicaeum monticulum* Sharpe, 1887, Mount Kinabalu, northern Borneo.

Forms a superspecies with *D. ignipectus*, *D. celebicum*, *D. sanguinolentum* and *D. hirundinaceum*; all sometimes treated as conspecific. Particularly close to *D. celebicum*. Proposed race *zita* (from Mt Dulit, in Sarawak) considered undiagnosable. Monotypic.

Distribution. Highlands of N, NW, C & SE Borneo.

Descriptive notes. 8 cm. Male has top of head and upperparts glossy bluish-black, face black, malar region and side of neck sooty black; central chin white, throat and breast scarlet, bordered greyish-black, upper flanks and upper belly dark grey, central lower belly white, lower flanks and side of belly olive, vent and undertail-coverts buffy yellow; underwing-coverts and pectoral tufts white; iris brown or black; bill black; legs brown to black. Female is olive-green above, with buffy wash on rump, grey face, whitish on throat, pale greyish below, some whitish mottling on breast, creamy on centre of belly, buffy on lower flanks, and

with white pectoral tufts. Juvenile is similar to female but darker below, with some fine dark streaking on chin to breast. **VOICE.** Sharp, piercing, metallic “zit”, a repeated “tit-tit”, also “tsweet-tsweet”, with second note slurred up and down; also a rapid ticking.

Habitat. Hill dipterocarp forest, montane forest and heath forest, also scrub; at 460–2540 m.

Food and Feeding. Fruits, particularly of mistletoes (Loranthaceae), seeds, probably also pollen and nectar of mistletoes; also aphids (Aphidoidea), flies (Diptera), leafhoppers (Homoptera) and other insects. Forages at lower levels, at times ascending to canopy.

Breeding. Males with enlarged testes in Dec in N Borneo (Sabah) and young observed in Nov–Feb in NW (Bario, in Sarawak). Nest a suspended purse of moss, lined with tree-fern pith and decorated with lichens. Clutches of 3 eggs reported. Female recorded feeding fledgling. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Restricted-range species: present in Bornean Mountains EBA. Local and uncommon. Very patchily distributed; occurs in highlands in Sarawak (Mt Penrissen, Mt Dulit, Mt Mulu and Bario), Sabah (Crocker Range, Mt Kinabalu and Mt Trus Madi), Kalimantan Barat (Mt Liang Kubung) and Kalimantan Selatan (Muratus Mts). Resident in Kinabalu Park.

Bibliography. Cheke & Mann (2001), Davison (1992), MacKinnon & Phillips (1993), Mann (2008), Salomonsen (1961a), Sheldon *et al.* (2001), Smythies (1957, 1960), Smythies & Cranbrook (1981), Smythies & Davison (1999).

40. Grey-sided Flowerpecker

Dicaeum celebicum

French: Dicée des Célèbes **German:** Schwarzwangen-Mistelfresser **Spanish:** Picaflor de Célebes
Other common names: Black-sided Flowerpecker(!)

Taxonomy. *Dicaeum celebicum* S. Müller, 1843, Sulawesi.

Forms a superspecies with *D. ignipectus*, *D. monticulum*, *D. sanguinolentum* and *D. hirundinaceum*; all sometimes treated as conspecific. Particularly close to *D. monticulum*. Race *talautense* very distinctive and may warrant treatment as a separate species. Five subspecies recognized.

Subspecies and Distribution.

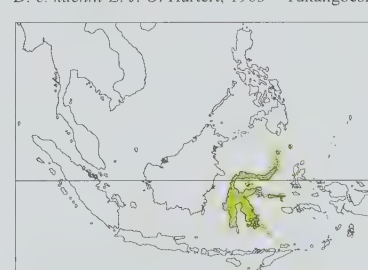

D. c. sanghirense Salvadori, 1876 – Sangihe Archipelago (Sangihe, possibly also Siau).

D. c. talautense A. B. Meyer & Wiglesworth, 1895 – Talaud.

D. c. celebicum S. Müller, 1843 – Sulawesi, including Manadotua, Bangka, Lembah, Togian Is, Muna and Butung.

D. c. sulaense Sharpe, 1884 – Banggai I and Sula Archipelago.

D. c. kuehni E. J. O. Hartert, 1903 – Tukangbesi Archipelago.

Descriptive notes. 9 cm. Male nominate race has crown and upperparts black, glossed dull purplish, face sooty; throat white, scarlet patch on lower throat and breast, abdomen creamy white with black central line, flanks sooty olive, undertail-coverts whitish; iris dark; bill dark brown; legs blackish. Female is greyish-brown above, whitish-grey on throat and breast, with flanks olive-grey, centre of belly and vent buffy white. Juvenile is similar to female but darker below, more greenish on upper breast, and darker, greyer, on throat; bill paler. Race *kuehni* male is more bluish-purple above than nominate, with paler

greyish-white abdomen and lighter, greyer-tinged flanks; *sulaense* male is lighter and more purplish-blue above than previous, has dark grey-olive flanks, greyish (not black) central stripe on abdomen; *sanghirense* male has dark inky blue gloss above, more greyish-white abdomen, purer dark grey (less olivaceous) flanks; *talautense* male is lighter, less glossy and more blue above than nominate, with uniformly greyish-black abdomen and flanks, female is generally darker below. Voice. Repeated, thin, upslurred "seei", short repeated "tjiti", short, dry, muted "trri-trri", and high-pitched "tsip"; flight call a sharp "chip, chip, chip...".

Habitat. Montane, lowland primary forest and tall secondary forest, forest edge, and plantations, cultivation, gardens and secondary scrub; sea-level to 1200 m.

Food and Feeding. Fruits, nectar and pollen of mistletoes (Loranthaceae), wild cherries (*Prunus*) and *Lantana camara*; small spiders (Araneae) and insects. Forages mostly in outer canopy. Gleans bare outer twigs. Forages singly and in pairs.

Breeding. No information on laying season. Nest a pear-shaped purse with entrance slit on side near top, or pendant-shaped ball, with or without porch, woven from fine grasses and down, decorated with twigs, spider webs and leaf debris, suspended 1.5–2 m above ground from outer branch. Clutch 3 eggs, white. No other information.

Movements. No information.

Status and Conservation. Not globally threatened. Widespread and generally common. Occurs in Lore Lindu National Park, in Sulawesi.

Bibliography. Atyeo (1971), van Bemmelen & Voous (1951), Blasius (1897), Cheke & Mann (2001), Coates & Bishop (1997), Coomans de Ruiter (1950, 1951), Holmes & Wood (1980), Meyer & Wigglesworth (1898a, 1898b), Riley, J. (1997), Riley, J.H. (1924), Salomonsen (1961a), Schönwetter & Meise (1980), Stones *et al.* (1997), Stresemann & Heinrich (1940b), White & Bruce (1986).

41. Blood-breasted Flowerpecker

Dicaeum sanguinolentum

French: Dicée sanglant **German:** Purpurnistelfresser **Spanish:** Picaflores Sangrante
Other common names: Javan Fire-breasted Flowerpecker

Taxonomy. *Dicaeum sanguinolentum* Temminck, 1829, west Java.

Forms a superspecies with *D. ignipectus*, *D. monticolum*, *D. celebicum* and *D. hirundinaceum*; all sometimes treated as conspecific. Particularly close to some forms of *D. ignipectus* and *D. celebicum*. Proposed race *ablutum*, described from Tamansari (Banjoevangi), in E Java, subsumed within nominate. Four subspecies recognized.

Subspecies and Distribution.

D. s. sanguinolentum Temminck, 1829 – S Sumatra (Lampung, two records), Java and Bali.

D. s. wilhelminae Büttikofer, 1892 – Sumba, in Lesser Sundas.

D. s. rhodopygiale Rensch, 1928 – Flores.

D. s. hanieli Hellmayr, 1912 – Timor.

Descriptive notes. 8–9.5 cm. Male nominate race has top of head and upperparts dark glossy blue, narrow white tips on tail feathers; throat and belly pinkish to creamy buff, breast scarlet, broad black stripe down centre of lower breast to belly, white pectoral tufts, flanks extensively smudged blackish-grey; iris blue or brown; bill black; legs dark grey. Female is dull olive-brown above, with scarlet rump and upperpart-coverts, throat and underparts ochre or orange-buff, streaked olive-grey, side of breast greyish, white pectoral tufts. Juvenile is similar to female but greyer, with bill paler. Race *hanieli* male has creamy-white throat and

chin, only small red patch, abdomen white, flanks yellowish; *rhodopygiale* has much thinner bill than others, male differs from nominate in having orange-pink (not buff) undertail-coverts, from other races in buff (not whitish) abdomen, blackish flanks; *wilhelminae* has thicker bill than others, male differs from nominate in being more violet above, in having white chin, scarlet throat to breast, grey belly and flanks, female is olive-grey above and pale buff-white and grey below, juvenile as female but olive-suffused white and grey below. Voice. Various sharp, high-pitched clicks; hard, sharp, buzzing double note. Song, lasting 1–2 seconds, a rather jerky series of 4–5 thin, very-high-pitched but sweet notes.

Habitat. Montane forest, hill forest and secondary forest, forest edge, casuarina (*Casuarina*) groves, open and degraded woodland, and lightly wooded cultivation. At 800–2400 m in Java and Bali; lowlands to 1000 m in Lesser Sundas, but higher on Timor and Flores.

Food and Feeding. Chironomid larvae, and spiders (Araneae); presumably also fruit, nectar and pollen of mistletoes (Loranthaceae). Forages usually in canopy, particularly near mistletoes. Forages singly and in pairs.

Breeding. Laying in Jan, Aug and Oct in W Java. Eggs described as lustreless white. No other information.

Movements. None recorded. Records from Sumatra possibly indicative of vagrancy.

Status and Conservation. Not globally threatened. Widespread in Java and Bali; common and widespread on Sumba and Flores; uncommon and apparently found only at high elevations on Timor. Status in Sumatra unclear; only two records, and perhaps only a vagrant there, but possibility that a small resident population exists merits investigation. Occurs in Gunung Gede-Pangrango National Park, in Java.

Bibliography. Cheke & Mann (2001), Coates & Bishop (1997), Hellebrekers & Hoogerwerf (1967), Hellmayr (1914), Hoogerwerf (1949, 1950), MacKinnon & Phillips (1993), Mayr (1944a), Mees (2006), Rensch (1928, 1931a), Robinson & Kloss (1923), Salomonsen (1961a), Schönwetter & Meise (1980), White & Bruce (1986).

42. Mistletoebird

Dicaeum hirundinaceum

French: Dicée hirondelle **German:** RotsteiB-Mistelfresser **Spanish:** Picaflores Golondrina
Other common names: Fire-breasted(!)/Australian/Mistle(toe) Flowerpecker, Australian Flower Swallow, Wallacean Flowerpecker (*ignicolle*)

Taxonomy. *Motacilla hirundinacea* Shaw, 1792, New Holland = Australia.

Forms a superspecies with *D. ignipectus*, *D. monticolum*, *D. celebicum* and *D. sanguinolentum*; all sometimes treated as conspecific. Race *fulgidum* perhaps sufficiently distinctive to warrant consideration as a separate species. Nominant race exhibits some clinal variation in size and colour, being

smaller in N, also females in N paler and whiter below, compared with greyer and browner in S and more variable in W. Proposed races *tormenti*, described from Point Torment (King Sound), in N Western Australia, and *yorki*, from Cape York, in N Queensland, considered insufficiently distinct from nominate to warrant subspecific separation. Four subspecies recognized.

Subspecies and Distribution.

D. h. keiense Salvadori, 1874 – Watubela Is, Tayandu Group and Kai Is, in E Indonesia.

D. h. ignicolle G. R. Gray, 1858 – Aru Is.

D. h. fulgidum P. L. Selater, 1883 – Tanimbar Is.

D. h. hirundinaceum (Shaw, 1792) – Australia (including islands in Torres Strait and Great Barrier Reef), except Tasmania.

Descriptive notes. 9 cm; male 7.5–11 g, female 7.5–10 g. Male nominate race has head and upperparts violet-glossed blue-black; throat and breast scarlet, broad blackish streak on centre of lower breast and belly, flanks grey, rest of abdomen greyish-white, undertail-coverts scarlet; iris grey, light brown, red or deep brown; upper mandible blackish or dark grey, lower mandible dark grey to brown, mouth salmon-pink (flesh-coloured in centre); legs dark grey, dark brown or black. Female is greyish-brown above, greyish-white below, with some darker mottling on throat and breast, pale scarlet undertail-coverts with whitish tips

(scaled effect); some individuals have a dark grey-brown central stripe on abdomen. Juvenile differs from female in having pink (not blackish) bill, and slightly rufous, indistinct scaling on throat. Race *keiense* male is purple-blue above, has narrow red band on breast, pale pink-orange below and lacking central belly stripe, pale grey-green flanks, whitish lower abdomen, female differs from nominate in being olive-brown above with reddish rump; *fulgidum* male differs from previous in paler pink underparts, white replaced by buffy yellow, reduced grey-green on side of abdomen, female differs in having deep crimson rump; *ignicolle* male differs from nominate in having dull yellowish underparts with olive-green flanks. Voice. Has wide vocabulary. High-pitched double and triple notes, various sibilant calls, a dry "tic", a "pretty-sweet", "tsew" and similar; sharp "dzee" in flight; contact call "see" or "seep"; soft buzzing warble during courtship by male, perhaps also by female; distress trill and "trrit-trrit" and "krik-krik" alarm calls described, also harsh or shrill scolding calls. Subsong a continuous stream of buzzing warbles, sometimes with mimicry. Song, by both sexes, a strident, whistled "wissweet...wissweet..." or repeated (usually) "wit-wissweet"; also high-pitched, clear, penetrating "wait-a-bit wait-a-bit zipp!" and variations on this; territorial song by male, from high perch, a clear, penetrating "kinsey kinsey kinsey" or "wicky wicky wicky" or "swizit swizit, weet weet swizit" or "witsoo witsoo witsoo...", wiss wiss wiss", or rapid "tang-tang-tang-tang" or "tar-tar-tar"; also a soft warbling song which includes much mimicry. Imitated bird species are Mulga Parrot (*Psephodes varius*) and 28 species of passerine, including White-throated Treecreeper (*Cormobates leucophaeus*), Rufous Whistler (*Pachycephala rufiventris*), Grey Fantail (*Rhipidura fuliginosa*), Weebill (*Smicrornis brevirostris*), Striated Pardalote (*Pardalotus striatus*), Silvereye (*Zosterops lateralis*) and New Holland Honeyeater (*Phylidonyris novaehollandiae*).

Habitat. Almost anywhere where mistletoes (Loranthaceae) are found, and often in areas of high mistletoe infestation. Forest, forest edge, sclerophyll and open savanna woodlands, and eucalypt (*Eucalyptus*) woodland, including low mallee; also mulga and other acacias (*Acacia*), mangroves, scattered trees, riparian zones in arid areas, and secondary growth. Lowland and middle elevations, and rare above 1000 m in Snowy Mts of Australia; sea-level to 250 m on Tanimbar.

Food and Feeding. Moths (Lepidoptera), syrphids and other insects, spiders (Araneae); fruits, particularly of mistletoes, also nectar and pollen. Fruits include those of pepper tree (*Schinus molle*), saltbushes (*Enchylaena tomentosa* and *Rhagodia spinescens*), figs (*Ficus*), African boxthorn (*Lycium ferocissimum*), native bryony (*Diplocyclos palmatus*), hawthorns (*Crataegus*), *Comprosmia lucida*, blackberry nightshade (*Solanum nigrum*), and the mistletoes *Amyema cambagei*, *Amyema quandong* and *Notoxizos*, among others. Young fed with spiders and other small arthropods. Deposits seeds of the mistletoe *Amyema miquelii* up to 500 m or more from parent tree. Forages mostly in upper levels of vegetation, often in canopy; sometimes lower down. Main techniques are gleaning and aerial sallying; frequently hovers, and sometimes probes in flowers. Usually singly or in pairs, occasionally in small groups; rarely in larger flocks, especially in areas of abundant food. Very occasionally joins mixed-species flocks.

Breeding. Laying in Australia mostly Aug–Apr (but also May–Jul), when mistletoes fruiting, but may occur also when fruits not abundant. Nest, built by female, a neat pear-shaped purse 75–114 mm long and 38–64 mm in diameter, with entrance slit on side, made from matted plant down, debris, lichen, feathers, wool, dried blossom, spider egg sacs and webs, sometimes decorated with brown or grey matter (including excreta of insect larvae) or faded wattle (*Acacia*) blossom, suspended 0.5–1.5 m up from thin leafy twig or frond of tree-fern, and often concealed among foliage. Clutch 3–4 eggs, white; incubation by female, period c. 10–12 days; chicks brooded by female, fed by both sexes, mostly by female, nestling period 15 days. Nest parasitism by Horsfield's Bronze-cuckoo (*Chrysococcyx basalus*), Shining Bronze-cuckoo (*Chrysococcyx lucidus*) and Fan-tailed Cuckoo (*Cacomantis flabelliformis*).

Movements. Non-breeding birds highly nomadic in some areas, in association with fruiting of mistletoes.

Status and Conservation. Not globally threatened. Common in mainland Australia, and moderately common on Tanimbar Is (Yamdena) and Kai Is. Widespread in Australia, where occupies home range of c. 20 ha; in one study, five pairs along a transect of 3.3 km. An important agent in dispersal of mistletoe seeds; in studies in Australia, it was found that 95% of mistletoe seeds defecated by this species germinated, and survival rates of seedlings was also high. In the past was sometimes persecuted because of its role in spreading mistletoe, which was regarded by some farmers and others as a serious pest.

Bibliography. Attenborough (1995), Atyeo (1971), Ballingall (1990), Beecher *et al.* (1986), Bellchambers *et al.* (1994), Blakers *et al.* (1984), Cheke & Mann (2001), Close (1991), Coates & Bishop (1997), Cowles (1974), Davis (1993), Eck (1976), Frith, H.J. 43. Scarlet-backed Flowerpecker

Dicaeum cruentatum

French: Dicée à dos rouge **German:** Scharlachmistelfresser **Spanish:** Picaflores Dorsirrojo

Other common names: Pryer's Flowerpecker (black-breasted morph "pryeri")

Taxonomy. *Certhia cruentata* Linnaeus, 1758, Bengal, India. Sometimes considered to form a superspecies with *D. trochileum*. Has hybridized with latter in E Borneo (Samarinda), and a hybrid between present species and *D. ignipectus* recorded in SE China (Fujian). Some races well differentiated, but situation complicated by presence of non-geographical colour morphs "pryeri" (mainly Malay Peninsula and N Borneo) and "hosii" (Borneo); race *ignitum* poorly differentiated, possibly better merged with nominate; in addition, named races *erythronotum* (China), *siamense* (from Lat Bua Kao, in E Thailand), *coccinea* (China) and *hainanum* (Hainan I) all subsumed in nominate. Population in N Borneo (Sabah) possibly represents an as yet undescribed race. Seven subspecies currently recognized.

Subspecies and Distribution.

D. c. cruentatum (Linnaeus, 1758) – E Nepal, NE India, Bangladesh, Myanmar and S China (SE Xizang, S Yunnan E, including Hainan I, to Fujian), S to Thailand and Indochina.

D. c. ignitum (Begg, 1834) – Peninsular Malaysia and Riau Archipelago.

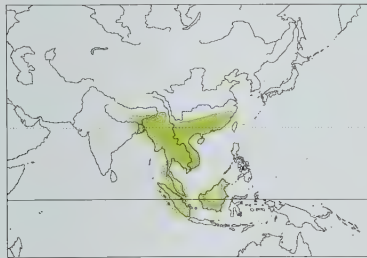

D. c. sumatranum Cabanis, 1878 – Sumatra and some satellites.

D. c. simalurensis Salomonsen, 1961 – Simelue I, off NW Sumatra.

D. c. niasensis Meyer de Schauensee & Ripley, 1940 – Nias I, off W Sumatra.

D. c. batuensis Richmond, 1912 – Batu Is and Mentawai Is, off SW Sumatra.

D. c. nigrimentum Salvadori, 1874 – Borneo.

Male is similar to female, but more buffish below, lacks red on rump (which may have orange tinge), and has orange bill with paler base. Race *ignitum* is very like nominate, but male slightly darker on flanks, in morph "pryeri" (less than 25% of population) male has black of throat sides extending to centre and onto breast; *sumatranum* is smaller than nominate, male has lighter red upperparts, black forehead, duller wings, greenish gloss on scapulars, smoky-grey throat (centre paler), side of neck, side of breast and flanks; *batuensis* male differs from previous in having centre of chin, throat and breast buffy white (as nominate, but area not so broad), and sides of head, neck and body slightly darker, female differs from nominate in having narrower white central line on underparts; *niasensis* male is similar to last, but wing-coverts purplish-blue (rather than greenish-blue), throat darker grey, buff central area of underside reaching only to upper chest, female as *sumatranum* but back brighter, more yellowish-green, and bill stouter; *simalurensis* is larger than *batuensis*, male differs further in being darker, more scarlet, above, with deeper blue gloss on wing-coverts; *nigrimentum* male is quite variable, has black throat and upper breast (morph "pryeri", less than 25% of population in NE Sabah) and much black on flanks, or may have creamy or buffy line of variable thickness through throat, and sometimes also breast, with variable amount of scarlet on breast, and some have chin and upper throat black, buffy white centre of lower throat and breast (morph "hosii"). Voice. Call "chip-chip", sometimes repeated; also a loud, staccato, clicking "tchik-tchik-tchik", high-pitched "chizee", thin metallic "tizz" and "tsi"; also much twittering, squeaks and shrill notes. Song a rising and falling "see-sip-see-sip-see-sip", a repeated "see-bit see-bit see-bit", a shrill, ringing "chipi-chipi-chipi dzee-dzee-dzee", or "zeekit-zeekit-zeekit-zeekit-zee"; another song described as short, high, buzzy rattles made up of rapidly delivered call notes.

Habitat. Variety of forest types, including mangroves, heath forest and alluvial forest, regenerating forest, forest edge, coastal scrub, secondary growth, open scrub, orchards, plantations and other cultivation, and gardens; generally below 1000 m, but to 1200 m in China and 2135 m in Nepal.

Food and Feeding. Fruits, including berries of *Muntingia calabura* and *Melastoma malabathricum*, figs (*Ficus*) and mistletoes (Loranthaceae), green seeds, nectar; also insects and spiders (Araneae). Forages at all heights. Hawks flying insects by sallying from perch and hovering. Occurs in pairs and family parties.

Breeding. Mar–Aug (chiefly May and Jun) in Nepal and India, Feb–Apr in Myanmar, Jan–Apr and Jul in Thailand, Jan–Jun in Peninsular Malaysia, Nov–Jan, Apr and May (also enlarged testes in Mar and Jun) in N Borneo (Sabah), and Jun–Aug in SE China (Hong Kong); nest-building Nov and Dec in Sumatra, mid-Dec, Feb, Jun and early Aug in Malay Peninsula; adult with noisy juvenile in Feb, in Cambodia; in Singapore, begging juvenile in Oct, and nest-building and nestlings in Nov.

Descriptive notes. 7–9 cm; male 5.5–8 g, one female 6 g. Male nominate race has crown to back and rump deep red, side of head black, upperwing and tail glossy blue-black; sides of throat and upper breast black, flanks grey, centre of throat, breast and belly pale buff, white pectoral tufts; iris brown; bill and legs black or blackish-green. Female is olive-brown to grey-brown above (with orange tinge on back), except for scarlet uppertail-coverts, black tail, dark brown wing; throat greyish-white, rest of buff underparts pale buff to whitish, sometimes with slight olive wash, sides and flanks usually greyer, narrow white central stripe. Juvenile is similar to female, but more buffish below, lacks red on rump (which may have orange tinge), and has orange bill with paler base. Race *ignitum* is very like nominate, but male slightly darker on flanks, in morph "pryeri" (less than 25% of population) male has black of throat sides extending to centre and onto breast; *sumatranum* is smaller than nominate, male has lighter red upperparts, black forehead, duller wings, greenish gloss on scapulars, smoky-grey throat (centre paler), side of neck, side of breast and flanks; *batuensis* male differs from previous in having centre of chin, throat and breast buffy white (as nominate, but area not so broad), and sides of head, neck and body slightly darker, female differs from nominate in having narrower white central line on underparts; *niasensis* male is similar to last, but wing-coverts purplish-blue (rather than greenish-blue), throat darker grey, buff central area of underside reaching only to upper chest, female as *sumatranum* but back brighter, more yellowish-green, and bill stouter; *simalurensis* is larger than *batuensis*, male differs further in being darker, more scarlet, above, with deeper blue gloss on wing-coverts; *nigrimentum* male is quite variable, has black throat and upper breast (morph "pryeri", less than 25% of population in NE Sabah) and much black on flanks, or may have creamy or buffy line of variable thickness through throat, and sometimes also breast, with variable amount of scarlet on breast, and some have chin and upper throat black, buffy white centre of lower throat and breast (morph "hosii"). Voice. Call "chip-chip", sometimes repeated; also a loud, staccato, clicking "tchik-tchik-tchik", high-pitched "chizee", thin metallic "tizz" and "tsi"; also much twittering, squeaks and shrill notes. Song a rising and falling "see-sip-see-sip-see-sip", a repeated "see-bit see-bit see-bit", a shrill, ringing "chipi-chipi-chipi dzee-dzee-dzee", or "zeekit-zeekit-zeekit-zeekit-zee"; another song described as short, high, buzzy rattles made up of rapidly delivered call notes.

Nest a very small oval or pear-shaped purse, 90 × 60 mm, entrance near top, with or without porch, consisting of vegetable down bound together with grass, rootlets and spider webs, lined with downy fibre, decorated externally with spider webs and bark fragments, suspended from terminal twig 2–15 m (usually 6–9 m) above ground. Clutch 2–4 eggs, unglossed greyish-white, unmarked or faintly and sparsely flecked brownish; incubation by both sexes, period 10–11 days; both also provision nestlings and tend fledglings; no information on duration of nestling period.

Movements. Probably makes seasonal altitudinal movements in higher parts of range.

Status and Conservation. Not globally threatened. Rare in Nepal and Bhutan; locally common, or common to very common, in NE India (especially in Calcutta area and Assam), Bangladesh, plains and hills of Myanmar, Thailand, lowland Malay Peninsula, and in Sumatra and Borneo; generally rather uncommon in China. Occurs in numerous protected areas, e.g. Dibru-Saikhowa National Park, in India, Khao Pra Bang Wildlife Sanctuary, in Thailand, and Cat Tien National Park, in Vietnam.

44. Scarlet-headed Flowerpecker

Dicaeum trochileum

French: Dicée à tête écarlate **German:** Feuerkopf-Mistelfresser **Spanish:** Picaflores Cabecirrojo

Taxonomy. *Certhia trochilea* Sparman, 1789, "America?"; error = Java. Sometimes considered to form a superspecies with *D. cruentatum*. Hybrid between present species and *D. cruentatum* recorded in E Borneo (Samarinda). Race *stresemanni* only weakly differentiated from nominate. Two subspecies recognized.

Subspecies and Distribution.

D. t. trochileum (Sparman, 1789) – Bangka, S Sumatra (Lampung), S & E Borneo, Java (including Madura), Karimunjawa Is and Bawean (both N of Java), Kangean Is and Bali.

D. t. stresemanni Rensch, 1928 – Lombok.

Descriptive notes. 8–9 cm. Male nominate race has head, upper back, rump, uppertail-coverts and chin to upper breast scarlet, upperwing and tail black; flanks and lower breast grey, belly greyish-white, white pectoral tufts and underwing-coverts; iris brown; bill and feet black. Female has crown and upperparts brown, washed red on head and mantle, rump scarlet; throat and underparts dull white. Juvenile is greenish-brown above, orange patch on rump, greyish below, paler on throat and centre of belly. Race *stresemanni* has shorter bill than nominate, female generally paler, particularly on head and flanks. VOICE.

Short, high-pitched "zit-zit-zit", and buzzing "seeeeeep...seeeeeep". Song a series of sweet, high-pitched double notes abruptly rising and falling, duration 2–3.5 seconds.

Habitat. Woodland, cultivation, mangroves, open areas and gardens; sea-level to 600 m.

Food and Feeding. Insects, small spiders (Araneae), also fruits, nectar and/or pollen of mistletoes (Loranthaceae). Occurs at high or low levels in vegetation, around mistletoes. Forages singly and in pairs.

Breeding. Laying Feb–Jul in W Java. Nest a globular mass 70–80 × 30–35 mm, large entrance hole stretching from top to middle point of side (finishing 25–30 mm from bottom), made from fine twigs and plant fibres, lined with plant down; one was suspended beneath a horizontal twig by an attachment broader than nest (but of same material), another was attached to vertical twigs in cluster of large leaves. Eggs white, glossed or unglossed, some with a few markings, one red-brown at pointed end. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Common in Java, on its outlying islands, and in Bali; uncommon in Sumatra and Lombok. Occurs in Bogor Botanical Gardens, in Java.

Class AVES
Order PASSERIFORMES
Suborder OSCINES
Family PARDALOTIDAE (PARDALOTES)

- Very small, plump passerines with short square tail and short bill, typically with loud but simple calls; some brightly coloured.
- 8.5–12 cm.

- Australia.
- Forests and woodlands, especially those dominated by eucalypts.
- 1 genus, 4 species, 12 taxa.
- 1 species threatened; none extinct since 1600.

Systematics

The family Pardalotidae consists of four species, all within a single genus, *Pardalotus*, confined to Australia and its islands. The genus is homogenous: the four pardalotes are united by distinctive morphological and ecological features. The family affiliation of the genus and the systematic treatment of some species within it have, however, varied over the years. For a long time, the pardalotes were placed with the mostly Oriental flowerpeckers (Dicaeidae), largely because of the shared features of small size, dumpy shape, bright coloration, and loss or diminution of the outermost, tenth, primary feather. More recent genetic and other evidence has indicated that this matching is simply a case of superficial resemblance.

Instead, the pardalotes appear to be taxonomically far closer to a set of small Australasian insectivores, the Acanthizidae, which includes the thornbills (*Acanthiza*), the scrubwrens (*Sericornis*), the *Gerygone* warblers, the Weebill (*Smicrorhynchus brevirostris*) and the heathwrens (*Hylacola*), among others. Indeed, some recent taxonomic treatments have combined the Acanthizidae and the Pardalotidae, the latter family name then taking precedence. The two groups, the pardalotes and the acanthizids, are, however, more homogenous when separated; the genomic distance between these two groups is sufficiently large to warrant separation, and there are substantial differences between them in mitochondrial DNA sequences. Further, the pardalotes and acanthizids differ in a range of anatomical features. R. Schodde and I. J. Mason, in their 1999 *Directory of Australian Birds*, list several distinctive features of the Pardalotidae. These include well-ossified narial apertures, a constricted palate with attenuately subulate transpalatine processes, a deeply bifid vomer with developed round-tipped horns, vestigial maxillo-palatine processes, ossified and thickened hinges of the pterygoids with the medio-palatine processes, temporal fossae nearly occluded by thickened zygomatic processes, more or less vestigial postorbital processes, undeveloped alae tympanicae, and a humeral fossa that is of the acanthizid type but with particularly deep twin furrows.

Within the family's sole genus there are two well-defined largely invariant species, the Red-browed Pardalote (*Pardalotus rubricatus*), the two subspecies of which are based largely on nuanced plumage differences, and the monotypic Forty-spotted Pardalote (*Pardalotus quadragintus*). In addition to these two species, the genus contains two distinct species groups, each with a varied history of taxonomic treatments. The Striated Pardalote (*Pardalotus striatus*) exhibits some geographical variation in

plumage patterning and, less markedly, in vocalizations, and this has resulted in several races at times being elevated to the rank of species. Thus, the name of "Striated Pardalote" has sometimes been reserved for the subspecies *substriatus*, with the nominate race treated as a separate species, the "Yellow-tipped Pardalote", and *ornatus* as a further species, the "Eastern Striated Pardalote"; the three northern subspecies, *uropygialis*, *melvillensis* and *melanocephalus*, are then combined as the "Black-headed Pardalote". Indeed, the complex geographical pattern of variation in these striated pardalotes has excited considerable debate and some significant biogeographical studies. This debate has now, it seems, largely settled, with general recognition of a single species containing six subspecies.

The fourth member of the genus in the current treatment, the Spotted Pardalote (*Pardalotus punctatus*), shows a somewhat similar, but simpler, geographical variation in plumage patterning. The inland subspecies, *xanthopyge*, has at times been elevated to full species rank, as the "Yellow-rumped Pardalote". In the far north of the Spotted Pardalote's range, in north-eastern Queensland, a probably disjunct population is generally recognized also as being subspecifically distinct, under the name *militaris*. The small size of this far northern isolate is consistent with Bergmann's Rule, which states that there is a tendency for body size to increase in cooler areas.

Relationships within the genus are somewhat obscure. The two most closely related species are evidently the Spotted Pardalote and the Forty-spotted Pardalote. The latter is an Endangered species (see Status and Conservation), now restricted to a few localities in Tasmania. It has been argued that the Forty-spotted Pardalote evolved from a previously isolated population of the Spotted Pardalote, and that its relatively dull plumage is neotenuous, meaning that immature features are retained in the adult plumage.

Morphological Aspects

The pardalotes are characteristically small, compact birds, often little larger than the leaves in which they forage. The Striated Pardalote is the largest of the genus, weighing an average of about 12 g. The average weight of the Spotted Pardalote is 8.5 g, and that of both the Forty-spotted Pardalote and the Red-browed Pardalote is 11 g. In the case of the widespread Spotted and Striated Pardalotes, size increases from the north to the south. There is no sexual size dimorphism.

The family Pardalotidae was until quite recently thought to be most closely related to the Oriental flowerpeckers (Dicaeidae) because of superficial similarities in pattern and structure. The evidence of genetic analyses places it much closer to other Australian insectivores, especially the thornbills (Acanthizidae). The four pardalotes form a well-defined group, as they are all rather stocky, with short, square-cut tails and stubby bills. Most are also strikingly marked, the most vividly patterned of all being the **Spotted Pardalote**. The bright male is distinguished by its rich yellow throat and breast, red uppertail-coverts, and white supercilium, whereas the fine white dotting on the dark crown and wings reappears to varying extents in other species. Female and juvenile present much more subdued versions of the male, with cream spots on a dark grey crown.

[*Pardalotus punctatus*.]

In body form, the four species are very similar to one another. Their profile is distinctive, with a notably short square-cut tail 2.5–3.5 cm in length, and a short but deep and robust bill measuring 0.65–1.1 cm. The wing length and shape vary among the species. The wings of the largely sedentary Forty-spotted Pardalote are relatively short, 5.5–6 cm, and rounded, whereas the far more dispersive Striated Pardalote has the most elongate wing, its length being 6–7 cm.

The bill shape, as well as an absence of rictal bristles, contrasts markedly with the long pointed bill more typical of small insectivorous birds, and it may be particularly suited for applying a powerful force to remove their main food item, lerp, from its attachment to eucalypt (*Eucalyptus*) foliage (see Food and Feeding). Their legs of pardalotes are reasonably long, with a tarsus measurement of 1.6–2.1 cm.

In contrast to the majority of arboreal insectivorous birds of Australia, which have a mostly sombre plumage in subdued greens and browns, the pardalotes are typically vividly coloured and/or strikingly marked. This patterning and colour are reflected in a common general vernacular name for this group of species, which are often referred to as “diamond-birds”.

The most brilliantly coloured member of the family is the male Spotted Pardalote, which has a rich bright yellow throat and breast, a finely vermiculated blue-grey face and neck side, a black crown with white spots, a white eyebrow, a black wing marked with a delicate line of white spots, red uppertail-coverts, and a rump that is either yellow or chestnut. The female of this species is duller, with paler yellow and less conspicuous throat markings; her eyebrow is less distinct and is creamy, rather than white, and the crown markings are less obvious, consisting of creamy spots on a dark grey background. There is no seasonal variation in plumage. Juvenile Spotted Pardalotes are similar in pattern to the female, but duller still, for example having the crown spotting far less distinct.

The Forty-spotted Pardalote is the least colourful of the pardalotes, but it retains a subdued beauty. It sports an unusual mix of lemon-yellow, present on the face and undertail-coverts, and pale olive-green plumage, with numerous distinct white spots on the blackish wing; there are, indeed, about 40 such spots. When the bird is viewed closely, it displays a delicate pattern of dark scalloping on the olive crown and neck. The sexes are alike, and the juveniles are duller than the adults.

The **Red-browed Pardalote** has the classic pale-marked crown characteristic of the family, but it also possesses features of its own. These include a distinct yellow panel on the wings, a yellow splash on the chest, a broad buffy eyebrow and a conspicuous fiery patch between the eye and the bill. This species is sexually monochromatic, but juveniles are considerably duller than adults. It is widespread in Australia, occurring in a wide variety of wooded habitats, especially where eucalypts (*Eucalyptus*) are abundant.

[*Pardalotus rubricatus rubricatus*, Lajamanu, Tanami Desert, Northern Territory, Australia. Photo: Don Hadden]

Striated Pardalotes are predominantly fawn-brown in appearance, with a distinct pale eyebrow that is yellow or orange closest to the bill and white behind the eye, and a black crown that is streaked white on some subspecies and unpatterned on others. The throat is yellow, the belly pale, and the black wings are marked with variably broad white edging and a white patch distal to a small set of single red, orange or yellow spots at the terminal end of each primary covert. The sexes are similar to each other. Juve-

For their size, pardalotes have very loud songs, usually consisting of a rich phrase, constantly repeated. In many areas of forest and woodland, these songs are amongst the most familiar sounds, and they often provide the first clue to the presence of pardalotes, which can otherwise remain inconspicuous in high foliage. The song of the **Spotted Pardalote** is typically ringing and persistent.

[*Pardalotus punctatus*, Murray-Sunset National Park, Victoria, Australia. Photo: Peter Fuller]

Pardalotes are insectivores that tend to glean their food directly from foliage, rather than hunting close to the ground or sallying after aerial prey. They often forage in eucalypts, and are particularly specialized in feeding on the exudates which form on their foliage, such as "lerps", or the "manna" of the manna gum. Lerps are protective shells made from carbohydrates in the leaf by nymphal stages of psyllid insects. They may offer particularly rich food resources, and the **Striated Pardalote** regularly snips them from eucalypt leaves with an audible clicking of the mandibles. Some pardalotes also consume manna, another solidified sugar-rich exudate found on the foliage of eucalypts, particularly where they have been damaged by herbivorous insects.

[*Pardalotus striatus*,

Photo: Peter Fuller]

niles are duller than adults, with a paler yellow throat and a paler crown and ear-coverts.

Finally, the Red-browed Pardalote is mostly olive-brown above and pale below. Its most obvious features are a white-spotted black crown, broad yellow edging on the primaries forming a distinct yellowish panel on the otherwise black wings, and a broad cream-coloured to yellow eyebrow with a conspicuous red spot or splotch on the brow between the eye and the bill. The sexes are alike in plumage. Juveniles are much duller and less patterned than the adults, with a paler and less pronouncedly marked crown and a less distinct eyebrow, and they have a yellowish wash on the underbody.

Pardalotes typically moult after the breeding season. Most moult records are from southern Australia and refer to Spotted and Striated Pardalotes. For adults of these species, the moult of the primaries takes place mainly from December to May. The primaries are replaced outwards, beginning at the innermost, P1. There are few available data on the time taken for completion of the moult, but the duration of the primary moult is approximately three months.

Habitat

Pardalotes are generally tightly associated with forests and woodlands dominated by eucalypts, and almost all of their foraging occurs among eucalypt foliage. Such habitats include a broad range of structural formations, from tall forest with a canopy height exceeding 30 m to sparse low mallee woodland with a canopy height of less than 3 m. The dominant trees can include a very wide range of eucalypt species. Indeed, at least 50 different species of eucalypt have been recorded as dominant in vegetation types occupied by pardalotes.

Of the four species in the family, the Forty-spotted Pardalote has by far the most narrow ecological range. It is typically associated with forests dominated by the manna gum (*Eucalyptus viminalis*).

Eucalypt-dominated vegetation types encompass a broad range of environmental settings, including alpine, coastal and inland areas, and pardalotes occur across this wide range. Eucalypts are less dominant across large tracts of arid and semi-arid

Australia, and the pardalote species characteristic of arid Australia, the Red-browed Pardalote, accordingly has a patchy and discontinuous range, typically occurring in the narrow band of eucalypts fringing inland waterways.

Pardalotes have been recorded also in vegetation types dominated by trees other than eucalypts, including some acacia (*Acacia*) woodlands and rainforests. Such habitats appear, however, to be suboptimal and their use by this family largely incidental and infrequent. Pardalotes may occur in urban and suburban areas, but typically only where there is an adequate cover of planted or retained eucalypt trees.

As is clear from the preceding paragraphs, this family, despite its paucity of species and their small size and general unobtrusiveness, is a characteristic feature of the diverse eucalypt-dominated forests and woodlands that typify large parts of Australia. Almost any such eucalypt formation can be expected to support at least one pardalote species, and the co-existence of two ecologically very similar species, the Spotted and Striated Pardalotes, is a feature of much of Australia. The pardalotes may, indeed, be the most eucalypt-specialized of any Australian vertebrate group, other eucalypt-specialist species, such as the koala (*Phascolarctos cinereus*), not extending across the full gamut of eucalypt formations. This tight association with eucalypts appears to be determined by a similar habitat specialization exhibited by the principal food source of pardalotes, lerp-forming psyllid insects (see Food and Feeding). The genetic evidence suggests that the specialized family of pardalotes derives from far more typically generalist insectivores, the Acanthizidae (see Systematics).

General Habits

Through a series of studies involving the three species occurring in south-eastern Australia, the Spotted, Forty-spotted and Striated Pardalotes, many aspects of the life history of these pardalotes are now tolerably well known. In contrast, the ecology and life history of the Red-browed Pardalote is far less well known. While there is much similarity in morphology and general ecology among the four species, there are also some interesting, if subtle, differences among them in breeding behaviour, foraging and social dispersion.

Although the evidence is meagre, pardalotes probably share with other Australian insectivorous birds a life history that contrasts sharply with that of European avian insectivores. The Australian insectivores typically have long lives, although, with few long-term studies, the longest interval between ringing and recapture for a pardalote is only 6.5 years; they also have a relatively small clutch size but an extended breeding season, and relatively lengthy incubation and fledging periods (see Breeding). These characteristics match a far less marked seasonality in Australian temperate systems, probably including less seasonal variation in invertebrate food resources. Pardalotes show these characteristics less pronouncedly than other Australian insectivorous birds. This may be because their hollow-nesting habit may allow larger brood sizes. Alternatively, their principal food resource, lerps, may undergo more substantial "boom-and-bust" cycles than is the case with most other foliage invertebrates, thus forcing pardalotes to be more nomadic and, hence, probably to suffer higher mortality rates than those experienced by sedentary insectivores.

Pardalotes are diurnal birds. They spend most of the daylight hours in foraging unobtrusively in foliage, often high in the canopy. It is usually only when they are breeding that they are amenable to close observation. Pardalotes are usually seen singly or in pairs during the breeding season. At other times, they frequently form parties, generally containing rather small numbers, although in the autumn-winter period the Spotted and Striated Pardalotes sometimes gather in flocks of up to several hundred individuals. Outside the breeding season, mixed flocks containing two or more pardalote species are by no means uncommon, and pardalote flocks are often accompanied also by *Acanthiza* thornbills.

During the breeding season, particularly, pardalotes perform a range of stereotyped simple displays (see Breeding). At other times, they tend not to be aggressive. In contrast to the marked intraspecific response to playback of calls (see Breeding),

pardalotes generally ignore playback of vocalizations of other pardalote species. On the other hand, there can be some substantial interactions between pardalote species in association with foraging, and chases involving two different members of the family are reasonably common. In south-eastern Tasmania, where three pardalote species co-exist, the Forty-spotted Pardalote is dominant over both the larger Striated Pardalote and the smaller Spotted Pardalote. All three pardalotes, however, are chased by larger aggressive honeyeaters. Some aggressive colonial honeyeaters can completely exclude pardalotes, as well as other small leaf-gleaning insectivorous birds. One observer reported a physical attack on a lone Striated Pardalote by Noisy Miners (*Manorina melanoccephala*). One of the miners caught the pardalote and held it by the wing, while another pecked it around the eyes and head; after 20 minutes of such attacks by up to five miners, the assailants dropped the pardalote to the ground, where it was found to be dead.

Information on the roosting habits of pardalotes in the wild is lacking, and extremely little has been documented with regard to the maintenance behaviour of this family. In the north Flinders Ranges, in South Australia, a pair of Red-browed Pardalotes was observed to take turns to bathe in a stream. Each individual splashed about actively for a few seconds, and then flew to a rock at the water's edge; here, it shook itself to remove water droplets from the plumage and preened vigorously, before flying into the top of some river red gums (*Eucalyptus camaldulensis*) bordering the stream. The only other relevant observation in the wild concerns a Striated Pardalote, which was seen to preen its left wing after displaying.

In captivity, two Forty-spotted Pardalotes, caught in the wild, roosted side by side on a low branch, usually selecting the same spot each night. It was noted that these captives appeared to indulge in preening more in the morning than they did at other times of the day, but the difference was not very marked. In addition, they bathed regularly in a dish which was half-filled with mud, over which lay a shallow depth of water covered with litter. The pardalotes splashed about in this until their plumage was thoroughly saturated and they were unable to fly; they then moved on to a low branch, where they spent many minutes as they dried out and preened. Incidentally, one captive Forty-spotted Pardalote was thought possibly to have drowned during bathing; it was found dead in a water dish.

Voice

Most pardalotes are loud-voiced for their size, having a simple song, typically of 3–5 syllables, that is frequently repeated. The song of the Spotted Pardalote is highly diagnostic, notwithstanding regional variations from the basic theme, and the presence of this small arboreal species may often be determined first by means of its voice, especially in tall forest. In addition to being extremely loud, it has been described as being brilliant, evocative, staccato and ringing: the song is a short set of 3–4 notes, typically, if quaintly, transcribed as “sa-weet ba-by” or “s-leep ba-by”, with the first note weak and the last two notes higher, the entire series lasting for just 1–2 seconds. This vocalization may be given frequently, and appears to be uttered only by males. Tasmanian

Pardalotes are usually monogamous. During the breeding season pairs often perform simple displays. These usually involve stereotyped forms of behaviour that show off the plumage to best advantage. For example, the **Red-browed Pardalote** raises the crown feathers while turning the head or body from side to side. This tends to accentuate the yellow chest and the white dotting of the crown.

[*Pardalotus rubricatus rubricatus*, Bowra Station, Cunnamulla, Queensland, Australia. Photo: Chris Sanderson]

All pardalotes are cavity nesters, capable of excavating tunnels in the ground. For some species tunnel excavation is rare, while for others it is the norm. The **Striated Pardalote**, for example, often digs tunnels into sloping ground or earth banks, either amongst vegetation or out in the open. Its tunnels are more or less horizontal, and are generally excavated by both pair members. During the initial phase they typically dig with the bill, later employing the feet to flick out excess soil in characteristic fashion. The entire process can take anything from two to 20 days.

[*Pardalotus striatus uropygialis*, Manning Gorge, Mt Barnett, Kimberley, Western Australia, Australia. Photo: Don Hadden]

populations of the species give a simpler version of this song. During the breeding season, males may respond in animated fashion to other singing males. They also respond vigorously to playback, with reported instances of their making physical attacks on speakers broadcasting taped calls. In addition, Spotted Pardalotes have a small range of quieter, simple calls, typically related to breeding or used for contact among flock-members, although the repertoire is limited and the use of these calls is infrequent.

Striated Pardalotes likewise have a simple loud distinctive song, typically rendered as "wit-e-chu", consisting of 2–7 notes. In the breeding season, especially, this song may be given repetitively, almost continuously. This species also has a range of other vocalizations that are given far less frequently: these include a trilling call, as well as a brief contact call in flocks. The song and calls of this species vary in nuanced but complex ways across its geographical range, and may be subtly but distinctively different among the various subspecies.

The song of the Red-browed Pardalote is similarly loud, simple and stereotyped. Typically, it consists of a single note repeated 3–6 times over an interval of 1–2 seconds, but often with the first note lower and longer, hence "do doo-doo-doo-doo". The notes have a pleasing, "liquid" quality, and this species is sometimes referred to colloquially as the "bellbird".

In contrast to the conspicuously loud but simple vocalizations of the other pardalotes, those of the Forty-spotted Pardalote are subdued and more complex. This species' repertoire includes a repeated loud "k-choo" as a song, a more frequently given low-pitched contact call, "where-where where-where", a short soft trill of 5–6 notes, and a churring call given in agonistic encounters.

Food and Feeding

Pardalotes are mostly insectivorous, but they do also consume some plant exudates (see below) and occasionally seeds. In addition, there is one record of a Striated Pardalote capturing and consuming a small scincid lizard.

While the diet of pardalotes includes a broad range of invertebrates, there is a particular specialization on members of the family Psyllidae. These are small hemipteran insects that, in the nymphal stages, attach themselves to leaves, especially those of

eucalypts, and suck juices from the phloem. The psyllid utilizes extra carbohydrates obtained to form a protective shell covering, known as a "lerp". Although there is considerable interspecific variation in size and chemical composition of the lerp, they can offer particularly rich food resources for birds, and also for other consumers, including ants (Formicidae) and indigenous humans. Given the immobility of psyllids with their lerp coverings, they are also relatively easy food items to exploit. Pardalotes are the most specialized lerp-feeders among Australian birds, and their short but strong bill appears to be particularly well suited for prising lerp from the leaves to which they are attached. There may, however, be strong interspecific competition among lerp-feeding birds, and this can result in substantial harassment and, in some cases, exclusion for pardalotes. This is especially so where aggressive colonial honeyeaters, notably the *Manorina* miners, are involved. In one study, it was found that pardalotes spent about 5% of their daylight time being chased by honeyeaters, which accounted for 9% of their expended energy.

Psyllids are attracted to foliage, particularly where a tree is stressed. Such trees may host extraordinary numbers of psyllids, with tens of psyllids on every leaf, and at these high densities the insects can themselves contribute to further stressing of the tree. Areas with psyllid outbreaks may be sought out by dispersing pardalotes, resulting in unusually high densities of the birds. The pardalotes may contribute to reducing the numbers of psyllids in outbreak areas, and thus play an important role in maintaining the health of the ecosystem. Where pardalotes, and other small insectivorous birds, are excluded by aggressive colonial honeyeaters, tree decline is more likely.

Each psyllid species builds a lerp of characteristic shape and chemical composition. An experimental study showed that pardalotes are more likely to consume lerp having a higher biomass and greater concentration of soluble sugars, such as those made by psyllids in the genus *Glycaspis*. This resource is a package, comprising both the sugary exudate covering, which is the lerp itself, and the sheltering psyllid nymph, which is higher in protein content.

Lerp is not the only sugary exudate to be found on eucalypt foliage. Some eucalypt species, especially the manna gum, may produce a sugar-rich exudate from the foliage, particularly where leaves have been damaged, as, for instance, by herbivorous in-

Not all **Striated Pardalote** nests are in excavated tunnels, as many pairs nest in natural tree holes, typically with an opening of 4–10 cm. Whether nests are placed in trees or in excavated tunnels, they tend to be a loose globular structure built from a variety of plant fibres, including grass stems, strips of eucalypt bark, and conifer needles. A lining of soft material, such as fur or feathers, is usually added. The clutch consists of 3–5 unmarked eggs, which are incubated by both sexes for a period of 15–23 days. There is much geographical variation in plumage characters in this species. The individual pictured here belongs to the race *ornatus*, with the strongly streaked ear-coverts and hindcrown of the nominate race, but with bright red rather than yellow tips to the primary coverts.

[*Pardalotus striatus ornatus*,
Flinders Chase NP,
Kangaroo I, South Australia.
Photo: Marie Read]

When it nests in earth banks, the **Striated Pardalote** excavates tunnels up to 1 m deep with a terminal chamber into which the nest structure is built. Unlike most members of the family, which are distinctly territorial with well-dispersed nests, this species is known to nest colonially on occasion, with up to 50 active cavities recorded in 30 m along one bank. Aggregations of this kind probably result from a limited supply of suitable nest-sites rather than colonial behaviour. The individual pictured here belongs to the race *melanocephalus*, which lacks striations on the ear-coverts and crown.

[*Pardalotus striatus melanocephalus*, Ipswich, Queensland, Australia.

sects. This solidified exudate, known as “manna”, can be common, at least in some trees and in some seasons. The highly restricted Forty-spotted Pardalote is closely associated with forests of manna gum, and manna comprises a large proportion of its diet. This food resource, however, may be readily dissolved or washed off leaves during rainfall, and its importance in the diet of this pardalote species is probably, as a result, seasonally variable.

The abundance and distribution of lerps, and of manna, vary with some seasonal regularity, but also with a more complex pattern of outbreaks. Pardalotes respond to this variable availability of key food resources by undertaking a range of dispersal movements. These may not always be successful searches: substantial episodes of mortality have been reported occasionally, probably because of food shortages.

Very detailed studies have been made of the foraging behaviour of Striated, Spotted and Forty-spotted Pardalotes, along with comparative studies of other, co-existing small insectivorous birds. The foraging of pardalotes is different from that of these other foliage-gleaning insectivores, which comprise members of the acanthizid genera *Acanthiza*, *Smicronis* and *Gerygone*. Pardalotes utilize eucalypts far more than do most other leaf-gleaning birds, and they are more sedate and stereotyped in their foraging activity, gleaning their prey from leaves, rather than flying after more mobile insects. In addition, their foraging is carried out almost entirely among leaves, rather than on other substrates, and they forage at higher levels, or in taller trees, than do most other species. The key food resources for pardalotes are found in eucalypt foliage. It is not surprising, therefore, that almost all foraging by pardalotes takes place in tree foliage, particularly in eucalypts. Some eucalypt species are preferentially selected, typically those holding a relatively high abundance of psyllids. Hence, eucalypts of the subgenus *Symphymyrtus* are selected preferentially for foraging by pardalotes, whereas those of the subgenus *Monocalyptus* are proportionately under-represented. Occasionally, lerps and, to a lesser extent, manna are dislodged from leaves by, for example, heavy rain, and may then accumulate on the ground beneath trees. In such cases, pardalotes will forage also on the ground.

While the pardalote species are generally very similar in foraging behaviour, there are nuanced differences among them. Spot-

ted Pardalotes typically forage lower in trees than Striated Pardalotes, and the smaller size of the former makes them slightly more agile and aerial in their foraging behaviour. Forty-spotted Pardalotes are generally very similar to Spotted Pardalotes in their foraging habits, but they are more selective, exhibiting a distinct preference for seeking food in manna gums. More so than other pardalotes, paired individuals of the Forty-spotted Pardalote typically forage close together in the same canopy, and they can be strikingly regular in their choice of locations, often restricting their foraging to just one or two particular trees.

Comparatively little is known about the behaviour of the Red-browed Pardalote. This species appears to forage mostly in foliage, typically that of eucalypts, but also among the leaves of other trees and occasionally in low shrubs. It has been reported as spending more of its feeding time on or close to the ground than other pardalote species.

As mentioned earlier (see General Habits), pardalotes are generally observed singly or in pairs during the breeding season, but they also forage in flocks of varying size at other times of the year. During the period of post-breeding dispersal, Spotted and Striated Pardalotes can gather in single-species or, frequently, mixed flocks of several hundred individuals.

A characteristic feature of pardalotes when foraging is the quiet clicking noise made by the birds. This sound is produced by the snapping of the mandibles as the birds dislodge lerps from their leaf attachments.

Breeding

In temperate Australia, the nesting season reaches its peak in the spring, from September to November. Nevertheless, for Striated and Spotted Pardalotes, at least, nesting has been reported in most months. It is common for two or more broods to be reared in a single season, with reported intervals between the successful fledging of one brood and the laying of a second clutch sometimes as short as 2–8 days.

Pardalotes are typically monogamous, and nest as simple pairs. The co-operative breeding characteristic of many other Austral-

ian passerines is not a feature of this family, although there are some reported instances, particularly for Striated Pardalotes, of three individual birds apparently using the same nesting tunnel at the same time. Both sexes are involved in nest construction, incubation of the eggs and feeding of the young. Partners may remain together for successive seasons, and they may reuse a nest-site in the same year or in successive years, but there are, unfortunately, too few data available to enable the frequency of this pattern of persistence to be determined with any degree of reliability.

Unlike most other Australian foliage-gleaning insectivorous birds, pardalotes generally nest either in tree hollows or in tunnels constructed in the ground. There are noteworthy differences among the four species in the relative use that they make of these two options, and also in the characteristics of their respective nest-sites.

Spotted Pardalotes nest almost exclusively in tunnels in the ground. These tunnels, typically horizontal, are usually constructed in sloping ground, often where there is some vegetation. Both sexes are involved in the task of excavation, some reports suggesting that the female does the majority of the work. The pardalote may initially use the bill to make indentations in the soil, but then subsequently digs with the feet, characteristically flicking out unwanted soil from the burrow entrance. The tunnel is almost circular in cross-section, with a diameter of about 4–5 cm, and it extends for about 25 cm or, sometimes, up to 1 m, ending in a larger nesting chamber of 5–10 cm in diameter. The work of digging the tunnel can take between 2 days and 20 days. Within the nest-chamber, the birds then construct a loose domed nest, mostly from the fibrous bark of eucalypts and from grass stems. Spotted Pardalotes occasionally nest in tree hollows, but such instances are comparatively few.

In contrast, Striated Pardalotes frequently nest in tree hollows, typically those with an opening diameter of 4–10 cm, but they also commonly nest in ground tunnels. The latter are typically in steeper banks and harder, more exposed soils than those used by Spotted Pardalotes. Otherwise, the two species are similar in terms of the shape and dimensions of the tunnel and nest. Striated Pardalotes will also exploit a wide variety of artificial situations, including exposed piping, cavities under house roofs and nestboxes.

Forty-spotted Pardalotes usually nest in tree hollows and in hollow logs or stumps, especially where these are in dead wood. Less commonly, they may nest in tunnels constructed in the

ground. Conversely, Red-browed Pardalotes typically nest in ground tunnels, characteristically in the eroded banks of water-courses, although they do sometimes nest in tree hollows.

The breeding dispersion of pardalotes exhibits some marked contrasts. Nesting aggregations may be formed by both Striated and Red-browed Pardalotes. One such example involved 50 pairs of Striated Pardalotes nesting in an earthen bank about 30 m long and 6 m high. This tendency for nests to be rather close together may be due more to spatial limitations on suitable nest-sites than to any inherent predisposition towards coloniality; indeed, where nest-sites are more common or widely spaced, nesting pairs of these species are more dispersed. In contrast, both Spotted Pardalotes and Forty-spotted Pardalotes show marked breeding territoriality. Both members of a breeding pair of Spotted Pardalotes will vigorously defend an exclusive territory of about 1–3 ha during the breeding season, while Forty-spotted Pardalotes similarly defend an exclusive breeding territory of 0.3–2 ha.

As is typical of cavity-nesting birds, pardalotes lay white eggs, in marked contrast to the splotched and speckled eggs typical of other small foliage-gleaning Australian birds, which for the most part use cup-nests placed in foliage. The clutches of pardalotes consist of 3–5 eggs, which are incubated for 16–24 days, and the fledging period of the chicks is 18–25 days. These details are notably different from those applicable to other Australian foliage-gleaning birds, which typically have smaller clutches and shorter development periods.

Particularly during the breeding season, pardalotes perform a range of stereotyped simple displays. Striated Pardalotes, for example, display most commonly with the tail held fanned and with the wings outstretched like an open fan and held forwards. A displaying individual may hold this position, motionless, for more than 30 seconds, or it may either quiver the fanned wings or rapidly fan and close them. This display is often, but not always, accompanied by repeated “chip-chip” calls or by a less distinct trilling. Displays may be directed at another bird and/or at and around the entrance to a currently used or potential nest-tunnel. Striated Pardalotes have been reported as using this display on a speaker broadcasting their calls. Displays can be particularly frequent at sites where many nests are in close proximity, especially at the outset of the nesting season. At the nest-site, Striated Pardalotes may direct this display also towards potential predators and towards other bird species that may compete for nesting hollows. In the same situation they will some-

The Spotted Pardalote never forms breeding aggregations. Instead, both members of pairs vigorously defend breeding territories of 1–3 ha, regularly countersinging with neighbours and fighting over territory boundaries. In fact, they are so aggressive in defending their territories that one set of experiments with taxidermic mounts had to be abandoned because the specimens were repeatedly destroyed by territory owners. Both sexes share incubation duties and co-operate to provision their chicks with a range of insect prey, in this case a caterpillar.

[*Pardalotus punctatus punctatus*,
Kettering, SE Tasmania.
Photo: Dave Watts]

times utilize another display, one that involves the wings being folded and the body moved from side to side.

Male Spotted Pardalotes, too, have a small set of stereotyped displays. When singing, they stretch as upright as possible, with craned neck and with the bill tucked into the chin, and they may twist the body in order to project their call in different directions. When displaying to a potential mate, the male raises the crown feathers, turns his head from side to side, and arches his neck upwards and then down, with the bill tucked into the chest; this display accentuates the vivid yellow throat markings and the conspicuous spotting on the crown. Interactions between males can at times be violent. In a study in which a freeze-dried specimen and playback of the calls were used as props, male Spotted Pardalotes adopted a crouched near-horizontal posture, with the crown feathers raised, as they approached the model, which they then attacked, pecking particularly at its yellow throat. One of these trials had to be discontinued when the attacking male flew off with the freeze-dried specimen; and replacement specimens rapidly became too damaged by attacks to be used for ongoing trials. Other agonistic types of behaviour reported for rival males include a wing-flicking display and complicated and long-lasting fluttering aerial chases.

The Forty-spotted Pardalote exhibits a range of breeding and agonistic displays. Aggressive encounters, which are frequent during the breeding season, mostly involve a "churr" display call. If this is not followed by the retreat of one individual, the aggressive behaviour may escalate to become a prolonged physical confrontation, involving males and females, as female Forty-spotted Pardalotes appear to take a far more substantial role in territory defence than females of other pardalote species. Such duels, which can last for at least 5–10 minutes, may involve two individuals, with claws locked together, falling from the canopy to the ground. When playbacks of the "churr" call are broadcast, territorial birds

approach and exhibit a characteristic display of rapid wing-flicks, 1–2 per second, with the folded wings raised and lowered quickly over the back. This display is accompanied by a responding "churr" call or a more subdued "whoowhoo" call, or is performed in silence. The approach and response may be sustained. In one instance, two individuals caught in mist-nets set around a speaker were recaptured four times within 20 minutes, because, following release, they flew straight back to resume "confrontation" with the broadcast call.

There are a number of reports of nesting pardalotes displaying to and/or chasing off other hollow-nesting bird species when these approach the pardalotes' nest-site. Conversely, some reports exist of pardalote nest-sites being usurped by other birds, such as, for example, Budgerigars (*Melopsittacus undulatus*). One intriguing record involved a Forty-spotted Pardalote which was found to be sharing a small nest-hollow with roosting bats.

Little information is available on the breeding success of the members of this family. On the basis of samples of 30–40 nests, the nest failure rate has been reported to range between 13% and 32%, for the Striated Pardalote and the Spotted Pardalote, respectively. These figures are better generally than the equivalents for other Australian foliage-gleaning insectivorous birds. Failure is due mostly to predation, including by snakes, lizards and carnivorous marsupials, but some failures have been reported as having resulted from the collapse of nest-sites or from the latter becoming saturated with water. There have been no confirmed records of pardalote broods being parasitized by cuckoos (Cuculidae).

Movements

The dispersal patterns of pardalotes are complex and not fully understood. These patterns include some regular seasonal move-

The Spotted Pardalote rarely uses tree holes, almost always nesting in burrows dug into earth banks. It typically lays 3–5 white eggs which are incubated for 16–22 days, with the chicks fledging after a further 18–25 days. Both the size of the clutch and the duration of the fledgling period are unusually large for Australian passerines. After the breeding season this species disperses in flocks which may number hundreds of individuals, sometimes mixed with Striated Pardalotes (*Pardalotus striatus*). These gatherings may roam over considerable distances, searching suitable woodland areas for outbreaks of lerp-forming psyllid insects.

[*Pardalotus punctatus punctatus*, Moggill State Forest, Brisbane, Queensland, Australia.
Photo: Raoul Slater]

The rarest of this quartet of species is the **Forty-spotted Pardalote**.

It occupies a restricted range in the Tasmania Endemic Bird Area, where it has a tiny overall range and population, estimated at only 3000–4000 individuals. This population is concentrated in optimum habitat, particularly where native eucalypts are common. It is thought to have contracted in range and declined in numbers drastically over the past century as a result of habitat loss, and perhaps in response to the spread of an aggressive competitor, the Noisy Miner (*Manorina melanocephala*). In plumage pattern and colour, the Forty-spotted Pardalote is the most subdued member of the family.

[*Pardalotus quadragintus*, Hobart, Tasmania.
Photo: Peter Fuller]

ments, directed away from colder areas in winter. Thus, most Striated Pardalotes migrate from Tasmania northwards across the 200-km stretch of Bass Strait to overwinter on the Australian mainland. Furthermore, both Spotted and Striated Pardalotes, during the winter months, become less abundant in the higher-altitude forests of south-eastern Australia and more numerous in lower-rainfall inland plains, a pattern consistent with the seasonal variation in the abundance of foliage invertebrates. Dispersal by these two species may involve large flocks, containing hundreds to thousands of individuals.

In addition to such regular trends of movement, the Spotted and Striated Pardalotes may make more convoluted or irregular movements, probably to seek somewhat spatially unpredictable outbreaks of psyllid infestations (see Food and Feeding). In other areas, populations of these pardalote species may be largely sedentary.

There have been few recoveries of individually ringed pardalotes away from the site of the initial capture. This is a common phenomenon in Australian ornithology, and is due largely to the fact that the human population density is very low. The sparsity of such records is further compounded for this family by the small size of the birds and their habit of foraging high in trees. Nonetheless, two long-distance movements by ringed Spotted Pardalotes have been recorded, one of 201 km and the other of 590 km.

Movement patterns of Forty-spotted Pardalotes are far more restricted, being confined entirely to eastern Tasmania and its adjacent islands. Although few data are available, populations of this species are probably mostly sedentary, or include some components that undertake relatively local seasonal dispersal. The movements, if any, of Red-browed Pardalotes are unknown.

Relationship with Man

Generally, the members of this family, being small, obscure and arboreal species, have a low profile and little interaction with humans. Nevertheless, there are some relationships with people, of varying intricacy.

When breeding, pardalotes can be extremely confiding and allow very close approach. Spotted and Striated Pardalotes will use a variety of artificial sites, such as roof eaves and nestboxes, or disturbed soil, as on road embankments or temporary soil heaps in gardens, for the siting of their nests, and at such times they may attract considerable interest and appreciation from humans. This may be particularly so in the case of the jewel-like Spotted Pardalote.

The Forty-spotted Pardalote, geographically highly restricted, acts as a magnet in drawing birdwatchers to its limited stronghold, particularly Bruny Island. Here, it is the focus of a range of ecotourism initiatives, including accommodation and other ventures.

Pardalotes may be highly beneficial in helping to maintain the health of forest and woodland trees. This is perhaps particularly the case where they can control or prevent outbreaks of psyllids, bugs which otherwise are likely to contribute to extensive tree decay or even to the death of trees.

Status and Conservation

Three members of this family, the Striated, Spotted and Red-browed Pardalotes, are widespread and common. The remaining species, the Forty-spotted Pardalote, is however, highly restricted, with an area of occupancy of less than 500 km² and a fragmented distribution within this. It has a small total population, estimated at 3000–4000 individuals, and has declined substantially over the last 200 years. As a consequence, the Forty-spotted Pardalote is recognized as Endangered by the IUCN and under Australian legislation. Even before European settlement of Australia this specialist species was apparently restricted in its distribution. Its decline since then has been due mainly to clearance of a high proportion of its preferred habitat, forests dominated by the manna gum, and to the partly consequential increase in aggressive colo-

nial honeyeaters, particularly the Noisy Miner, which harass and exclude pardalotes and other small foliage-gleaning insectivorous birds.

Research and management activities over the last three decades have delineated important populations of Forty-spotted Pardalotes; have identified major threats to the species; and have enhanced habitat suitability and levels of protection at key sites. Much of the remaining range of the Forty-spotted Pardalote is now included within national parks and other reserves, or lies on private lands managed with conservation agreements. The species' population is now probably stable.

While the Striated and Spotted Pardalotes are still widespread and abundant, their populations have probably decreased over the last two centuries as a result of extensive clearing of their habitat, particularly in eastern, south-eastern and south-western Australia. These two species are presumably disadvantaged also by commercial forestry in native eucalypt forests. This is because young regrowth eucalypts are less suitable as foraging habitat. Also, in the case of Striated Pardalotes, timber-harvesting reduces the abundance of tree hollows suitable for use as nesting cavities.

Pardalotes are dependent upon native forest and woodland habitats, and are disadvantaged wherever these are cleared or substantially modified. The clearing of eucalypt forests and woodlands may have not only direct site impacts but also consequential impacts, because loss of forest linkages will often disrupt essential dispersal patterns connecting pardalote populations over broader, regional scales.

PLATE 30

Family PARDALOTIDAE (PARDALOTES) SPECIES ACCOUNTS

Genus *PARDALOTUS* Vieillot, 1816

1. Spotted Pardalote

Pardalotus punctatus

French: Pardalote pointillé **German:** Fleckenpanthervogel **Spanish:** Pardalote Moteado
Other common names: Diamond-bird; Yellow-rumped Pardalote (*xanthopyge*)

Taxonomy. *Pipra punctata* Shaw, 1792, "New Holland" = Port Jackson region, New South Wales, Australia.

Most closely related to *P. quadragintus*. Race *xanthopyge* sometimes treated as a separate species, but intergrades with nominate in South Australia (Mt Lofty Ranges); *militaris* less clearly distinct. Three subspecies recognized.

Subspecies and Distribution.

P. p. militaris Mathews, 1912 – NE Australia (coastal and subcoastal NE Queensland).

P. p. punctatus (Shaw, 1792) – coastal and subcoastal SW, S, E & SE Australia (in E, as far N as Clarke Range), including Bass Strait islands (King I, Flinders I) and Tasmania.

P. p. xanthopyge McCoy, 1866 – semi-arid inland SW & SE Australia.

Descriptive notes. 8.5–10.5 cm; 7–12 g. Tiny passerine with exquisite coloration and pattern of spots, short square-cut tail and short deep bill. Male nominate race has black crown with bright white spots, white supercilium, bright yellow throat and breast; face and side of neck to breast side vermiculated blue-grey; upperparts with coarse yellowish-buff spots and black scalloping, rump chestnut, uppertail-coverts red; upperwing black, remiges and wing-coverts tipped white; uppertail black, feathers with small white subterminal spots; underparts below breast mostly pale buff, darker or browner on lower breast and flanks, brighter yellow undertail-coverts; iris brown to blackish or dark greenish; bill black, paler base of lower mandible; legs brown to pinkish-grey. Female is similar to male but duller, with creamy spots on greyer crown, duller and less contrasting supercilium, and yellow of throat less intense and not extending to breast. Juvenile is even duller, with less distinct spotting on crown. Race *militaris* resembles nominate, but spots on upperparts paler; *xanthopyge* has rump and most of uppertail-coverts yellow or orange-yellow, underparts paler than nominate. **Voice.** Surprisingly loud and rich song of 3–4 syllables, "s-leep ba-by", first note weak, last two at higher pitch; Tasmanian populations give simpler, shorter version, usually of 2 notes; race *xanthopyge* song "wit wee-eee". Calls include small range of simple, quiet notes, used as contact and also during breeding.

Habitat. Wide range of eucalypt (*Eucalyptus*) formations, varying from tall open forests with canopy above 30 m to sparse low woodland (canopy below 2 m); accidental or rare in vegetation formations lacking eucalypts. From coastal and semi-arid inland areas up to alpine areas above 2000 m.

Food and Feeding. Diet invertebrates and plant exudates; main items are lerps (the carbohydrate-rich cover of some psyllid insects) and manna (sugary exudate produced by some eucalypts). Arboreal; forages almost exclusively in foliage of eucalypts. Usually singly or in pairs when breeding; at other seasons often in flocks of 10–20 individuals, occasionally several hundreds together; in autumn–winter often joins mixed flocks with congeners, especially *P. striatus*, and thornbills (*Acanthiza*).

Breeding. Season recorded as Jun–Mar, principally Aug–Dec; two broods per season perhaps normal, but proportion of pairs rearing further broods unknown. Monogamous. Nest built by both sexes, a loose dome of bark and grass stems located at end of nearly horizontal shaft dug into sloping ground. Clutch 3–5 eggs, white; incubation by both sexes, period 16–22 days; chicks fed by both sexes, fledging period 18–25 days; young probably independent within 8 days of leaving nest.

Movements. General tendency for post-breeding dispersal to drier inland lowlands and/or more N parts of range, and away from higher altitudes and more S regions (e.g. Tasmania); dispersal pattern, however, possibly complex and irregular, and some individuals or populations may be resident. Dispersal in flocks, at times large (hundreds of individuals), sometimes mixed with *P. striatus*.

Status and Conservation. Not globally threatened. Generally common throughout an extensive range; somewhat elusive, often detected more readily by call. Reported densities 0.1–1.7 birds/10 ha across a set of 16 widely spaced sites in Victoria. Present in many protected areas.

Bibliography. Barrett *et al.* (2003), Christidis & Boles (1994), Cowles (1974), Higgins & Peter (2002), Johnstone & Storr (2004), Keast (1961), Lane (1967, 1974), McCarthy (2006), Mollison (1960), Richards (1972), Rogers *et al.* (1986), Salomonsen (1961b), Schodde & Mason (1999), Short *et al.* (1983), Sonter (1986), Woinarski (1974, 1984a, 1984b, 1984c, 1985a, 1985b, 1988, 1989a), Woinarski & Bulman (1985), Woinarski & McEvey (1983), Woinarski & Rounsevell (1983), Woinarski, Cullen *et al.* (1989), Woinarski, Recher & Majer (1997).

2. Forty-spotted Pardalote

Pardalotus quadragintus

French: Pardalote de Tasmanie **German:** Tasmanpanthervogel **Spanish:** Pardalote Tasmano
Other common names: Forty-spotted Diamond-bird, Many-spotted/Tasmanian Pardalote/Diamond-bird

Taxonomy. *Pardalotus quadragintus* Gould, 1838, "Van Diemen's Land" = Tasmania.

Most closely related to *P. punctatus*. Single specimen from King I (W Bass Strait) named as a geographical race *rex*, but indistinguishable from birds elsewhere in range. Monotypic.

Distribution. E Bass Strait (Flinders I) and SE Tasmania, including some offshore islands (Schouten, Maria, Bruny).

Descriptive notes. 8.5–11 cm; 9–13 g. Tiny passerine with short square tail and short deep bill; lacks pronounced vivid coloration of congeners. Has forehead, crown and most of upperparts subdued olive-green, subtle colour variation on feathers resulting in scaling pattern, generally inconspicuous (other than on close inspection) but most evident on crown; contrasting black upperwing with two regular lines of small but distinct white spots (tips of wing-coverts), tertials with distinct white spots at tips, primaries tipped white; uppertail dark grey, grading to black distally, feathers thinly tipped white;

lores, face, side of neck and undertail-coverts yellowish, rest of underparts paler, grey-white; iris brown; bill blackish; legs pinkish-brown. Sexes similar. Juvenile is duller than adult, with less scalloping on greyer crown, has thin black stripe behind eye, overall body colour more brownish than green-yellow. Voice. Far less conspicuous voice than those of congeners, but larger repertoire. Moderately loud and possibly ventriloquial "k-choo", repeated as song by male. Calls include quieter and more frequently uttered "where-where" as contact, churring call that accompanies agonistic encounters, also a short soft trill of 5–6 notes.

Habitat. Restricted to coastal and subcoastal eucalypt (*Eucalyptus*) forests and woodlands, especially those dominated by manna gum (*Eucalyptus viminalis*).

Food and Feeding. Insectivorous, but diet comprises principally lerps (the carbohydrate-rich cover of some psyllid insects) and manna (sugary exudate produced by some eucalypts); manna appears to be a more important food resource for this species than for its congeners. Arboreal; feeds almost exclusively in foliage of eucalypts. Forages usually in twos or in small flocks, occasionally singly; sometimes associates with *P. punctatus* and *P. striatus* and with Black-headed Honeyeater (*Melithreptus affinis*).

Breeding. Sept–Jan; two broods per season probably common. Monogamous. Nest built by both sexes, a compact dome or cup constructed mainly from fibrous bark of some eucalypt species and grass stems, often with lining of wool, fur and/or feathers; located usually in tree hollow, hollow log or stump (typically in dead wood), rarely in tunnel dug in ground. Clutch 3–5 eggs, white; incubation by both sexes, period 18–23 days; chicks fed by both parents, fledging period 23–25 days.

Movements. Limited data; probably sedentary, but some localized post-breeding dispersal possible. Periods of wet weather, with local food shortages, perhaps force short-distance wanderings.

Status and Conservation. ENDANGERED. Restricted-range species: present in Tasmania EBA. Has tiny global range and small total population, estimated at 3000–4000 individuals. Distribution is closely associated with that of the eucalypt species known to provide greatest abundance of manna. Where present, may occur at reasonably high densities, e.g. 86 breeding adults in 55-ha site. Range formerly more extensive, covering much of E & C Tasmania; substantial decline over last 100 years, probably associated with forest clearance and with spread of Noisy Miner (*Manorina melanocephala*), and aggressive colonial honeyeater. Old record from King I, in 1887. Occurs in several protected areas.

Bibliography. Anon. (2006a, 2007c), Barrett *et al.* (2003), Brown (1989), Brown & Rounsevell (1986), Bryant (1991, 1998a, 1998b), Bulman (1981), Bulman *et al.* (1986), Butchart & Stattersfield (2004), Christidis & Boles (1994), Cochran (1995), Garnett & Crowley (2000), Higgins & Peter (2002), Keast (1961), Rounsevell & Woinarski (1983), Salomonsen (1961b), Schodde & Mason (1999), Stattersfield & Capper (2000), Wall (1982), Woinarski (1984b, 1984c, 1985a), Woinarski & Bulman (1985), Woinarski & Rounsevell (1983), Woinarski *et al.* (1997).

3. Red-browed Pardalote

Pardalotus rubricatus

French: Pardalote à sourcils rouges **German:** Rotbrauen-Panthervogel **Spanish:** Pardalote Cejirrojo

Other common names: Pallid/Red-lore Pardalote, Fawn-eyed/Red-browed Diamond-bird; Cape Red-browed Pardalote (*yorki*); Pale Red-browed Pardalote (*rubricatus*)

Taxonomy. *Pardalotus rubricatus* Gould, 1838, "Australia" = New South Wales. Races intergrade in NW Queensland. Other proposed races are *parryi* (N Western Australia), which is merged with nominate, and *carpentariae* (subhumid zone of NW Queensland), merged with *yorki*. Two subspecies currently recognized.

Subspecies and Distribution.

P. r. rubricatus Gould, 1838 – inland N & C Australia S to SC Western Australia, NE South Australia (L Eyre region) and SW New South Wales.

P. r. yorki Mathews, 1913 – N Queensland (Cape York Peninsula).

Descriptive notes. 9–11.5 cm; 9–14 g. Tiny, attractively patterned passerine with short square-cut tail and short deep bill. Male nominate race has black cap with distinct white spots, pale buff forehead leading on to creamy supercilial stripe with red spot near bill, rather indistinct thin dark eyestripe; neck side and upperparts fawn-brown with thin dark shaft streaks, rump unstreaked yellow-brown, lower rump and uppertail-coverts yellowish with dark shaft streaks; underparts blackish, feathers broadly edged yellow (forming broad yellow panel), edges of remiges and tertials white distally; uppertail black, narrowly tipped white;

throat and underparts creamy, yellow patch on breast; iris straw-coloured to brownish-yellow; bill dark grey, contrasting whitish cutting edges and lower mandible; legs grey to blue-grey or brown. Sexes similar. Juvenile is duller than adult, has dull yellow-brown crown with darker scalloping, less pronounced supercilium, yellow wash over entire underside. Races differ mainly in plumage tones: *yorki* has darker and more heavily patterned back and more pronounced yellow rump than nominate, also deeper yellow in wing. Voice. Loud simple song of 2–6 syllables, "do doo-doo-doo-doo", lasting 1–2 seconds, quite melodious, often with first note lower and longer than others.

Habitat. Wide range of woodlands and open forests, especially riparian woodland dominated by eucalypts (*Eucalyptus*). More likely than congeners to use woodlands dominated by non-eucalypts, especially acacia (*Acacia*) low woodland.

Food and Feeding. Diet poorly known; consists mainly of invertebrates. Arboreal; forages mostly in foliage, typically of eucalypts, but also including other plants. Sometimes feeds on the ground. Usually singly, in pairs, or in small groups of up to five or six individuals; often forages with *P. striatus*.

Breeding. Recorded in all months, mostly Aug–Oct. Nest built by both sexes, cup-shaped and substantial, mostly of bark, lining of grass stems and other finer material, placed in chamber at end of narrow tunnel excavated in ground, typically in eroded bank of creek, tunnel length 45–120 cm, chamber c. 10 cm × 10 cm; occasionally in tree hollow. Clutch usually 3–4 eggs, white; incubation and brood-feeding by both sexes; no information on duration of incubation and fledging periods.

Movements. Little known; resident in much of range.

Status and Conservation. Not globally threatened. Generally common throughout its extensive range. Can be elusive; often detected more readily by means of its voice than by direct observation.

Present in many protected areas.

Bibliography. Barrett *et al.* (2003), Christidis & Boles (1994), Cowles (1974), Ford & Sedgwick (1967), Higgins & Peter (2002), Hornsby (1996), Johnstone & Storr (2004), Lavery (1986), Salomonsen (1961b), Schodde & Mason (1999), Senter (1978).

4. Striated Pardalote

Pardalotus striatus

French: Pardalote à point jaune **German:** Streifenpanthervogel **Spanish:** Pardalote Estriado **Other common names:** (Striated) Diamond-bird; Black-headed Pardalote (N races); Northern Pardalote (*uropygialis*); Eastern (Striated) Pardalote, Red-tipped/Orange-tipped Pardalote (*ornatus*); Yellow-tipped Pardalote (*striatus*)

Taxonomy. *Pipra striata* J. F. Gmelin, 1789, "in America australi"; error = Adventure Bay, Tasmania. Geographical variation in plumage patterning complex, and has led to various taxonomic treatments. At times, nominate race, *substriatus* and *ornatus* treated as three separate species, with N races *uropygialis*, *melvillensis* and *melanocephalus* combined as a fourth species; further, race *uropygialis* has sometimes been proposed as an additional species. Treatment of all races as representatives of a single variable species now considered more appropriate, as substantial evidence exists of interbreeding and intermediates where races come into contact. Other proposed races include: *bowensis* (CE Queensland) and *barroni* (Cairns, N Queensland), synonymized with *melanocephalus*; and *restrictus* (Jardine R, N Queensland), synonymized with *uropygialis*. Six subspecies currently recognized.

Subspecies and Distribution.

P. s. uropygialis Gould, 1840 – N Western Australia E to N Queensland (Cape York Peninsula).

P. s. melvillensis Mathews, 1912 – Tiwi Is (off Northern Territory), in N Australia.

P. s. melanocephalus Gould, 1838 – NE Australia from NC Queensland (foot of Cape York Peninsula) S to NE New South Wales.

P. s. substriatus Mathews, 1912 – much of W & C Australia (except N parts, deserts and Nullarbor Plain).

P. s. ornatus Temminck, 1826 – SE Australia.

P. s. striatus (J. F. Gmelin, 1789) – breeds Bass Strait islands and Tasmania; non-breeding E & SE Australia.

Descriptive notes. 9–12 cm; 9–15 g. Tiny, attractively patterned passerine with short square-cut tail and short deep bill. Nominative race has cap, nape, loreal stripe and ear-coverts black with distinct white streaks, broad supercilial stripe bright yellow near bill and white posteriorly; upperparts fawn-brown, rump pale brown; underparts black, primaries narrowly edged white (forming very narrow white stripe on wing), tertials edged more prominently white, outer tertial partly edged rufous-brown, small yellow tips of primary coverts; uppertail black, feathers narrowly tipped white; bright yellow chin and throat, yellowish breast,

creamy belly to vent, yellowish-olive band on flanks; iris dark brown to blackish; bill black, sometimes pale base of lower or both mandibles; legs dark slate to brown or pinky brown. Sexes similar. Juvenile is duller than adult, with less marked head pattern, less distinct yellow on throat. Races differ mainly in plumage pattern, especially of head and wing, and in colour tones: *ornatus* is very like nominate, but tips of primary coverts red (not yellow), crown streaking extending somewhat less on to forehead; *substriatus* closely resembles previous, but has much more white in wing (forming broad white panel on primaries); *melanocephalus* is distinctive, has cap, eyestripe and ear-coverts solid black (lacking white streaks), anterior supercilium deeper yellow to orange, rump and uppertail-coverts richer buff, wing as previous (broad white wingpanel, red tips of primary coverts); edge of outermost tertial less extensively rufous-toned or, instead, pale yellow; *uropygialis* is very like previous, but rump and most of uppertail-coverts yellow to orange-yellow or yellow-buff, red on primary coverts darker, outer tertial usually all white-edged, black eyestripe narrower, anterior supercilium usually deeper orange; *melvillensis* is very like last, but rump and uppertail-coverts deeper orange-yellow. Voice. Loud song of 2–7 notes, most typically "wit-e-chu" or "wit-wit", with some regional variation; uttered frequently, especially in breeding season. Various other vocalizations, given far less frequently, include trilling call, and brief contact call when in flocks.

Habitat. Wide range of eucalypt (*Eucalyptus*) formations, varying from tall open forests with canopy higher than 30 m to sparse low woodlands with canopy below 2 m; accidental or rare in vegetation formations without eucalypts. From coastal and semi-arid inland areas to alpine areas above 2000 m.

Food and Feeding. Food predominantly invertebrates, especially lerps (the carbohydrate-rich cover of some psyllid insects); in some areas, also takes the plant exudate manna. One record of an individual capturing and consuming a skink (Scincidae). Arboreal; feeds almost exclusively in foliage of eucalypts. Usually singly or in pairs in breeding season; in autumn and winter often forms flocks, sometimes of hundreds of individuals, and often joins mixed flocks.

Breeding. Recorded in all months, typically Aug–Dec in temperate S Australia; two broods per season possibly normal, but proportion of pairs rearing multiple broods unknown. Monogamous. Nest built by both sexes, a loose dome or cup-shaped structure made from bark, grass stems and/or "needle" foliage from pines and similar species, sometimes with some fur or feathers in lining, located in tree hollow or in tunnel constructed in ground, in latter case generally in eroded creek bank, cliff or similar nearly vertical surface; tunnel generally horizontal, variably 15–100 cm in length, with opening 4–6 cm wide, and with larger nest-chamber at distal end. Clutch 3–5 eggs, white; incubation by both sexes, period 15–23 days; chicks fed by both parents, fledging period 21–25 days.

Movements. Movement patterns not well known, and probably vary across range. Tasmanian population (nominate race) makes post-breeding migration to Australian mainland, extending N at least to SE Queensland, and populations breeding in mountain areas in SE Australia move to coastal or inland lowland areas for winter; movements by other populations may be less regular; some individuals or populations probably resident. Post-breeding dispersal often in large flocks (hundreds of individuals), sometimes mixed with *P. punctatus*; such flocks may search for outbreaks of psyllids.

Status and Conservation. Not globally threatened. Generally common throughout range; can be hard to locate, and often detected more readily from call than by direct observation. Reported densities of 0–1–16 birds/10 ha across 16 widely spaced sites in Victoria. Present in many protected areas.

Barrett *et al.* (2003), Bell (1959), Christidis & Boles (1994), Cooper (1961), Cowles (1974), Dell (1984), Ford (1986), Girvan (1994), Green (1971), Higgins & Peter (2002), Hindwood & Mayr (1946), Hyett (1963), Johnstone & Storr (2004), Keast (1961), Lane (1974), Macdonald (1969), Mayr (1961), McCarthy (2006), Mees (1965b), Reid & Cox (1981), Rogers *et al.* (1986), Salomonsen (1961c), Schodde & Mason (1999), Woinarski (1974, 1984b, 1984c, 1985a, 1985b, 1988, 1989a), Woinarski & Bulman (1985), Woinarski & McEvey (1983), Woinarski & Rounsevell (1983), Woinarski, Cullen *et al.* (1989), Woinarski, Dorward & Cullen (1983), Woinarski, Recher & Majer (1997).

Class AVES
Order PASSERIFORMES
Suborder OSCINES
Family ZOSTEROPIDAE (WHITE-EYES)

- Small, warbler-like passerines with brush-tipped tongue, all except one species having vestigial outermost primary; often with olive-green upperparts and yellow throat, and yellow or white belly, many with conspicuous white eyering.
- 9.5–16 cm.

- Old World.
- Forest, open woodland and gardens to offshore islets and alpine shrubland.
- 14 genera, 98 species, 250 taxa.
- 20 species threatened; two species and two subspecies extinct since 1600.

Systematics

The first white-eyes ever scientifically described, all in 1760, were the Mascarene White-eye (*Zosterops borbonicus*) and Malagasy White-eye (*Zosterops maderaspatanus*), believed by the author, M. J. Brisson, to be *Ficedula* flycatchers, and the Reunion Olive White-eye (*Zosterops olivaceus*), thought at the time to be a *Certhia* treecreeper. Before receiving the present generic name, white-eyes were successively included in the wagtail genus *Motacilla*, the Old World warbler genus *Sylvia*, and the flowerpecker genus *Dicaeum*. In 1827, the name *Zosterops* was introduced by N. A. Vigors and T. Horsfield, and this word was finally decreed to be of masculine gender, although there is still disagreement about the respective genders of the composite words *zoster*, meaning a belt or girdle, and *ops*, eye. This remarkably homogeneous genus now includes a large number of similar-looking birds, encompassing 210 different forms belonging to 74 species. Other, closely related genera, believed to be derivatives of *Zosterops*, have been described alongside.

Most classifications have regarded the white-eyes as representing a distinct family. The brush-tipped tongue has been the basis for placing them next to the nectarivorous groups of sunbirds (Nectariniidae) and honeyeaters (Meliphagidae), and they have sometimes been treated as a subfamily of the sugarbirds (Promeropidae). More recently, DNA data have indicated that they are part of a sylvioid lineage that diverged about 40–42 million years ago, in the Oligocene, and they have therefore been included within the superfamily Sylvioidea, between the Old World warblers (Sylviidae) and the largely African cisticolas and allies (Cisticolidae). This suggests that the white-eyes may be only distantly related to the Meliphagidae, which are put in the “parvorder Corvida”, whereas the white-eyes are accommodated in the “parvorder Passerida”, together with the Nectariniidae. The latest molecular studies indicate a relationship with the babblers (Timaliidae), and place the white-eyes in a clade with *Yuhina* and *Stachyris* babblers. Ironically, the Sumatran race *frigida* of the Golden Babbler (*Stachyridopsis chrysaea*) was described by G. Hartlaub, in 1865, under the generic name of *Heleia*, a white-eye genus, before being included in the babblers, and it was not until a long time thereafter, in the 1990s, that the true position of the Golden White-eye (*Cleptornis marchei*) was realized, this monotypic genus having previously been considered to belong in Meliphagidae, the species then being known as the “Golden Honeyeater”.

The abundance of morphologically very similar forms may appear to present a promising opportunity for the study of speciation and evolution. Morphology and distribution have guided most museum workers in their attempts towards a synthesis, apparently supported by facts known about general behaviour, nesting, vocalizations and other aspects. Nevertheless, it is still practically impossible to postulate relationships among the species of the Zosteropidae, despite numerous serious attempts by such authorities as R. E. Moreau, for the western taxa, and E. Mayr and G. F. Mees, for the eastern taxa. In particular, the complex colour variations within and between populations, the result of differences in the amount and distribution of melanins and yellow carotenoids, as well as the dispersal of polymorphic populations, have led to confusion with regard to the taxonomic affinities within the family.

Ecology is not a very reliable guide to relationships among species. The Oriental White-eye (*Zosterops palpebrosus*), for example, includes a subspecies restricted to hills above 400 m,

Subdivision of the
Zosteropidae

[Figure: Douglas Pratt]

The family *Zosteropidae* comprises nearly 100 species, shared among 14 genera. The most speciose genus, *Zosterops*, contains roughly three-quarters of the species. Typical white-eye features include olive-green upperparts, a yellow throat and a prominent white eyering. This last gives the family its morphologically inexact vernacular name, for only a few white-eyes have the irides themselves white. Several species show patches of distinctive coloration, as is the case of the **Chestnut-flanked White-eye**. The flank patch may be less intensely coloured in the female, which can also have grey lores as opposed to the male's black.

[*Zosterops erythropleurus*,

as well as others on coral islands. An extreme case is found with the subspecies *maxi* of the Lemon-bellied White-eye (*Zosterops chloris*), which has populations on small coral islands in the western part of its range, but occurs throughout the mainland of large islands in the east.

Similarly, the possession of a brush-tipped tongue has proved to be of minor taxonomic significance, as demonstrated by the modern rearrangement of the former "trinity" of the sunbirds, the white-eyes and the honeyeaters into the superfamilies of, respectively, Passeroidea, Sylvioidea and Meliphagoidea. Likewise, belly colour has minor importance as a specific character, as is suggested by apparently unhindered interbreeding of "different-bellied" races of the Cape White-eye (*Zosterops pallidus*) in South Africa, and by the equivalent behaviour by Oriental White-eyes in Java. The dismissing of belly-colour differences as representing no more than colour "phases" or morphs, as has sometimes been done, is not really an acceptable option, as white-eyes generally do not have morphs. The difference between yellow and grey is determined by multiple genetic factors, as indicated in western Java, where the grey subspecies *buxtoni* and the yellow race *melanurus* of the Oriental White-eye overlap. The gradual transition in Oriental Mountain White-eyes (*Zosterops montanus*) from a yellow median streak to an entirely yellow belly is also indicative of such a multiple factor. Whereas in South-east Asia the belly seems to change from grey to yellow, as is the case with the Oriental Mountain White-eye, in Africa it changes from yellow to grey. Throughout the global range of the family there are species that are in the process of losing the yellow pigment, and the Micronesian Grey-brown White-eye (*Zosterops cinereus*) has even lost its yellow pigment entirely, as well as its white eyering.

Vocalizations are of variable use in determining relationships. Calls appear to have little or no taxonomic value. Call notes resembling those of a sparrow (*Passer*) are shared by distantly related species such as the Bridled White-eye (*Zosterops conspicillatus*), the Lemon-bellied White-eye, the Sri Lanka White-eye (*Zosterops ceylonensis*) and the Solomon White-eye (*Zosterops kulambangrae*), whereas both of the closely related species from the Kai Islands, the Golden-bellied (*Zosterops uropygialis*) and Pearl-bellied White-eyes (*Zosterops grayi*), have very different calls. Song may be a more trustworthy criterion for judging relationships, and some African white-eyes have been split on the basis of song differences. It has been suggested that, among some Micronesian forms, the lack of a complex song, as illustrated by the Citrine White-eye (*Zosterops semperi*), indi-

cates a Melanesian ancestor, whereas a relatively complex song, as sung by the Bridled and Plain White-eyes (*Zosterops hypolais*), is indicative of derivation from continental forms to the north, which also have complex songs. A closer and more general study of calls, song and behaviour may lead to a better understanding of relationships.

Morphology does not always correspond with variation in mitochondrial DNA (mtDNA), and this is demonstrated by Silvereyes (*Zosterops lateralis*), the present subspecies boundaries of which are not entirely congruent with the distribution of mtDNA haplotypes. This may reflect local processes, rather than evolutionary ones. The same is true for the poor correspondence of boundaries between the Australian Yellow White-eye (*Zosterops luteus*) and the Silvereye and the distribution of mtDNA haplotypes, in which eastern samples of the former appear more closely related to eastern Silvereyes than they do to western samples of the Australian Yellow White-eye. This is probably due to historical hybridization.

It is postulated that dispersal of the white-eye family took place from Africa and Asia into the Central Pacific. In the Indian and Pacific regions in particular, white-eyes are widespread and are represented by many species; they have been able to colonize the most remote archipelagos, with high rates of endemism in both regions. Unlike trends found in other bird groups, with white-eyes there is a greater incidence of congeneric sympatry on small islands than on continental mainlands. Their social behaviour, preferences for marginal habitats, and good flying abilities make white-eyes good colonizers of small islands. When these "marginal" species colonize islands, they move into the native forest, in which their competitors in forest on the mainland are absent. Increased specialization by the species arriving first facilitates a second successful invasion. When new colonists arrive, the first-comers are replaced in the lowlands, resulting in rarity, extinctions, restriction to interior mountain areas, relict distributions and, ultimately, sustained co-existence of two species.

There are a number of cases of apparent sympatry of *Zosterops* species, although only a minority of these are genuine, because, in most cases, altitudinal, geographical or major ecological separations are involved. The largest assemblages are on the large island of New Guinea, where the Black-crowned (*Zosterops atrifrons*), Capped (*Zosterops fuscicapilla*) and New Guinea White-eyes (*Zosterops novaeguineae*) can be found at one locality, as well as on the tiny island of Norfolk, where the closely related Slender-billed (*Zosterops tenuirostris*) and White-chested White-eyes (*Zosterops albobularis*) and the Silvereye co-occur.

The broad white eyering of many members of Zosteropidae is formed by scale-like feathers around the eye. In some species, these feathers are grey or black rather than white. In others, such as the **Black-ringed White-eye**, the white feathers are present but reduced in number, their place being taken by a continuation of the black loreal line that loops around the eye. In common with other zosteropids, the Black-ringed White-eye has slender but strong legs that are an adaptation to the family's arboreal life.

[*Zosterops anomalus*, Karaenta Forest, near Makassar, Sulawesi. Photo: Pete Morris]

Two types of colonists of small and remote islands can be distinguished. The first is endemic species, usually confined to a single geologically fairly old island, with at most some adjacent islands; examples are the Christmas White-eye (*Zosterops natalis*) and the Enggano White-eye (*Zosterops salvadorii*). The second type consists of widely ranging taxa usually inhabiting coral islets of recent origin; examples include the subspecies *maxi* and *chloris* of the Lemon-bellied White-eye, the race *albiventris* of the Ashy-bellied White-eye (*Zosterops citrinella*) and the race *eichhorni* of the Louisiade White-eye (*Zosterops griseotinctus*). The seasonality of food resources of small coral islands, and their poor flora and fauna, coupled with a size hardly large enough to support a viable population for any length of time, do not permit their inhabitants to be sedentary, as sedentary birds could easily become extinct. When remote islands or groups of islands are colonized, however, selection pressure may strongly favour the development of sedentariness.

Difference in the speed of the speciation process among white-eyes is nicely demonstrated by four forms in the Australasian region. These are the extinct Robust White-eye (*Zosterops strenuus*), which formerly occurred on the offshore island of Lord Howe, the White-chested and Slender-billed White-eyes on Norfolk Island, and the nominate race of the Silvereye of Flinders Island, Tasmania and New Zealand. The first three island forms developed from the last, as indicated by plumage characters such as a pale throat and deep brown flanks; the "islet" species must, therefore, have developed into species after the nominate race of the Silvereye had become racially differentiated from neighbouring populations in south-east Australia, but it is apparent that the three did so in a much shorter time. Another example of rapid speciation is that of the Silvereye, following its arrival in 1904 on Norfolk Island, where the two endemic species, the White-chested and Slender-billed White-eyes, both originating from Silvereyes, already existed. Measurements in 1926 indicated narrower bills than in 1912–1913, a possible selective adaptation, not produced by hybridization among local species, which had been reversed by 1968–1969. A relatively old Silvereye race, *tephropleurus* of Lord Howe Island, often regarded as a full species, has an estimated age of hundreds of thousands of years; less distinct races, such as *chlorocephalus* of the Bunker and Capricorn Groups, in the Great Barrier Reef, are reckoned to be some 3000–4000 years old. In contrast, an old species, the Slender-billed White-eye, which is confined to Norfolk Island, is millions of years old.

In north-east Australia, DNA "fingerprinting" revealed an absence of significant gene flow between isolated populations of Silvereyes in the Capricorn Islands, in the Great Barrier Reef,

and in mainland Queensland. The mtDNA haplotypes of the distinct Capricorn subspecies *chlorocephalus* and the adjacent mainland race are identical, but frequencies of their variants differ. This suggests that *chlorocephalus* may be a recent derivative from the mainland, but one that has become effectively isolated. Indeed, mainland Silvereyes do winter on the islands, but they never stay on to breed. Populations inhabiting the mainland are thousands of years old, while that on Heron Island is some 3000–4000 years old, and that on Lady Elliott Island is just two decades old; the degree of genetic variability reflects both their size and the time elapsed since colonization. Other molecular research showed that founder effects in populations of the Silvereye in Tasmania, on both of the main islands of New Zealand and in the Chatham Islands, to the south-east of Australia, are weak, and it is assumed therefore that the new populations, with large effective founder numbers of 150–200 individuals, were not founded by small flocks of fewer than 100 individuals, but by a large flock or several average-sized flocks, as genetically diverse as the source

The largely olive-green plumage of white-eyes appears to be an adaptation to their habitat, providing camouflage amidst arboreal foliage. In species such as the **Golden-green White-eye**, bright colours are almost entirely forsaken in favour of tones that promote concealment. Apart from a bright yellow area around the forehead and lores, the plumage of this white-eye is yellow-olive. Intriguingly, some individuals lack the short black loreal line found in almost all Zosterops. The presence of this line may be related to the foraging behaviour of open-bill probing known as "Zirkeln".

[*Zosterops nigrorum innominatus*, Mount Makiling National Park, Luzon, Philippines. Photo: Doug Wechsler/VIREO]

Many white-eyes have several subspecies, and these commonly vary in plumage. The **Abyssinian White-eye** is a case in point, with six subspecies spread over an area extending from the Middle East south to Tanzania. These taxa vary principally in the tone of the upperparts and underparts, and the presence or absence of a discrete throat patch. The race *jubaensis* occurs in south Ethiopia, north Kenya and south Somalia; it differs from most other races in its more yellow-green upperparts and uniform warm yellow underparts. The race *arabs* of Saudi Arabia, Yemen and Oman is similar to nominate *abyssinicus* of north-east Sudan, Eritrea and north and central Ethiopia; both have greyish-green upperparts, a pale yellow chin and throat, and greyish underparts. Race *socotranus* of north Somalia and Socotra is similar, differing mainly in its brighter yellow throat and blackish bill. Some authors consider that the four subspecies mentioned constitute one species, with the two other races accepted herein forming a distinct species.

population. An island such as Norfolk Island, with an effective number of founders of 20, was probably colonized by a single flock of moderate size.

Typical features of the white-eye family include the occurrence of montane and lowland species on the same island. Although rarely more than two species are sympatric, many islands have had double invasions of white-eyes, and Norfolk Island has been invaded three times. Further characteristics of the Zosteropidae are the alternation of yellow and grey in the abdomen colour among representatives of the same species, and a great similarity between taxa which must, in fact, be distinct species. Examples of virtually indistinguishable but distantly related taxa are the south Indian subspecies *nilgiriensis* of the Oriental White-eye and the nominate, Lesser Sunda race of the Ashy-bellied White-eye. A similar pair is the Annobon White-eye (*Zosterops griseovirescens*) and the Christmas White-eye. This insular plasticity in closely related *Zosterops* species is illustrated by the Golden-bellied White-eye and the Pearl-bellied White-eye, two species living on two separate but near-contiguous islands. These two species of the Kai Islands show how a narrow stretch of water, the two main islands of the group being separated by only about 7 km of sea, can perfectly isolate two different populations which could subsequently differentiate into very distinct forms. A similar situation is found with the Louisiade White-eye group in the Solomon Islands.

The genus *Zosterops* seems to be the most "primitive", with species closest to the ancestral forms of the family. All other genera have a limited number of species, with often very restricted geographical ranges, and are merely modified offshoots from a stock of *Zosterops*-like ancestors. The Asian-Pacific branch of the genus *Zosterops* comprises eight superspecies, involving a combined total of some 31 species; in addition, there are 29 independent species.

The Oriental White-eye forms a superspecies with the Japanese (*Zosterops japonicus*) and Lowland White-eyes (*Zosterops meyeri*). The Oriental White-eye is a widespread species, represented in eleven subspecies distributed from Oman, in south Arabia, eastwards to Flores, in the Lesser Sunda; these include a number of races on offshore islands, such as the race *nicobaricus*, which must have colonized the Andamans and Nicobars from the continent, rather than from the closer Sumatra. An offshoot of much older date is the Sri Lanka White-eye. Other species possibly closely related to this superspecies are the Chestnut-

flanked White-eye (*Zosterops erythropleurus*) and the Enggano White-eye.

In Micronesia, the Bridled, Rota (*Zosterops rotensis*), Citrine and Plain White-eyes form a superspecies occurring in the Northern Mariana, Palau and Caroline Islands. This group exhibits some affinity to species to the west and south-east of Micronesia, rather than to the north and north-west, and it may therefore have colonized Micronesia from the Philippines or the Moluccas, rather than directly from Melanesia; the Citrine White-eye, which bears a resemblance to the Golden-green White-eye (*Zosterops nigrorum*) of the Philippines, appears to be a possible connecting link. Mitochondrial-sequence data indicate that the Yap Olive White-eye (*Zosterops oleagineus*), previously placed in the genus *Rukia*, is better accommodated under *Zosterops*, and it may be most closely related to the Citrine White-eye, both occurring allopatrically in the Caroline Islands. It is distinguished from this and other *Zosterops* species by its large size and its melanistic plumage, possibly reflecting rapid differentiation in an island population.

Within *Zosterops*, the Yellow-spectacled White-eye (*Zosterops wallacei*) is unique in having an orange forehead, a colour found in few other members of the genus, and a yellow, not white, eyering, but above all in having speckled instead of uniformly white or bluish eggs, an aberrant wing formula and a trace of a superciliary stripe. It is possibly an intermediate form between the genera *Lophozosterops* and *Zosterops*, and may be better placed before or after the Grey-brown White-eye. The Javan White-eye (*Zosterops flavus*) seems to be an old inhabitant of the south-eastern border of the Pleistocene Sunda shelf; its once contiguous range was apparently split up into Java, Madura and southern Borneo by the rising of the Java Sea.

The Lemon-bellied and Ashy-bellied White-eyes form a superspecies, and the Golden-bellied and Pearl-bellied White-eyes constitute another. The last two are found on the periphery of the Kai Islands, which were recolonized by the Lemon-bellied White-eye in postglacial times, and they are therefore sometimes included in the same superspecies as the latter. It is possible that the Pale-bellied White-eye (*Zosterops consobrinorum*) of Sulawesi also belongs to this group. The superficially very similar Oriental, Oriental Mountain, Lemon-bellied and Ashy-bellied White-eyes include yellow-bellied and grey-bellied forms, and they apparently have a common history associated with successive invasions or reinvasions.

In recent times, several white-eyes new to science have been discovered. The predilection of the family for small islands has produced a number of restricted-range endemics, for example in the islands around Sulawesi. Another example comes from the island of Vanikoro in the Solomon Islands. In 1994, the hitherto unknown white-eye seen here was discovered, and found to be not uncommon. The taxon differs from the Santa Cruz White-eye (*Zosterops sanctaecrucis*) of the nearby island of Santa Cruz by dint of its more slender bill and yellow-orange (rather than blue-grey) legs. The scientific description of this taxon is shortly to be published.

The genus *Lophozosterops* contains six largely montane species from Indonesia and the Philippines. Three of these species, including the **Javan Grey-throated White-eye**, form a superspecies. They are similar in ecology and morphology, all, for example, lacking a white eyering. As a genus, *Lophozosterops* is morphologically distinct from other Zosteropidae in two characteristics: the bill has a gently curved culmen; and the wings are long and pointed, in contrast to the short, rounded wings of most family members.

[*Lophozosterops javanicus frontalis*,
Gede-Pangrango National
Park, Java.
Photo: Ketil Knudsen]

The genus *Heleia* contains two monotypic species that are restricted to the Lesser Sundas. The **Thick-billed White-eye** occurs in forests up to 2000 m on the islands of Flores and Sumbawa, whereas the **Spot-breasted White-eye** (*Heleia muelleri*) occurs in lowland and mid-altitude forest on Timor. Morphologically, this stocky genus is characterized by a strong bill, a long tail and a very short second primary. In contrast to the predominantly yellow and olive plumage of its congener, the **Thick-billed White-eye** is drab olive-brown above and whitish below. It does, however, have a striking head pattern.

[*Heleia crassirostris*, Flores, Lesser Sundas. Photo: Morten Strange]

The genus *Chlorocharis* contains a single species, endemic to moss forests and stunted growth in montane Borneo. The affinities of the **Mountain Black-eye** with other white-eyes are unclear. It is relatively long-tailed and has a long, slender, decurved bill with an orange-yellow lower mandible. Its most striking plumage feature is a small black eye mask with a broad yellow border. There are four subspecies, which vary clinally, with larger, longer-tailed, darker birds in north Borneo gradually giving way to smaller, short-tailed, paler birds in the south.

[*Chlorocharis emiliae*, Kinabalu Park, Sabah, Borneo. Photo: Doug Wechsler/VIREO]

Another superspecies in this region consists of eight species, each a geographical representative on islands or island groups around New Guinea. They appear quite different from one another, with the belly yellow or white, the forehead black or olive, the eyering broad or lacking altogether, and the throat orange, yellow or whitish. These eight are the Creamy-throated White-eye (*Zosterops atriceps*) from Halmahera, the Black-crowned White-eye from north Sulawesi and the Sula Archipelago, the Togian White-eye (*Zosterops somadikartai*), the Sangihe White-eye (*Zosterops nehrkorni*) and the Seram White-eye (*Zosterops stalker*) from their respective islands, the Black-fronted White-eye (*Zosterops minor*) from mainland New Guinea, the White-throated White-eye (*Zosterops meeki*) from Tagula, in the Louisiades, and the Black-headed White-eye (*Zosterops hypoxanthus*) from the Bismarck Archipelago. The Capped White-eye may be an old offshoot of this "species group", as is suggested by the striking similarity of its nominate subspecies to the Black-headed White-eye. Likewise, the Buru Yellow White-eye (*Zosterops buruensis*) may be a geographical representative of the group. The Christmas White-eye is likely to be a derivative of the Lemon-bellied White-eye, but it has a relatively longer tail than almost any of the other Indo-Australian white-eyes; interestingly, African white-eyes seem generally longer-tailed than the Asian species.

The next superspecies consists of six species native to the Louisiades and the Solomon Islands, where they replace each other geographically. They differ from one another in colour, rather than in morphology or size; thus, they vary in having no black to much black on the forehead, no green to much green on the breast, a white belly or a yellow one, a yellow or black bill, and a large eyering to no eyering at all. Four of the species occur in the New Georgia Group, each living within 8–14 km of an island holding another member of the superspecies. One of these, the Solomon White-eye, is further subdivided into three very distinct subspecies, these differing distinctly in, for instance, song pattern in places where they are separated by only 3.4 km of water. The Louisiade White-eye may have evolved after the last glacial period from the island of Misima, known also as St Aignan Island, which was cut into smaller islands by rising sea-levels. The subspecies which then evolved could have colonized the other islands. In particular, the race *eichhorni* is an inhabitant of small coral islands, having a good facility for colonization and expansion; this form is therefore found over a fairly large range, within

which it shows no geographical variation. The Splendid White-eye (*Zosterops luteirostris*) has weak but distinct bristles on the gape, something which is not of general occurrence in *Zosterops*, but the phylogenetic significance of which is unclear. The Rennell White-eye (*Zosterops rennellianus*) differs in bill shape, in lacking an eyering and in having yellow feet, and its plumage is intermediate between the soft plumage of the nominate race and subspecies *pallidipes* of the Louisiade White-eye and the stronger, almost shiny plumage of the Solomon and Admiralty Islands subspecies *eichhorni* of the latter species. The Kolombangara Mountain White-eye (*Zosterops murphyi*) is morphologically extremely similar to, and apparently very closely related to, the Louisiade

Four islands in Micronesia each have their own large, distinctive species of white-eye. On Palau is the **Giant White-eye**, the sole member of its genus. Morphologically and vocally it is so different from other white-eyes that observers seeing it for the first time might not initially realize what group it belongs to. The Giant White-eye has a large, deep bill, a fairly short tail, broad flight-feathers, including a short second primary, and surprisingly stout legs for an arboreal bird.

[*Megazosterops palauensis*, Ngeremdiu beach, Ngeruktabel Island, Palau. Photo: Mandy Etpison]

White-eye and should perhaps be included in this group. It inhabits the mountain area of Kolombangara Island, where the lowlands are inhabited by the Solomon White-eye, which is of later arrival at the island but evidently derived from the same ancestral species within northern Melanesia.

Although the taxonomic affinities of the Yellow-throated (*Zosterops metcalfei*) and Grey-throated White-eyes (*Zosterops rendovae*) are unclear, it has been speculated that both may be related to the "*Z. atrifrons* group". The two species, however, co-occur on Bougainville, and they are therefore probably old endemics of the Solomon Islands. A rather speculative proposal is that the Fiji (*Zosterops explorer*), Yellow-fronted (*Zosterops flavifrons*), Small Lifou (*Zosterops minutus*) and Green-backed White-eyes (*Zosterops xanthochroa*) form a superspecies, on the basis of their sharing of yellow underparts and living in the same general region.

The taxa within the "*Z. lateralis* group" are characterized by their grey back, and their origin is therefore more easy to trace back than is that of most other members within the family. The most likely hypothesis is that the group evolved from an ancestral Silvereye on the Australian mainland, from where successful colonizations of islands in the south-west Pacific followed. Their specific status is elucidated by their co-existence with second and sometimes even third invaders derived from the mainland stock. Vanuatu, New Caledonia, the Fiji Islands and New Zealand are now inhabited by Silvereyes; Lord Howe Island is home to two forms, the Silvereye subspecies *tephropleurus*, also known as the "Lord Howe Island White-eye", and the now extinct Robust White-eye; Norfolk Island is inhabited by the Slender-billed and White-chested White-eyes and the nominate race of the Silvereye; and Lifou, in the Loyalty Islands, has been colonized by two forms, the Large Lifou White-eye (*Zosterops inornatus*) and the Silvereye race *melanops*. DNA research shows that all continental Silvereye forms intergrade through broad zones, and that neighbouring subspecies are each other's closest relatives; this suggests that the group should not be split into separate species.

The Grey-brown White-eye and the Dusky White-eye (*Zosterops finschii*) share a total lack of yellow, a nearly total absence of green in the plumage, and the absence of a white eyering. Their relationship to other species is unclear. It has been suggested that they are derived from the Creamy-throated White-eye of the northern Moluccas, but this is unconvincing.

The African and Oriental forms of *Zosterops* must have been isolated from each other a long time ago. Although the Sri Lanka White-eye is most likely a derivative from the Oriental White-eye on the Indian mainland, its affinities may be found just as well in the west, considering its morphological resemblance to the Malagasy White-eye. It is very likely also that the Abyssinian White-eye (*Zosterops abyssinicus*), with a population in Yemen, extended much farther east during the Neolithic humid episode in these latitudes, about 6000 years ago. The Oriental White-eyes recently found in Oman are the closest oriental forms, but these do not represent a relict population but, rather, recent colonists, as indicated by the analysis of their DNA and tape recordings.

In the African representatives of *Zosterops*, a complex situation is presented by the five or more mainland species, with 33 distinct subspecies. In past decades various forms have been switched across species and species complexes, and a definitive arrangement appears still to be elusive. One superspecies can be distinguished, that formed by the African Yellow White-eye (*Zosterops senegalensis*), a mainland species, and the Pemba White-eye (*Zosterops vaughani*), a small-island endemic. Sometimes, the Abyssinian, African Montane (*Zosterops poliogastrus*), African Yellow and Cape White-eyes are put in one superspecies, but the relationships among these are unclear. Speciation in the 19,400-km² mountain area of Kilimanjaro east to Taita and the Usambara Mountains, on the Kenya-Tanzania border, has been extreme, and five species or subspecies of montane *Zosterops* have developed on mountains separated by extremely narrow gaps. One of these is the African Montane White-eye, which some authors split into six full species on the grounds mainly of vocal differences.

On the tiny islands in the Gulf of Guinea, off West Africa, two endemic species occur. These are the Principe White-eye (*Zosterops ficedulinus*) and the Annobon White-eye. The Malagasy region has seven *Zosterops* species. Of these, two species of the Mascarene Islands, the Reunion Olive White-eye and the Mauritius Olive White-eye (*Zosterops chloronothos*), form a superspecies, and are adapted to nectarivory to a greater extent than are the other white-eyes; their long, fine, curved bill and strong legs very much resemble those of members of the family Nectariniidae. Their wing-flicking action and "chipping" calls may suggest a relationship to the similar Seychelles Grey White-eye (*Zosterops modestus*), although DNA results do not support

this. The other Mascarene endemic, the Mascarene White-eye, is apparently of more recent origin, within the last 1.2 million years, although not particularly close to others in the genus; vocally, it seems closer to mainland African species and the Seychelles species than it does to the two olive white-eyes. It is interesting that the first white-eyes to colonize the Mascarene Islands became more specialized flower-feeders, rather than more generalized in the absence of competitors, which is counter to the expectation that a reduced competitive environment would allow niche expansion. The co-existence with a generalized second successful colonizer was therefore facilitated. Socially, the species differ noticeably, the Reunion Olive and Mauritius Olive White-eyes being territorial throughout the year, whereas social feeding is common for the Mascarene White-eye. The Chestnut-sided White-eye (*Zosterops mayottensis*) and the extinct Seychelles Yellow White-eye (*Zosterops semiflavus*), of Mayotte and the Seychelles, respectively, are probably related to the mainland African Yellow White-eye, and thus of more recent arrival than the Seychelles Grey White-eye.

In the Comoro Islands, the Mount Karthala White-eye (*Zosterops mouroiensis*) inhabits the main island, and has a larger size and more melanin in the plumage, as is typical of montane *Zosterops* throughout Africa. The other islands are inhabited by the Malagasy White-eye, a species of much wider distribution; on Grand Comoro (Njazidja) it is segregated by altitude from the Mount Karthala White-eye.

Turning now to the other genera in the family, the genus *Woodfordia* consists of two species of very large size. Indeed, Sanford's White-eye (*Woodfordia lacertosa*) is the second largest member of the white-eye family. Both are relatively short-tailed, sturdy birds with a long, pale bill and rounded wings, and both are atypically coloured, with the plumage mainly brown and citrine. The two species are found in the Solomon Islands, the Bare-eyed White-eye (*Woodfordia superciliosa*) on Rennell and Sanford's White-eye in the Santa Cruz Group, their ranges being separated by 750 km of open sea. Considering the fact that white-eyes have crossed much larger stretches of sea elsewhere, colonization of one island from the other appears very possible.

The Micronesian islands of Palau, Yap, Chuuk and Pohnpei each have their own endemic species of large white-eye. These are the Giant White-eye (*Megazosterops palauensis*) of Palau, the Yap Olive White-eye, the Faichuk White-eye (*Rukia ruki*) of Chuuk, and finally, on Pohnpei, the Long-billed White-eye (*Rukia longirostra*). These are so distinctive that at one time each one was placed in its own monotypic genus, the Yap Olive White-eye then being put in *Kubaryum* and the Long-billed White-eye in *Rhamphozosterops*, with the Faichuk White-eye the sole member of *Rukia* and the Giant White-eye, as today, the only *Megazosterops* species. All were then united in a single genus, *Rukia*, after which the Palau species was returned to its monotypic genus and the Yap species placed in *Zosterops*, whereas the other two remained in the new genus *Rukia*. The present genus *Rukia* therefore consists of two large, slender-billed species with brownish plumage and unusually coloured feet, and with an incomplete eyering or none at all, a fairly short tail, and the second primary as long as the seventh or eighth. The two are confined to the Caroline Islands, the Faichuk White-eye in the tiny Faichuk Group within the Chuuk Islands, and the Long-billed White-eye on Pohnpei, some 600 km to the east.

North of the Carolines, the genus *Cleptornis* is restricted to the Northern Mariana Islands. Its single species, the Golden White-eye, is morphologically different from the other white-eyes in having large eyes and a first (outermost) primary, the latter being reduced or absent in most other members of the family. It was formerly treated within the Meliphagidae, but on the basis of DNA studies it is now included in the Zosteropidae, being perhaps a basal member of the family and appearing to be most closely related to *Rukia*.

Until recently, *Apalopteron*, now known as the Bonin White-eye (*Apalopteron familiare*), was likewise assigned to the honeyeaters in the family Meliphagidae, a treatment based primarily on its quadrid and fringed tongue, but also on its nest structure and "nares perviae" (open nostrils). The species had previously been associated with the bulbuls (Pycnonotidae), the

babblers, the Old World warblers and the white-eyes. Molecular research has indicated that its relationship is with the white-eyes, in particular *Cleptornis*.

The monotypic genus *Tephrozosterops*, with the Bicoloured White-eye (*Tephrozosterops stalkerii*), was formerly united with *Lophozosterops* because of an alleged structural resemblance, but it differs greatly in plumage colouring owing to an absence of lipochromes. The validity of the genus, however, is subject to debate, and it resembles *Lophozosterops* no more than it does *Zosterops*; in fact, there exists a great resemblance between the Bicoloured White-eye and the Mascarene White-eye, the Seychelles Grey White-eye and, in particular, the Grey-brown White-eye.

Madanga is another single-species genus, this one containing the Rufous-throated White-eye (*Madanga ruficollis*). This species is confined to the island of Buru, thus occupying a blank spot in the range of the genus *Lophozosterops*, of which it is most likely a derivative. It differs from this and other genera in plumage colour, and the second primary is longer than in any *Lophozosterops* species. Other peculiarities are the pointed, rather than square-ended, rectrices, and the rather long and strong toes, which may be adaptations to its bark-foraging habits (see Food and Feeding).

Lophozosterops consists of six species of large white-eye. These are distributed over the mountains of Java, Bali, Sumbawa and Flores, Sulawesi, Seram and, in the south Philippines, Mindanao. Three species, the Javan Grey-throated White-eye (*Lophozosterops javanicus*), found in Java and Bali, the Scaly-headed White-eye (*Lophozosterops squameiceps*), on Sulawesi, and the Black-masked White-eye (*Lophozosterops goodfellowi*), inhabiting Mindanao, are very similar morphologically and ecologically, but to unite them in one species would be to obscure the existence of the three to six subspecies in which each species is divided. The Yellow-browed White-eye (*Lophozosterops supercilialis*), confined to the mountains of Sumbawa and Flores, is also very close, but the other two, the Grey-hooded White-eye (*Lophozosterops pinaiae*) of Seram and the Crested White-eye (*Lophozosterops dohertyi*) in the hills of Sumbawa and Flores, are more distinct in appearance and behaviour from the others. The blackish lores shared by the Scaly-headed, Black-masked and Javan Grey-throated White-eyes have become white in the central, nominate race of the last-mentioned; the juvenile males of this race have greyish lores. It may possibly be better to split the heterogeneous genus *Lophozosterops* into several different genera, or, conversely, to unite it with *Zosterops*.

The single species in the genus *Oculocincta*, the Pygmy White-eye (*Oculocincta squamifrons*), is small in size, smaller

The genus *Speirops* contains four monotypic West African species, three of which inhabit islands and the other a single, island-like mountain. The genus is thought to have originated on São Tomé, home to the **Black-capped Speirops**, and to have speciated following colonization of the other three areas. They are quite large for white-eyes, and show a dark crown and reduced white eyering; all lack yellow or green tones in the plumage.

[*Speirops lugubris*, São Tomé, Gulf of Guinea. Photo: Walter Mankel]

than any other member of the family, but with a normal rounded wing and a relatively short tail. It is differentiated from *Zosterops* mainly by the scaly appearance of the frontal feathers and the pale greyish-yellow throat, combined with a more clear yellow breast and belly. From *Lophozosterops*, to which it seems most closely related, it differs in its small size, short tail and whitish iris. It is restricted to Borneo.

Heleia is a well-marked genus with a relatively long tail, a remarkably short second primary, and a comparatively heavy bill. Its two members are mainly lowland species, the Spot-breasted White-eye (*Heleia muelleri*) found on Timor and the Thick-billed White-eye (*Heleia crassirostris*) on Sumbawa and Flores.

The monotypic genus *Chlorocharis* harbours the Mountain Black-eye (*Chlorocharis emiliae*), a fairly large dark species distinguished by its black lores and circumorbital region, its long, very slender, partly orange-yellow bill and its relatively long tail. It has no clear affinities within the family. The genus is endemic to the mountains of Borneo.

As both its generic and its English names suggest, the single species of *Megazosterops*, the Giant White-eye, is very large, and at first sight does not look like a white-eye at all. It is atypically coloured, and has a yellowish eyering, soft plumage, broad primaries and secondaries, a relatively short tail, a short second primary, a rather heavy horn-coloured bill and strong legs. In addition, its vocalizations are unlike those of other white-eyes. As mentioned a few paragraphs above, it has sometimes been placed with the other large species in *Rukia*, but it is clearly differentiated by the aforementioned characters, and it may be no more closely related to this than it is to the other white-eye genera.

The genus *Speirops* is characterized by the large size, stout bill, complete lack of yellow or green in the plumage, and the possession of a darkish cap and reduced white eyering. The four species are mainly montane and occur in disjunct areas of Africa. They are morphologically well characterized and differ in the morphometric proportions of wing, tail and tarsus lengths. All four form a monophyletic group and are sometimes regarded as members of one superspecies. The Black-capped Speirops (*Speirops lugubris*) and the Mount Cameroon Speirops (*Speirops melanocephalus*) are the two most closely related to each other, however, and it is probably better to treat these two alone as forming a superspecies. The genus is hypothesized to have originated

on the island of São Tomé, from where it would have colonized the other three areas.

The placement in Zosteropidae of the genus *Hypocryptadius*, with its single species, the Cinnamon Ibon (*Hypocryptadius cinnamomeus*), has been queried by several researchers, who have pointed out that the tongue is only slightly divided at the tip, with a short fringe laterally, whereas all other members of this rather uniform family have a deeply bifid tongue, ending in filaments. Other characters that would justify its placement in another family, or perhaps even in a family of its own, are the rounded nostril openings entirely closed posteriorly by an operculum, whereas the nasal opening of virtually all other white-eyes is a slit covered by an operculum, with the lower border entirely free; the short tarsus, which is shorter than that of any other white-eye; the deep cinnamon colour of the plumage; the complete absence of an eyering; and the larger size, the wing length of *Hypocryptadius* being 10 mm longer than that of the second largest white-eye. Furthermore, the relatively short bill is much wider and deeper than that of any other member of the family. The only feature which the Cinnamon Ibon shares with the other white-eyes, and with various other passerines, too, is the reduced outermost primary. With the possible exception of the diverse babbler family Timaliidae, no family other than the Zosteropidae is usually suggested by taxonomists to accommodate the genus *Hypocryptadius*. Little or nothing is known about its vocalizations and nidification which could provide some clues to its relationships. In the meantime, it is probably best to place it in an old subfamily Hypocryptadiinae, of which it is the sole member, although it may merit placement in a separate family altogether.

Finally, there are a number of more or less recently discovered white-eyes awaiting formal description. In particular, the island of Sulawesi and its satellites, already known to be home to 15 taxa of largely endemic white-eyes, have proven to be very productive during surveys since the 1970s. The Togian White-eye, for instance, was described as recently as 2008, although its distinctiveness had been noted a few years earlier. In northern Sulawesi, Lemon-bellied White-eyes on Dodepo Island, in Tomini Bay, were found to be paler, and with less well-defined loreal streaks and a larger bill, than mainland individuals of this species. A Black-crowned White-eye found in 1979 near Soroako, in south-central Sulawesi, had measurements differing from those of known subspecies of this species. The islands of south-eastern Sulawesi may harbour a number of undescribed taxa. For example, during surveys in 1995 on Butung, the local Pale-bellied White-eye was found to differ morphologically and vocally from the mainland individuals of the species, and on Wangiwangi, in the Tukangbesi Archipelago, a large, pale-bellied, orange-billed white-eye found in 1999 showed no clear affinities with known species, and co-occurred there with the much smaller local race *flavissimus* of the Lemon-bellied White-eye. On Kabaena Island, both the Lemon-bellied and the Pale-bellied White-eyes are significantly larger than their conspecifics on nearby Butung, and may therefore be undescribed races. Far to the west of Sulawesi, in the Andamans, the Oriental White-eye population may represent an undescribed subspecies, and on Panay, in the Philippines, an undescribed race of the Oriental Mountain White-eye was found in 1987. On the island of Vanikoro, in the Solomon Islands, what is probably a not uncommon white-eye, similar to the Santa Cruz White-eye (*Zosterops sanctaecrucis*) but differing mainly in its yellowish-orange legs, was found in 1994.

Morphological Aspects

The majority of the white-eyes are small, 10–12 cm long, with average weights of about 11 g. A total of 1500 individuals of the Cape White-eye had weights ranging from 8 g to 20 g. The family giants are the Cinnamon Ibon, with a wing measurement of 92 mm and weighing up to 30.1 g, Sanford's White-eye, with a wing of 83 mm, and the Giant White-eye, with a wing of 82 mm and weighing up to 30.5 g. The largest members of the genus *Zosterops* are the White-chested White-eye, the wing of which measures 77 mm, and the Malaita White-eye (*Zosterops stresemanni*), which has a wing length of 68 mm and weighs up to 23 g.

The Cinnamon Ibon is a taxonomic oddity whose placement in the Zosteropidae is often questioned, but without convincing alternatives being offered. A monotypic species in a monotypic genus, Hypocryptadius is morphologically distinct from the rest of Zosteropidae, being the only white-eye to lack a deeply bifurcate tongue and the only one to have deep cinnamon plumage. Whereas it is considerably larger than even the second largest white-eye, it has, in contrast, the shortest tarsus. In addition, compared to other zosteropids, its nostril structure is different; it has a far wider and deeper bill; and it lacks an eyering.

[*Hypocryptadius cinnamomeus*, Baracatan, Davao, Mindanao, Philippines. Photo: Doug Wechsler/VIREO]

White-eyes are highly sociable birds. In many species, individuals regularly congregate in small foraging flocks that call constantly as they move through their environment. When reaching a natural break in their foraging route, such as an open area, white-eyes often become nervous. They may ascend a bare tree, which serves as a look-out post from which they can survey the terrain for potential predators and determine the safest route to their next destination. Outside the breeding season, flocks can be very large, those of the **Oriental White-eye** sometimes numbering over 100 individuals. Flock size seems to depend, in part, on food availability. In times or areas of plenty, flocks can be larger than in impoverished, arid habitats or dry seasons, where groups typically comprise just a handful of individuals, perhaps family units. Evidence from some white-eyes suggests that long-term bonds form between group members, and flocks can remain much the same for several years. In addition to such single-species groups, white-eyes are frequently core members, and even leaders, of mixed-species foraging flocks. For example, in Sumatra, Oriental White-eyes have been seen flocking with nuthatches (*Sitta*), tits (*Paridae*), Old World flycatchers (*Muscicapidae*) and minivets (*Pericrocotus*).

Gruisen/Ardea]

Bergmann's Rule, that warm-blooded animals increase in size with cooler climatic temperature, and thus also with increasing altitude, is confirmed for the New Guinea White-eye, all montane races in which are larger than the lowland races. Similarly, within the same race of the African Yellow White-eye, the montane populations are slightly larger in wing length than those in the lowlands, and this may be to compensate for lower air pressure. These examples are, however, counterbalanced by the Black-crowned White-eye superspecies (see Systematics), in which the lowland race *dehaani* of the Creamy-throated White-eye is the largest of all. The tendency of small bird species to be larger in size in insular populations, a phenomenon known as the "small-island effect", is found in a number of the Zosteropidae, and is most clearly illustrated by Silvereyes, with various populations of large races and derivative species on offshore islands. Other examples are found on Annobon, in the Gulf of Guinea, Christmas Island, in the Indian Ocean, Great and Little Kai, in the Banda Sea, and on several other islands. There are a few exceptions, such as the subspecies *maxi* of the Lemon-bellied White-eye; the western populations of this race that occur on tiny islands are, on average, smaller than the eastern population occurring on the larger island of Lombok.

It has been postulated that very small, and remote, islands have a limited number of resources, and that the act of becoming larger enables *Zosterops* to take a wider range of foods, thus expanding its niche. A later-colonizing, normal-sized *Zosterops* will be sufficiently different to be able to co-exist with the species already present, and both will diverge further, not only in size, but also in wing and bill shape, plumage structure and colour. Studies of the Silvereye showed that island populations do, indeed, have a wider feeding niche than those of comparable mainland populations. The island-dwelling individuals, however, are in fact more specialized than would be expected by chance. Moreover, neither large body size nor large bill size is associated with generalist foraging behaviour in itself. These studies suggest that generalist foraging and niche expansion cannot fully explain morphological shifts in island-dwelling white-eyes; alternatively, these can be explained by environmental effects, reduced predation, physiological changes, limited dispersal and intraspecific dominance. Where two species of *Zosterops* co-occur, the larger is always more different from the ancestral *Zosterops* and is presumably the first of the two to have arrived. A striking reversal of size has been found for Lemon-bellied and

Pale-bellied White-eyes that occur sympatrically on the islands of Butung and Wangiwangi, off south-east Sulawesi: the first species is the larger one of the two on the first island, but the smaller one on the second. Proportionate differences in wing and bill lengths, an indication of ecological separation within co-existing white-eye species pairs, can vary: for wing length, the figure ranges from 5%, as on Réunion, to 45%, as on Chuuk; for bill length it is from 15% to 30% on most islands, with extremes of 75% for the white-eyes on Pohnpei but less than 5% for a number of other species pairs.

The weight of adult Mascarene White-eyes usually increases during the breeding season, but in the case of the Reunion and Mauritius Olive White-eyes, which inhabit the higher parts of the Mascarene Islands, very cold winter nights demand that the birds have some body fat, resulting in higher weights during that season. Higher weights can be attained also when females are gravid: a female Mauritius Olive White-eye reportedly increased from 7.5 g to 9.6 g within a period of two weeks. Weights fluctuate in a seasonal pattern, as well as a daily pattern, as has been shown in South Africa for Cape White-eyes in Western Cape Province. Here, the lowest average weights were found in the peak breeding months of September–October, when the figure was 11.1 g, whereas an increase in weight was noted in the austral winter months of May–August, when the average was 12.4 g. Further, weight increases at food trees can be considerable; a preliminary study showed increases of about 6% of body weight during a single visit, this countered during the night, when weight losses of 12% were recorded. In New Zealand, diurnal fluctuations of 7% were found in the mean weight of Silvereyes, which were lightest at 09:00 and 10:00 hours, gradually increasing until 17:00 hours; maximum mean weights, of 14.55 g, were recorded in June, in the southern winter. Lastly, weights appear to be inversely correlated with the mean daily air temperature.

Bills of the Zosteropidae are quite uniform, generally short to medium-long, slender, pointed, and slightly arched on the culmen. In the genus *Zosterops*, the operculate nostrils are exposed, and no rictal bristles are present. There is a correlation between larger bills and small islands in the Louisiade White-eye. The bills of the Mauritius Olive White-eye and the Reunion Olive White-eye are the longest in the white-eye family, as also are the tongues; the bills, long, fine and curved, are almost identical to those of the specialized honey-eating sunbirds in the family Nectariniidae, in addition to which the thick legs appear to be

Feathers provide birds with their means of movement, their insulation, and much of their colour. Feather care is thus an essential daily activity for all birds. This **African Montane White-eye** is using its bill to preen its underwing-coverts. It nibbles individual feathers, delicately mandibulating each part of the feather in order to restore feather structure and remove dirt and other unwanted extras. The **African Montane White-eye** inhabits a variety of wooded habitats, particularly highland forest above 1500 m, from Eritrea south to Tanzania.

[*Zosterops polioastrus kikuyuensis*, Mount Kenya National Park, Kenya. Photo: Greg & Yvonne Dean/World Wildlife Images]

Close physical contact is an integral part of white-eye sociability. *Zosteropids* regularly huddle together, and in some species they roost communally.

Allopreening and heteropreening are also important forms of social behaviour. The **Japanese White-eye** being preened sits in a hunched position, with feathers fluffed out and head tilted back.

This posture facilitates the preener's access to the areas that a bird cannot reach itself, particularly the throat, eyes, ears and neck. The direct benefits of such heteropreening include tactile stimulation and the removal of ectoparasites, but its main function is probably to strengthen social bonds.

[*Zosterops japonicus japonicus*, Tobishima, Yamagata-ken, Japan. Photo: Hirozo Maki]

adapted for the various awkward positions adopted in order to reach flowers. In the genus *Lophozosterops*, the bill is small and slender, the culmen slightly curved, and the nostrils are covered with a membrane.

The typical long, slender, tubular, slightly curved tongue of the white-eyes is double-cleft, with each of the four ends fimbriated at the tip. This is apparently an adaptation for feeding on nectar and pollen. A brush-tipped tongue is found without any known exception in all Zosteropidae, even in the aberrant genera *Woodfordia* and *Rukia*, and nectar-feeding must therefore be a quite old habit of the family. The lacinate tongue of the Reunion Olive White-eye is the most deeply cleft of that of any member of the family. The tongue of *Apalopteron*, which was formerly assigned to the Meliphagidae, is quadrifid only at the distal end. Finally, the Cinnamon Ibon's only slightly bifid tongue, with just a short fringe laterally, is one among several reasons to assign this species to a family of its own (see Systematics).

In *Zosterops*, the wings are in general short and rounded, with the third to fifth primaries, P3–P5, the longest and of about equal length, while the first, outermost, primary (P1) is vestigial. In some species, the wing length increases by 0.7 mm with every 300 m of increasing altitude. Migratory populations of birds tend to have pointed wings, expressed in the possession of a relatively long second primary, whereas sedentary ones have more blunt wings, with a relatively short P2. In the strongly migratory Chestnut-flanked White-eye and the nominate race of the Silvereye the wings are, indeed, pointed, with a long second primary, this being intermediate in length in the wandering race *chloronotus* of the Silvereye and short in the sedentary *griseonota*. Further, Silvereyes of the Lord Howe Island subspecies *tephropleurus* and the Loyalty Islands race *nigrescens*, two small-island endemics, have blunt wings. Blunt wings are also an adaptation to forest life, and pointed wings to a life in open country. This would explain the relatively pointed wings of the two Afrotropical species the Cape White-eye and the African Yellow White-eye, which range extensively in comparatively open country.

White-eyes generally have medium-small, slender but strong legs with medium-sized toes. They are thus adapted to an arboreal life, and suited to hanging upside-down from twigs, hopping from one branch to another, and similar actions and movements. Adaptation to a terrestrial life by the Bonin White-eye is expressed in its long tarsi. Relatively long toes are a feature of the Rufous-throated White-eye, confined to the Moluccan island of Buru, where they are apparently an adaptation to bark-gleaning.

The plumage of white-eyes seems primarily an adaptation to their favourite environment of green foliage. For instance, the yellow of the Javan White-eye or the Australian Yellow White-eye blends perfectly with the yellowish-green colour of mangrove leaves, and many more such examples can be found. The dry lowland races of the African Yellow White-eye are paler in colour than the humid montane races. In contrast, the nominate race of the Malagasy White-eye of the Glorios Islands and the drier parts of Madagascar is the most yellow of all; a reduction of melanin has been linked to drier climates, in accordance with Gloger's Rule that pigment increases with humidity. The fading of black to brown is known to occur in the genera *Zosterops* and *Chlorocharis*, and the loss of the yellow pigment in specimens kept in spirit, as well as live birds kept in captivity, is well known. Xanthochroism, referred to also as flavism, a condition in which all pigments but yellow are lost, has been reported for the Cape White-eye, as also has the opposite, an almost complete loss of yellow or green. Lutino individuals of the Christmas White-eye, with the green colours replaced by yellow, have been recorded, and albinos of the Slender-billed White-eye and, in contrast, an almost completely melanistic individual of the Silvereye have been documented. Differences in the structure of the plumage exist between subspecies of the Louisiade White-eye, *eichhorni* having harder and stronger feathers than the nominate race; interestingly, the latter is a better colonizer of small islands, and a smoother plumage may be a prerequisite for better flying.

A striking feature of the small-island forms of white-eyes is the tendency to lose the yellow colour and the white eyering, and to increase in size. In the Capricorn race *chlorocephalus* of the Silvereye, under field conditions significant selection was de-

tected in three cohorts of nestlings for wing and tail lengths and culmen depth.

Polymorphism has been described for the Mascarene White-eye on Réunion, but the large-scale modification of the natural vegetation here has undoubtedly changed its balance by altering the parameters of optimal adaptation. The white rump patch of this species is unusual among white-eyes and it seems to play a part in the "follow-my-leader" behaviour of its flocks, in which the patch is conspicuously displayed in flight.

The average number of feathers, filoplumes excluded, of an adult white-eye totals approximately 3300, which is comparatively many for a passerine. Moulting is therefore a subject of interest. The eastern populations of the Cape White-eye start to moult about one month after the western ones, this correlating well with early breeding of the latter; the duration of primary moult does not differ among the populations and is possibly a species-specific trait. The main moult takes place in a period of one to three months after the breeding season, but some species, such as the Bridled White-eye in the North Marianas, moult and breed throughout the year. Migratory subspecies of the Silvereye, such as the nominate race, begin their moult, and complete it, earlier in the year than members of the non-migratory subspecies, such as *cornwalli* and *westernensis*, and they also exhibit a general uniformity among individuals in timing and duration, whereas the two more sedentary races show a greater degree of variability among individuals. Moulting is of the normal passerine type, in which the primaries are normally shed and replaced from the tenth outwards to the second. In captivity, the moult of juvenile Oriental White-eyes into adult plumage begins at an age of 20–23 days. Full moult of the juveniles takes place in August, when the wing and tail feathers also are replaced; in the same period the adults undergo their summer moult, whereas juveniles of a third brood start to moult in mid-September. In India, the Oriental White-eye's moult is completed in 8–9 weeks; the secondary moult was noticed after primary moult had a score of 15 (BTO scoring system); the number of primaries in growth at any one time varies from one to three, but the majority of individuals examined had only two feathers in growth simultaneously. The tail-feather moult sometimes commences before primary moult has started. Interestingly, in Cape White-eyes, feathers soiled with nectar were shed outside the moult periods, and this could be a general feature of short-billed nectarivores.

The eyering of white-eyes, which is such a prominent character of the family, ranges from being broad to being narrow, and

White-eyes bathe freely and regularly in various water bodies. This Australian Yellow White-eye is bathing in shallow water amidst mangroves, its principal habitat. White-eyes bathe by crouching in the water and flicking the wings to shower water droplets over the upperparts. The extent to which the bird gets wet depends on the occasion. Cleaning the feathers and underlying skin requires a thorough soaking. Making them more pliable to facilitate preening, on the other hand, merely needs them moistened.

[*Zosterops luteus balstoni*, Crab Creek, near Broome, Western Australia, Australia. Photo: Don Hadden]

in several cases is rudimentary. The ring consists of scale-like feathers, which are white on most species, but can also be dark grey, as on the Santa Cruz White-eye, or black, as on the Mountain Black-eye, or yellow, as on the Yellow-spectacled White-eye, and it may have recognition value. A few *Zosterops* species, the Dusky White-eye being an example, lack a contrasting eyering altogether. In the case especially of the African Montane White-eye, the eyering is very well developed. The eyerings of some sympatric and extremely similar-looking species, such as the Oriental and Japanese White-eyes, are much the same in appearance, and the function of this feature may therefore be of intraspecific importance. Some observers have hypothesized that the delay in the development of the eyering until the precise age at which the chick is fully capable of flight, 23 days in the case of the Japanese White-eye, is a mechanism to protect the vulnerable young from aggression by adults other than the parents. This assumes, of course, that the white eyering is a device that provokes aggression.

One of the very few species of white-eye that really does have white irides is the Plain White-eye, most other members of the family having eyes ranging in colour from greyish-white to reddish and to dark brown. The eye colour of the juvenile is usually somewhat duller than that of the adult. The large eyes of the Golden White-eye are said to be an adaptation for life in the shade of its understorey habitat.

With very few exceptions, one such being the subspecies *meyleri* of the Golden-green White-eye, the members of the Zosteropidae have a dull black, short-feathered loreal line, which interrupts the white ring anteriorly. The function of this dark line is uncertain, but it has been associated with the food-searching behaviour of open-bill probing, known as "Zirkeln", in which a bird pushes its bill into a small hole or crevice, opens it with some force, and looks down its bill in order to inspect the hole for something edible. The black line guides the bird and prevents reflections that could otherwise hinder its view, important only if the eyes can be focused to a distance of only a few centimetres. A groove, imbedded in the skull between the eye and the bill, improves vision; although the eyes are not in one line with this groove, which would be ineffective on account of the slight curvature of the bill, they are so with the anterior part of the bill, the part which is active in the *Zirkeln* movement. This groove, inci-

dentally, is found in the skulls also of starlings (Sturnidae) and New World blackbirds (Icteridae), and it is interesting that these avian groups, too, practise *Zirkeln*.

Only a few cases of sexual dimorphism have been reported for white-eyes, and even these indicate very slight differences between the sexes. In Chestnut-flanked White-eyes, the males have black lores, whereas those of the females are grey. In the so-called "Kulal White-eye" the subspecies *kulalensis* of the African Montane White-eye, the females are reported as only faintly yellowish-white on the belly, and have paler grey sides and flanks than those of males. Male Silvereyes reportedly have darker or more reddish flanks than females, although this may be the case only during the breeding season. In most white-eye populations, including the genera other than *Zosterops*, the males are on average 1–2% larger than the females, as expressed by wing length, but in the case of the Golden White-eye the males are up to almost 10% larger than the females in wing length. Females and males of the Japanese White-eye on Hawaii, however, do not differ in weight, the average for 568 individuals being 11.12 g. Female Oriental White-eyes may have slightly longer wings than those of the males, but the tail is shorter, and they weigh only slightly more. Similarly, the males of the Seychelles Grey White-eye are sometimes slightly smaller than the females. In Sri Lanka White-eyes, females as a rule have a greener-tinged yellow throat than that of males, and at times they have the eyes reddish rather than light brown. Apart from slight differences in size and, seasonally or not, in colour, the sexes of Silvereyes, and undoubtedly those of more species, differ in some call notes (see Voice).

Juveniles of the Zosteropidae are generally very similar to or identical to the adults, although those of a few species may be identifiable to age. For example, juvenile Oriental White-eyes have a duller yellow coloration and a narrower eyering, with a dark grey loreal stripe that later becomes black. Juveniles of the nominate race of the Grey-brown White-eye are darker in plumage than the adults, and have a conspicuously yellow bill with a dark tip. In most cases, the eyering starts to appear at around 17 days, first below the eye and then above it, and is fully developed in about five weeks, as illustrated by, for instance, the young Cape White-eye. Young Reunion Olive White-eyes gain the eyering very rapidly, whereas it takes a much longer period to

In arid areas or during the dry season, water is often a precious commodity and water bodies of sufficient size for bathing are frequently in short supply. Little wonder then that such gregarious birds as white-eyes regularly bathe together. This flock of **Silvereyes** is taking advantage of the opportunity offered by a tiny but nevertheless eminently suitable rock pool. Some species of white-eye are known to bathe in dew, wet foliage and rain, and this is probably true of most family members.

As is typical of sociable birds, white-eyes are very vocal. The family as a whole, and the genus *Zosterops* in particular, are fairly homogeneous in terms of vocalizations. Members of a foraging flock maintain contact through calls that recall those of newly hatched domestic chickens. Alarm calls are sharper and have an instantaneous effect on flock members, prompting them to flee. Most *Zosterops* sing primarily at dawn, and their song is described as resembling morse code. That of the **Oriental White-eye** is a short feeble jingle, and is given only during the breeding season.

acquire the blackish face of the adults. By the age of 30 days the juveniles are indistinguishable from the adults.

Habitat

White-eyes are found in a large variety of habitats and climates and at a wide range of altitudes. From extreme low elevations, such as offshore islets and mangroves, to the highest mountain tops, they are often one of the most abundant birds. On certain small islands they can even comprise 30% of the passerine avifauna, as on Norfolk Island, where three out of ten of the native passerines are white-eyes.

The habitat tolerance of mainland white-eyes and the amazing capacity of some species, notably the Silvereye, for crossing hostile habitats have been important factors in speciation processes, as these characters have made white-eyes excellent colonizers of remote islands. Disturbed habitats, such as open woodland, urban parks and the like, are often colonized from natural habitats with similarly simple vegetation structures, in particular mangroves. One of the possible reasons why the Silvereye and its relatives are able to exploit such a wide variety of environmental conditions lies in its ability to reduce its daily energy expenditure by employing nocturnal hypothermia, in which the body temperature fluctuates from day to night by as much as 5.5°C, and the resting metabolic rate and conductance are reduced by up to 50%. Daily fluctuations in, especially, metabolic rate are more pronounced in winter than in summer; this should maximize energy use and increase the probability of survival of this typical island-colonizer. White-eyes living naturally at higher latitudes, typified by the Japanese and Chestnut-flanked White-eyes, may experience extremely low ambient temperatures, but temperatures of minus 5° C have reportedly been endured by Oriental White-eyes of tropical origin kept in captivity in the UK. The race *egregius* of the Oriental White-eye in India also seems rather hardy, and a party of eight or nine reportedly remained high up in the mountains during the winter of 1906–1907. Owing to their lack of specialization in the driest areas, and even at the end of the worst droughts in southern Africa, white-eyes are able to find food in the form of various berries, such as those of *Rhus* and *Lycium*, and nectar.

Mutual exclusion has resulted in a checkerboard pattern in the distribution of the twelve *Zosterops* species occurring in the Moluccas and the New Guinea region, including the Bismarcks.

A situation of “first come, first served”, or slight competitive advantages related to small ecological differences among the islands, determined which were the locally successful species. Very small islands appear to be not large enough for the co-existence of both white-eyes and honeyeaters. On the atoll of Sapwuahfik, known also as Ngatik, near Pohnpei, in the Carolines, no white-eyes occur, but the Micronesian Honeyeater (*Myzomela rubrata*) is very common there. In the Solomons, the islands of Mono, Murray, Russell, Ramos, Savo, Gower, Santa Ana and Ongtong Jawa have no white-eyes, and in the West Papuan Islands, off north-west New Guinea, the same is true of the islands of Waigeo, Salawati, Batanta and Misool. The *Zosterops* species on Sulawesi more or less replace each other geographically, as illustrated by the distribution of the Lemon-bellied White-eye compared with that of the Black-ringed White-eye (*Zosterops anomalus*), and by the comparative distributions of the Black-crowned and Pale-bellied White-eyes. In north Sulawesi, the Black-crowned White-eye is found on Mount Emoung, whereas, on the nearby, slightly higher Mount Lokon, it is the Oriental Mountain White-eye that is present. In the north Sumatran mountains, the Black-capped White-eye (*Zosterops atricapilla*) is abundant in the absence of the Oriental Mountain White-eye, which occurs elsewhere in the highlands of that island.

The greatest number of white-eyes is found in the Solomon Islands. Eleven species occur here, but most replace each other geographically, and no more than two species co-exist on any one island. Some of the species are separated by narrow sea gaps, in extreme cases of only 1.7–2 km. In general, forest-dwelling white-eyes are highly sedentary and have restricted ranges, whereas the successful colonizers of distant islands are typical of low coral islands, as illustrated by the Lemon-bellied White-eye, and open woodland, as in the case of the Silvereye.

Other than by altitude, for which numerous cases are known, habitat segregation among species is found in several places in southern Africa, such as north Namibia and east Botswana, where the Cape White-eye occurs in open woodland and the African Yellow White-eye occupies evergreen forest and coastal bush. Habitat preferences can vary within one and the same species, as with the Oriental White-eye, both montane and lowland races of which are found adjacent to each other in, for example, Sumatra. In the case of the Lemon-bellied White-eye, the subspecies in the far east and that in the far west are restricted to small islets, although sometimes with seasonal movements to adjacent mainland areas; in the central part of its range the species is widely

White-eyes such as the **Sri Lanka White-eye** have a varied diet. Insects appear to provide the bulk of the nutrition for the vast majority of species, but fruits, berries and nectar are also consumed to a notable extent. The combination of this dietary plasticity and the ecological adaptations of the Zosteropidae have caused the family as a whole to develop a wide variety of foraging techniques. When searching for arthropods, they may glean a prey item from a surface while perched or hovering, probe a crevice or other cavity, or sally to capture an insect in mid-air.

distributed on large islands such as Sulawesi, where it is found at elevations of up to 1800 m.

The two members of the family present on Saipan, in the Northern Mariana Islands, namely the Bridled White-eye and the Golden White-eye, can persist on this tropical island despite periodic typhoon damage and human-caused habitat change. This is believed to be due to their high flexibility in habitat choice and their ability to use a range of foraging methods. They are able to forage in various tree zones, to change to different foraging surfaces, and to feed both in herbaceous vegetation and on the ground. It was found that there was no difference between the two main habitat types, limestone forest and the far more simple-structured "tangantangan" thickets, with regard to the amount of time that the birds spent on four different foraging modes. For the Bridled White-eye, gleaning accounted for 92.1% of its foraging time, probing for 5.1%, hovering for 2.5% and sallying for 0.3%; the corresponding figures for the Golden White-eye were 75%, 23%, 2% and 0%. Although the two species differ in foraging ecology, they appear to compete for food resources.

Population sizes of Australian Silvereyes in vineyards are influenced by the local abundance in flowering of two species of eucalypt trees, the grey box (*Eucalyptus microcarpus*) and the marri (*Eucalyptus calophylla*), but also by the prevalence of downy mildew, which suppresses the quality of the grapes. In the south-east of the country, it has been shown that only juvenile Silvereyes move into vineyards near Sydney, while the adults stay on their breeding grounds. In the south-west, migratory Silvereyes move through the area north of Perth in June–July, when nectar production is high.

General Habits

Rather a lot is known of the natural history of white-eyes, but much of it is based on studies of only a few members of the family. The Silvereye, as it is readily trapped and ringed, has been the subject of a number of studies focused on social behaviour, migration and other aspects of wild-living individuals. The Oriental White-eye is often kept in captivity, and much information on this species' social behaviour and breeding biology has therefore been gathered. Of the African members of the family, the Cape White-eye especially is well studied under field conditions. The Bridled White-eye is an example of a well-studied small-island endemic. Altogether, it appears that white-eyes are similar in their life his-

stories, and what is observed for one of the better-studied species is generally applicable to many other zosteropid species.

White-eyes are distinctly social. They congregate in small or, especially outside the breeding season, in large flocks, which move rapidly through bushland, orchards, gardens and other habitats, calling constantly as they move. The flocks of, for instance, Japanese White-eyes are formed by parent birds, which join together after breeding, and juveniles, which remain in flocks until the following breeding season, often near their natal territory. In the case of Silvereyes, the first, early immatures form the core of the post-breeding flocks, which in the course of the breeding season are joined by moulting adults that have completed their last broods. Unlike most white-eyes, the Mascarene White-eye associates in flocks throughout the year.

Flocks are very cohesive and ringed individuals in parties of Silvereyes have been retrapped together after intervals of several years. The members of Abyssinian White-eye flocks move between trees in ones and twos, creating pairs, which perch and forage closely together while travelling. The flight of Cape White-eyes between trees is generally rapid, straight and level, with bursts of flaps, but without undulating. Within flocks, African Yellow White-eyes generally keep in twos or threes, the former not always mated pairs. These "clumping alliances" fly and forage together, but their membership often changes. Many times during the day the members of such alliances stop foraging in order to preen one another, this behaviour being a form of sublimated aggression. There is constant quarrelling among flock-members, and a dominant individual will pursue another in short flights within trees, displacing it from several perches in succession. The supplanting by several dominant white-eyes is immediately followed by a higher intensity of foraging and by onward movement of the flock. Individual Bridled White-eyes can be attracted to playback of recordings of various flocking calls, and Silvereyes can recognize the calls of their mates in flocks.

Large flocks containing hundreds of individuals have been recorded for Sri Lanka White-eyes and Oriental White-eyes, and winter flocks of Silvereyes reportedly can comprise as many as 500 birds. In contrast, some large species, such as the White-chested White-eye, have lost the habit of being social and living in parties, but one of the other large zosteropids, the extinct Robust White-eye, is known to have lived in flocks. Smaller flocks are formed by the Golden White-eye, which typically occurs in family groups of three or four individuals. The genetic variation that has been assessed within and between flocks of Cape White-eyes at several

Many species of white-eye forage thoroughly and systematically, a process known as the "trap-line" method. A flock may take the same route around the territory at the same time each day, each individual carefully scouring vegetation for lurking arthropods or ripening fruits. The **Silvereye** feeds mainly by gleaning or probing. Its main animal prey comprises earthworms (*Oligochaeta*), spiders (*Araneae*) and insects like this caterpillar (*Lepidoptera*). Caterpillars may be prepared for consumption by being beaten against a branch and compressed by the bill.

localities showed that the flocks are cohesive units. Flocks of the Bridled White-eye on the small island of Saipan have characteristics intermediate between those indicative of permanent membership and those suggesting that the flocks are site-dependent.

In mixed-species foraging flocks white-eyes are often core species, determining the direction in which the flock moves. Various reasons have been given to explain the formation of mixed-species flocks, examples being the avoidance of predation, the flushing of insects, and the enhancing of foraging efficiency. On Mahé, flocks of Seychelles Grey White-eyes are frequently accompanied by Seychelles Sunbirds (*Cinnyris dussumieri*); the latter leave their haunts in temporarily insect-poor vegetation in order to join the white-eyes in tight flocks at insect-rich trees. An explanation for this behaviour is that the usually solitarily foraging and intraspecifically aggressive sunbirds benefit from the momentum of the white-eye flock, which reduces the duration of confrontations, and the sunbirds forage altogether more efficiently. Flocks with two species of white-eye are known to occur in several places, examples being parties containing New Guinea and Black-fronted White-eyes in eastern New Guinea, Yellow-throated and Grey-throated White-eyes on Bougainville Island, and Oriental and Oriental Mountain White-eyes in east Java, but different subspecies, too, may mix in areas where both overlap in range. In north-east South Africa, three taxa have been found in single flocks, the races *virens* and *atmorii* of the Cape White-eye mixing with African Yellow White-eyes. Although white-eyes associate with other species in bird parties and travel with them, the association often appears to be a loose one and the white-eyes are often seen to be detached from the rest.

Resting and sleeping postures adopted by white-eyes include one in which the head is partly or entirely hidden in the bend of the wing or in the back feathers, one with the bill resting on the breast, one in which the head is sunk between the shoulders in typical warbler fashion, and, finally, a posture in which the bill is pointed slightly upwards. A most peculiar way of sleeping, observed for captive Oriental and Japanese White-eyes, involves the bird hanging upside-down, the claws clinging tightly to the wire-netting roof of the aviary; this posture may be influenced by the birds' disturbed physiological condition, such that they look for the highest position in their cage. If possible, white-eyes will roost together with at least one partner. They move on to a roosting perch while uttering contact calls, and restlessly shuffling around; the feathers are somewhat fluffed, and some individuals briefly preen. At dusk the white-eyes are distributed in small

resting groups of three to five or more individuals, but with increasing darkness these groups merge into one row of tightly huddled birds, often covering each other with the wings and tail. The birds in one row do not necessarily face all in the same direction, and one individual can look as if it has two or more heads.

Ten to fifteen Japanese White-eyes were found to be coming to a communal roost every night, and Oriental White-eyes and other species are known to gather in large roosts. Indeed, the largest recorded roost for Oriental White-eyes, on an islet in Thailand, held as many as 750–1000 individuals. The urge for contact is so strong in white-eyes that even individuals of species belonging to other families are accepted as sleeping and preening partners; various estrildids and even quails (*Phasianidae*) have been reported as partners in captivity. Birds with similar plumage colours, olive above and yellow below, are, however, not tolerated. In a captive mixed flock of Silvereyes and Australian Yellow White-eyes, separation of the species occurred during roosting, and this coincided with a very subdued musical twittering suggestive of subsong; it is possible that this vocalization, in addition to the colour of the plumage, functioned in keeping the two species apart. Birds with more than normally fluffed feathers are especially attractive, almost irresistibly so, even in the presence of conspecifics. Abyssinian White-eyes roost in trees, two perching huddled close together; in the heat of midday, flocks sit in rows along sheltered twigs, dozing, loafing, warbling and preening. Bonin White-eyes always roost in pairs, with only a single pair in any one tree; only very seldom are two pairs found in the same tree, but they are then separated by a distance of two metres or so.

As with many other bird groups, fighting and threat displays are common among the comparatively aggressive white-eyes, which are well armed with their relatively long and sharp bill. Oriental White-eyes and Silvereyes have been described as using the half-open bill to peck the opponent, preferably in the nape and rump, and pulling at feathers, including those of the wing or tail, but never do the bills of the two rivals touch. When two antagonists fly upwards in aerial combat, the lower one will always beat a retreat. Various threat displays associated with aggressive behaviour have been noted for Silvereyes, including the commonly observed "wing-fluttering" and, in addition, the "head-up" posture, "beak-clattering" and pecking. Other elements of low-intensity threat behaviour include holding the bill open, pushing the body forward, and the challenge call. The flared eyerings and the yellow gape would seem to be two attributes for an in-

No information has been published on the diet of the **Creamy-throated White-eye**, which inhabits a few islands in northern Indonesia. Given the comparative dietary homogeneity of white-eyes, this species probably takes insects and other small arthropods. This individual has located a snail, which it may have located by open-bill probing into a crevice, a technique known as Zirkeln. The crevice may be in bark, twigs or even rolled-up leaves. The white-eye forces the edges apart with its bill so that it can investigate the contents.

[*Zosterops atriceps fuscifrons*,

timidating threat display. Threat display by Silvereyes is performed more often against higher-ranked opponents and unfamiliar opponents, and when prior food deprivation was of short duration; attack is used more often against lower-ranked and/or familiar opponents and after food deprivation of 90 minutes. Chasing occurs among breeding birds as a means of territory defence.

Occasionally, Bridled White-eyes can be seen to communicate with flock-members by tilting the head at a 45-degree angle, moving the head from side to side, and flicking the wings, while giving whining calls. The same calls are used during chases of a third individual by a pair, and during mobbing of presumed predators.

Within foraging flocks of African Yellow White-eyes there is a high level of aggression. A common posture employed to denote threat is that of crouching with the bill held wide open and the plumage sleeked. If unsure whether to pursue or to flee, a perched individual, with the body held stiffly and the bill pointing downwards at about 45 degrees, pivots slowly from side to side through 30 degrees or so without pausing at the turn, and without uttering a sound. Between spells of pivoting it calls loudly. Another, more common posture of the Oriental White-eye is "wing-dropping", in which the perched bird adopts a stiff-bodied posture, with the bill pointed down, the wings drooping loosely to leg level and quivering in short bursts, and the wrists held away from the body. During foraging, challenges are indicated by bill-snapping. Submission is shown by freezing while fluffing the crown feathers and sometimes opening the bill, or by fluffing up the crown and back feathers, or by fluffing the entire plumage and half-closing the eyes so that the white eyering becomes an oval shape. Aggression often sublimates into allopreening, of which appeasement and courtship are derived behaviour.

Among Bridled White-eyes, dominance relationships within flocks are suggested by the frequent chases and supplanting on perches. Fighting within wintering flocks of Silvereyes is believed to have the function of establishing and maintaining the social hierarchy and organizing the sharing of various objects among the individuals in a flock; this contrasts with the situation in summer, when breeding pairs have their individual territories and tend not to form flocks. About two-thirds of the winter fighting by Silvereyes takes place over food, in particular pieces of fig (*Ficus*) and insects longer than 8 mm, the frequency of fighting increasing with the item's energy contents, much in accordance

with cost-benefit theories. Fights over food also last longer than do other conflicts.

There is much variation in aggressiveness between the sexes, but in Silvereyes the male tends to be the dominant sex and may defend the territory more vigorously than the female does. At the nest and in its immediate vicinity, however, the female is dominant over the male. With this species, there is no correlation between lengths of wing, tail, tarsus and exposed culmen and the dominance class. Under crowded conditions, subordinate birds may be eliminated more quickly by increased aggression of dominant ones, and food shortage towards the end of the winter may have little effect on dominants. Such a case, though rather exceptional, was described for the Silvereyes of Heron Island, in the southern Great Barrier Reef, in 1968, where an influx of mainland birds of the subspecies *cornwalli* boosted the local population of the much larger *chlorocephalus*. Although some mainland individuals were aggressive, they had little access to patchily distributed stationary food items, such as figs, as these were successfully defended by dominant island residents. At feeding stations some mainland Silvereyes continued to attempt to feed, but they sustained severe head injuries from attacks by the larger subspecies. Many mainland individuals were found dead on the island.

Territoriality is not of the same intensity throughout the white-eye family. Generally speaking, white-eyes seem to defend the area within a short radius of the nest, but they are non-territorial outside this area and, obviously, when foraging in flocks. During the egg-laying and incubation stages, Oriental White-eyes defend the nest vigorously against any intruders, threaten them with bill-snapping, and chasing them far beyond the borders of the territory. The Cape White-eye, on the other hand, does not exhibit territoriality and does not occupy songposts. No evident territoriality is known to exist in the African Montane White-eye, either, and two nests of this species were once found together with three nests of Abyssinian White-eyes in a small bamboo clump. Reunion Olive White-eyes are not social, occurring in isolated pairs, and they are highly territorial throughout the year in relation to flowers; they spend much of the time in aggressive chasing and chattering. Similarly, the Golden White-eye is territorial, and defends its territory boundaries against other males; it also responds to playback of its recorded song. When one Giant White-eye male begins to sing, others in the vicinity do likewise and a chorus ensues; after a while they all suddenly stop and dash away into

The fact that insects provide the bulk of the diet of white-eyes should not conceal the important nutritional contribution of fruit. The **Black-capped White-eye** of the foothills and montane forests of Borneo and Sumatra feeds on a variety of small fruits, including those of wild raspberry (*Rubus*), mistletoes (*Loranthaceae*) and purple figs (*Ficus*) of just a few millimetres in length. During a drought, this white-eye was also recorded taking grass seeds. Small flocks of Black-capped White-eyes forage in fruiting trees in the lower and middle storeys of forest and in shrubby vegetation on the forest edge.

[*Zosterops atricapilla atricapilla*, Kinabalu Park, Sabah, Borneo. Photo: John & Jemi Holmes]

Research into the diet of the **Silvereye** has revealed that it consumes the fruits of a number of trees and shrubs. It prefers medium-sized fruit, over 4 mm long; larger fruit contains relatively more flesh and thus offers greater energetic reward. To minimize the energetic costs of feeding on larger fruits, the Silvereye often penetrates the skin of the fruit and extracts the pulp from around the seed, rather than consuming it whole. When fruit is scarce, Silvereye flocks often venture into orchards and vineyards to raid commercial harvests. In Australia, such behaviour has resulted in the Silvereye being called "Grape-eater", and being regarded as a pest by some farmers.

The Roving Tortoise]

the vine tangles, bursting into song again some 15–30 minutes later from a different group of trees.

The Bridled White-eye appears socially subordinate to the three other small forest passerines occurring within its range, these being a larger white-eye, a fantail (*Rhipidura*) and a honeyeater. It is always the object of chasing or supplanting on perches by these other species; indeed, a Bridled White-eye can be seen to wait for the larger and dominant Golden White-eye to finish feeding at a cluster of fruits before flying to the food source to investigate it for itself. In complete contrast is the behaviour of the extremely aggressive and inquisitive Mauritius Olive White-eye; this species chases bulbuls, Red Fodies (*Foudia madagascariensis*) and Mascarene White-eyes out of its territory, although it will tolerate fodies if both species are at the same feeding site. No interspecific aggression initiated by Bridled White-eyes has been recorded, other than the scolding of a Collared Kingfisher (*Todiramphus chloris*). Seychelles Grey White-eyes have been observed to exhibit interspecific aggression, towards fodies and Seychelles Black Bulbuls (*Hypsipetes crassirostris*), only near nests. In Hawaii, serious competition with the native honeycreepers (Drepanididae) has been cited as an important factor in the decline of the latter, but there is no conclusive evidence of competition for nesting sites or food, as little is known about behavioural interactions between native birds and the introduced white-eyes. Normally, Japanese White-eyes in Hawaii permit other bird species to nest and feed within their territory without aggression, and trees in heavy fruit or nectar are not defended. In fact, there are reported cases of Japanese White-eyes being kept away from nest trees or feeding territories by introduced Red-vented Bulbuls (*Pycnonotus cafer*) and native Elepaos (*Chasiempis sandwichensis*). On flowering trees, the Silvereye is aggressive only towards conspecifics, and is chased off by the larger honeyeaters, and even by the smaller Scarlet Myzomela (*Myzomela sanguinolenta*). Golden White-eyes chase other birds, such as Eurasian Tree Sparrows (*Passer montanus*), Bridled White-eyes and other Golden White-eyes, from its nest. A male Giant White-eye will chase starlings and kingfishers from the tree in which it happens to be singing.

In captivity, the feeding of young House Finches (*Carpodacus mexicanus*) by mature Japanese White-eyes in the same cage has been reported. The finches even approached the white-eyes to be fed, although there was an adult finch in the same cage. Later,

nestling House Sparrows (*Passer domesticus*) were fed by the same white-eyes. The Japanese White-eye has been seen to feed a wild nestling House Finch in Hawaii, and a pair of Oriental White-eyes was observed to visit, and possibly feed, the young of a pair of Asian Paradise-flycatchers (*Terpsiphone paradisi*) in a nest 2 m from the white-eyes' own nest on the same branch.

An interesting hypothesis involves the Tetepare race *tetiparius* of the Solomon White-eye. The white-eye's song is so similar to that of a distant Singing Parrot (*Geoffroyus heteroclitus*) that some authors have suggested that the latter's absence from the island is caused by the white-eye's "jamming" of the parrot's vocal communication system. This, however, seems unlikely, and it is perhaps equally possible that so large a parrot is unable to sustain itself with the limited food resources available on this small island.

Preening is carried out in the same way as it is by most other passerines. The white-eye preens the breast and belly areas, and the neck and back feathers, very intensively. The wing and tail feathers are drawn through the bill, the tail being fanned sideways and each feather pulled forwards; the upperwing-coverts are preened, with the wing slightly raised and held away from the body, the carpal joint is pecked and nibbled, and the underwing is treated from below while the wing is slightly spread. The white-eye scratches the head feathers with the middle claw of one of the feet, for this purpose employing the indirect method of head-scratching whereby the leg is raised over the slightly drooped wing. This scratching begins early in the individual's life, even before fledging. The preening movements are of variable duration, depending on need, and have no fixed sequence. The Japanese White-eye has been observed to perform open-bill probing in its own feathers.

Close huddling and allopreening are also practised. When allopreening, two individuals preen each other in those places which they cannot reach with their own bill, mainly the head, neck and throat, but also the contour feathers in general and even the tail. Sometimes they use open-bill preening, but this has been described for only a few species in the family. During allopreening, which probably serves to reinforce social relationships, the white-eyes are typically seen huddled together in head-to-tail positions, one pulling mainly the rump, belly and tail feathers of the other through its bill. It was once noted that the female preened the belly of the male, which was hanging

under the branch on which the female was perched; only when she got under the wings, or came too close to the cloaca, did the male become unquiet, peck at her and fly off. The contour feathers are treated with open-bill probing, known as *Zirkeln* (see Morphological Aspects), with the bill sunk deeply into the feathers; this has been reported especially for the Cape White-eye. Whether this is a specifically distinct method of allopreening, or is done simply for extrinsic reasons, such as searching for small particles under the feathers, is unclear. With African Yellow White-eyes, the preened individual sits with the legs bent, the body hunched and the plumage ruffled; the other bird nibbles around the eyes, ears, chin and neck, for which the recipient turns its head in order to facilitate the treatment. In the case of Cape White-eyes, the feathers of the throat, the side of the head, including the eyering, and the nape are treated, during which the preened individual points its bill upwards. Although allopreening is reported to be practised by all *Zosterops* species, and the above description of an allopreening session may be considered the standard procedure for white-eyes, it has so far been documented for only a few species.

Even their human attendants are accepted as preening partners by tame white-eyes, which will stretch the neck, fluff the feathers, and turn the head in various directions in order to be scratched. When white-eyes are housed with larger birds, such as mousebirds (Coliidae), these, too, are subjected to preening, and in captivity these other species have been observed while, willingly or unwillingly, they were having the belly preened by white-eyes hanging beneath the perch.

Unlike the situation with finches and weaverbirds (Ploceidae), the fluffed plumage of Oriental White-eyes and Silvereyes is not part of a posture expressing subservience, but always a sign of readiness for contact. During threat, aggression and fleeing gestures, the plumage is tightly sleeked. Eyering-pecking has been observed among Seychelles Grey White-eye during the incubation period, involving helpers at the nest, as well as breeders, and may have a general social function, rather than just courtship. It may also have a function in intraspecific aggression, and in this connection it could explain the delay in the development of the eyering of young white-eyes (see Morphological Aspects), al-

though there are arguments against this reasoning. Feather-plucking by captive white-eyes has been observed, this most likely being a result of boredom.

Bathing is carried out in the conventional way. The white-eye dips the bill into the water, throws the water sideways, crouches in the water, and uses rapid wing movements to bring water over the back, the downward-held tail and beyond. White-eyes are fond of bathing, for which various water sources serve. Oriental White-eyes often descend in the morning to bathe in the dew which carpets the grass, and they also use the wet topmost branches of small-leaved shrubs; this species is also fond of rain showers, even if quite heavy and persistent. Bathing is often done gregariously, and up to 35 Cape White-eyes may bathe together if waterside space permits. A flock first comes down to low bushes, after which a few individuals at a time fly to the water to drink and dive into the shallows, shaking the body and flapping the wings. The birds plunge into dew-laden vegetation and rain-soaked leaves, and they utilize water taps by hanging upside-down underneath them and pecking at drips. In the Comoro Islands, a party of Chestnut-sided White-eyes was seen to bathe in a small water-filled hollow about 7 m up in a forest tree. Tame, hand-raised white-eyes will bath in the dry or wet hand of a human attendant, making all the normal movements as if bathing in a water-filled dish.

White-eyes sometimes sit motionless for two minutes or so, with the wings spread over leaves by the perch, apparently sunning. During sun-bathing the head hangs deeply forwards, often to below the level of the perch, and the body feathers are strongly fluffed up, with the wings spread horizontally. There are no known observations of dust-bathing or sand-bathing by members of this family.

Anting has been reported for the Oriental and Cape White-eyes. After wet weather, the latter species seizes the stingless but venomous ants *Camponotus rufoglaucus* and, especially, *Anoplolepis custodiens* in its bill and rubs the insect along the underside of the flight-feathers, treating first one wing and then the other. Similar behaviour, but with mealworms *Tenebrio molitor* employed, has been seen to be carried out by juveniles in the first 3–5 weeks after fledging, but ants were used later; one individual

While white-eyes tend to favour fruits of small and medium size, they do not ignore considerably larger fruit if sufficiently ripe. Several *zosteropids*, including the **Green-backed White-eye** of New Caledonia, are known to feed on fruit as large as papaya (*Carica papaya*), a tree native to Latin America but now cultivated in many tropical countries. The Green-backed White-eye also consumes berries, including those of Lantana, another widely introduced plant that is taken by many species of white-eye. This species mainly inhabits primary forest, but flocks are attracted into less wooded areas in search of ripening fruits and berries.

Being groove-shaped and brush-tipped, the tongue of white-eyes is well adapted to nectarivory.

These morphological characteristics enable the birds to suck up liquids, such as nectar, without needing to tilt back the head. In turn, this enables the white-eye to imbibe large volumes more quickly.

In spring, **Japanese White-eyes** commonly visit flowering trees such as Japanese apricot (*Prunus mume*), camellia (*Camelia japonica*) and broad-leafed mangrove (*Bruguiera gymnorhiza*).

The species is also renowned for robbing nectar from Hibiscus flowers by splitting the base of the corolla. The short bill of white-eyes means that they are frequent nectar thieves and, consequently, the family is not a particularly important pollinator.

[*Zosterops japonicus simplex*,

reportedly used a small stink bug (Pentatomidae) for “anting”, before consuming it.

Known predators of the Oriental White-eye are the Black Drongo (*Dicrurus macrocerus*), and possibly the false vampire bats (*Megaderma*). The Sri Lanka White-eye is reported as prey of the Chestnut-backed Owlet (*Glaucidium castanonotum*), and is known to be impaled by the Brown Shrike (*Lanius cristatus*). Cape White-eyes are preyed on by shrikes, boubous (*Laniarius*) and snakes, and have also been found entangled in spider webs and impaled on cactus thorns. Christmas Hawk-owls (*Ninox natalis*) are known to prey on Christmas White-eyes, remains of which have been found in the owl’s pellets, and the remains of Silvereyes have been found in the regurgitated pellets of the New Zealand Morepork (*Ninox novaeseelandiae*). Despite its abundance in Hawaii, the Japanese White-eye has never been documented as falling prey to cats or mongooses (Herpestinae), but its nests and fledglings are preyed on by both of those mammals, as well as by the introduced arboreal lizard *Anolis carolinensis* and House Sparrows. Somewhat unexpected natural enemies have been recorded for the Silvereye in the shape of the Australasian Bittern (*Botaurus poeciloptilus*) and the Great White Egret (*Egretta alba*), the latter reportedly having developed a special technique for catching and swallowing white-eyes.

Anti-predator behaviour by white-eyes is recorded only sporadically. A Bridled White-eye has been seen to mob a Collared Kingfisher, a presumed regular predator, and in New Zealand the Sacred Kingfisher (*Todiramphus sanctus*) is mobbed by various other birds, among them Silvereyes, which are occasionally caught. The “confusion chorus” of Bridled White-eyes, invariably heard upon the dramatic arrival of a kingfisher, consists of ordinary call notes uttered at maximum intensity and frequency by all flock-members. It lasts for a minute or so, during which time the white-eyes remain stationary. They respond in this manner to the kingfisher only when it is in flight. After it has alighted, the chorus dies down and they resume foraging, only to be thrown again into consternation at the next attack by the kingfisher, which may have been sitting in the same tree with them all the time. The Mauritius Olive White-eye gives distraction displays, feigning injury, when it has young. The Lemon-bellied White-eye practises a similar “exhausted bird” technique to distract the human

observer at the nest, whereby it drops to the ground and fakes lameness; this species sometimes congregates in a large, very agitated chirping flock for seemingly trifling reasons, such as a cat walking on the ground or an arboreal lizard approaching a nest too closely. The discovery of a Sulawesi Owl (*Tyto rosenbergii*) or Grey-headed Goshawk (*Accipiter poliocephalus*) causes much excitement among the white-eyes, and birds of prey are scolded, as are bulbuls and sunbirds. In Hawaii, the Short-eared Owl (*Asio flammeus*) may be mobbed by mixed flocks of introduced Japanese White-eyes and native Oahu Alauahio (*Paroreomyza maculata*) and Iiwis (*Vestiaria coccinea*). Elsewhere, Oriental Mountain White-eyes react to human intruders by scolding and approaching them to a very close distance, and Giant White-eyes will gather around a human observer while creating a loud scolding commotion, with the bill held continuously open and showing the bright orange-yellow mouth-lining. Adult Japanese White-eyes have been seen to lead dogs away from fledglings by flying just ahead of the dog.

Parasites are often regarded as important for elucidating the relationships of their hosts, but insufficient is known of this subject with regard to the white-eyes. Nevertheless, a large number of species, mainly of Protozoa and Sarcophagales, have been found on and in white-eyes. Surprisingly, chewing lice (Mallophaga) are virtually absent among the parasites, although two genera were found on Bare-eyed White-eyes. *Haemaphysalis* blood parasites were found almost universally and Microfiliariae were present in about 15% of Bridled White-eyes on Saipan and Tinian, but neither parasite was found in the Guam race of the same species. On Mauritius, both the Mascarene White-eye and the Mauritius Olive White-eye are extremely sedentary, and this is expressed in the incidence of endoparasites: both species are heavily infested by the endemic *Leucocytozoon zosteropsis* in the undisturbed native forest, where the avian malaria *Plasmodium* does not occur at all. In disturbed upland native forest both parasites are found in the Mascarene White-eyes, and some individuals even carry both of them. In lowland exotic plantation no *Leucocytozoon* occurs, but about a third of the Mascarene White-eyes were infested with *Plasmodium*. Avian malaria may limit the distribution of these species outside the undisturbed forest. Avian poxes were found in 13.5% of the Silvereyes captured in

As is frequently the case with white-eye taxa that occur only on remote islands, little is known about the diet or foraging strategies of the **Chestnut-sided White-eye**. This species has been recorded feeding on vegetable matter, caterpillars (Lepidoptera), other insects, and spiders (Araneae), but probably also consumes nectar. It is the only member of the genus *Zosterops* within its restricted range on islands in the south-east of the Comoro archipelago. The species inhabits forest, open woodland and mangroves.

[*Zosterops mayottensis*, Mayotte, Comoro Islands. Photo: Roland Seitze]

1978 in Western Australia, when they were very numerous. The mildly pathogenic parasitic *Ataxoplasma paddae* has been found in, for example, the Rennell White-eye and the Bare-eyed White-eye, and it appears to occur in many species of the family Zosteropidae.

The daily activity pattern of white-eyes exhibits two peaks. The first is in the early hours of the morning, when the birds are busy with foraging, and the second, after a resting period around noon, is in the late afternoon, shortly before or after sunset, when they gather in loudly twittering groups for roosting. During the day the birds spend the time mainly in working through the vegetation, interspersed with resting periods of various lengths during which they huddle together, preen or take a nap. The following account of a typical winter day in a Cape White-eye's life may be regarded as representative of many other white-eye species. In the early morning, pairs, which have been roosting during the night, awake well before dawn, but remain huddled for 15 minutes or so. They then rouse themselves, stretch the wings and legs, and fly to a place up to 400 m away where pairs and single individuals assemble in a tall tree, such as a *Eucalyptus*, often the same tree being used for up to a week. Still well before dawn, the assembled flock then moves out and starts to forage in surrounding vegetation. As the day unfolds, the single large flock splits up into smaller groups, these foraging widely and independently of each other. Their composition changes constantly as pairs or individuals leave or join from other parties. Towards the end of the day, most small flocks have disintegrated into pairs. After a tree has been worked over by a flock, one white-eye flies to the next tree, soon followed by the remainder, flying over in pairs and singles. From time to time the birds settle to rest in a tree, to doze, or to preen themselves or, two huddled side by side, preen each other. Foraging is often alternated with brief spells of social excitement, including wing-flicking and tail-flicking, dashing flights between bushes, chases during which clicking noises are made with the bill or wings, and quarrelling, in which two individuals flutter together in mid-air and fall earthwards, soon separating. At sunset a large flock reassembles, and from this the pairs disperse to roosting sites. During the night, the white-eyes sleep on a small branch, in pairs, the partners close to each other and facing in the same direction, with the head tucked in the back feathers.

Voice

White-eyes are highly vocal, and their voices, although rather weak and simple, are quite far-carrying. When heard from a whole flock, the cumulative sound is a loud one. The contact calls are given at all times of the day, but especially in the early morning and late afternoon. When alone or in small flocks, however, white-eyes are usually silent. The primary song is delivered during 20–45 minutes around sunrise, sometimes starting 45 minutes before, and is given sporadically also throughout the day. Bonin White-eyes are occasionally observed to sally from perches and then perform song flights.

The members of this family present relatively little variation not only morphologically, but also acoustically, and this is true particularly of the genus *Zosterops*. Even distantly related forms, such as the African Cape White-eye and the Australian Silvereye, are very similar in their songs and call notes, differing only in minor details. On the other hand, some species have very simple songs or no song at all, as typified by the Christmas White-eye, or have very distinct songs. The most complex and bizarre song of the family is that of the Giant White-eye. A solo performance by this species is said to sound like a chorus; it has a mechanical quality, with abrupt starts and stops as if the bird is being turned on and off by a switch, and rhythmic rattling or clicking and simultaneous canary-like whistles, trills and slurs.

Where two related bird species overlap, their songs tend to differentiate (character displacement), whereas no selection for song differentiation takes place with remotely related species, resulting in very similar songs and calls. Very strong differentiation in songs and calls has certainly occurred with the closely related Pearl-bellied and Golden-bellied White-eyes of the Kai Islands; although these two do not overlap in range, they may have done so historically. In the case of the Mascarene White-eye, the call notes of the nominate race of Réunion resemble more those of the subspecies *virens* of the Cape White-eye and those of the Silvereye than they do those of the conspecific *mauritanus* of Mauritius; the latter has also lost its evening warble, the challenge song.

Singing in a dawn chorus can act as an indicator of male quality, because the amount of fat available in the morning to fuel singing depends on such factors as foraging success. Indeed,

When feeding on nectar, white-eyes typically cling either to the flower or the umbel itself or to an adjacent twig. With feet wide apart to assist balance, they lean forward and incline the head to facilitate access. The chosen method of nectar retrieval depends on the species of both white-eye and plant. In some instances, the bird inserts its head and bill into the flower. Depending on the respective lengths of the flower tube and bill, this method can result in the white-eye's forehead being dusted with pollen, which means that it may act as a pollinator. In other situations, white-eyes will pierce the base of the calyx or sides of the tubes and simply steal the nectar, with no corresponding benefit to the plant. A taste for nectar sometimes brings white-eyes into conflict with nectarivores, especially honeyeaters (Meliphagidae); in such case, the larger honeyeaters usually dominate. The **Silvereye** has learned to take advantage of alternative sources of sugar, and is a regular visitor to garden birdtables, where it seeks sugar-rich products such as honey, syrup and jam. It tends to forage in smaller flocks than many congeners, groups not normally numbering more than eight individuals.

The Roving Tortoise]

Some flowers are not designed for easy arboreal access. This is particularly true of plants pollinated by the aerial-feeding hummingbirds (Trochilidae), of the Americas. Some of these have been introduced elsewhere in the world. In order to gain access to the nectar of such plants, white-eyes need to hover alongside the flower and insert the bill into the tube. While hovering may not come as naturally to a white-eye as to a hummingbird, several species, including the **Cape White-eye**, are relatively well prepared, and habitually catch aerial insects in sallying flight.

[*Zosterops pallidus*.

experiments with Silvereyes showed that supplementary food increased both the quantity and the quality of the song. Experimental playback of the tape-recorded song of the Seychelles Grey White-eye elicited a response in song from only one individual, possibly a breeding male, out of a group of this species, although the other group-members were immediately alerted and approached the tape recorder. Silvereyes in the Capricorn Islands, in the Great Barrier Reef, almost always responded to playback of their songs with visual displays and calls, but rarely with song, suggesting a strong emphasis on mate attraction, rather than territorial defence, as a function of song. There is also no differential response to playback of the songs of neighbours or strangers, this being due to the continuous nature of individual variation in the species' songs.

Song mimicry is described for many species, including, among others, the Cape White-eye, the Black-capped Speirops, the Silvereye and the White-chested White-eye, and is often given in subsong. The last-mentioned species is found only on Norfolk Island, where it imitates perfectly the song of two introduced species of thrush (Turdidae). In the white-eyes of the Mascarene Islands, mimicry occurs during periods of singing at any time of the day during the breeding season; both Reunion Olive and Mauritius Olive White-eyes give long song sequences that sound exactly like those of the imitated species, but in addition they incorporate short phrases of mimicry in their own distinctive songs. The song of the Mascarene White-eye, as is the case with a number of other species in the family, appears to be derived from flocking and flight calls. A typical song session starts when, after an individual has landed on a vantage point, its continuous calling slows in tempo and then continues in a song, interspersed with soft and elaborate phrases, including mimicry. The most elaborate songs of the Mascarene White-eye are heard within the nesting area, and can in fact be used as a means of locating the nest.

The vocabularies of several species of white-eye are well described, and the following descriptions of vocalizations and their functions focus mainly on two species, the Silvereye and, at the other end of the global range of the family, the Cape White-eye. The repertoires of these two *Zosterops* species exhibit some striking resemblances to each other. Silvereye song is divided

into three different types, the warbling song, the challenge song and the whisper song. The first of these, given apparently during the earliest stages of territory establishment, is of low volume but varied, including trills, warbles and slurs. The second, the challenge song, normally begins after mating and before building, and is made up of a rapid succession of high-pitched call notes with very occasional trills interposed; compared with the warbling song, it has less range in tone and pitch but is louder. Finally, the whisper song, given by both sexes, consists of whispered trills punctuated by a normal call note and is inaudible at more than a few metres' distance. In addition, an autumn subsong is described which is very like the whisper song, but includes some mimicry. The whisper song is given also by the Japanese White-eye when resting during the afternoon.

In the course of the year, the song of the New Zealand Silvereye changes. The warbling gradually becomes longer in July and August, when a territory tree is being attended but no attempts at nest-building are made; during September the Silvereye spends much time in the tree, delivering the warbling song or performing courtship with the whisper song; in late September, when a particular branch or twig has been selected for regular visits, the male begins his challenge song from a vantage point nearby. During October the amount of challenge song decreases as the male participates in incubation of the eggs, and song stops entirely with hatching. After the young have become independent, at the end of November, there are short periods of warbling and challenge songs before the second clutch is started.

The song of the male Cape White-eye in the breeding season is of two types. The rambling daytime song, normally lasting for 7–40 seconds and occasionally more than five minutes, starts with a short phrase of subdued sibilant twittering, followed by a somewhat louder subsong of disjointed chips, chirps and whistles, including imitations of robins (Turdidae), bulbuls, canaries (*Serinus*), sunbirds and others, and finally breaks into a series of sweet, slightly burred warbles and whistles. The second type, the regular song, given alone, is short, one transcribed example lasting about six seconds, as “chup, chipway-cheeo, wur-lee, cheeu-chu, cheeu, chu-chayee-chuchoo-cheeo”. A shorter version of the daytime song, without the initial twittering, is about 6–10 seconds in duration and is delivered at dawn.

White-eyes foraging on flowers are primarily seeking food directly from the plant, in the form of sugar-rich nectar. But flowers also offer indirect food resources, as they attract arthropods that are potential prey. This **Silvereye** has reaped such a benefit, as its probing amidst the flower has located a grasshopper (Orthoptera). A large item such as this will need to be mandibulated and perhaps beaten against a branch prior to being swallowed. To discover lurking arthropods, white-eyes probe with vigour between salient parts of the plant.

[*Zosterops lateralis chloronotus*, Wanneroo, Western Australia, Australia. Photo: Bert & Babs Wells/Oxford Scientific Films]

The song of most *Zosterops* species has been likened to the sound of a telegraph message being transmitted by Morse code: more or less a series of notes closely similar in pitch, but differing in quality and in form, being single notes, upslurs or downslurs. Although seemingly a haphazard sequence of trills, warbles and slurs, in song bouts with an average of 16 syllables, and lasting about five seconds in total, the song of Capricorn Silvereyes has a well-organized hierarchy. An average repertoire contains 53 syllable types, organized into 30 different sequences each of five or more syllables, and repeated several times, but interspersed with “filler” syllables. During one morning chorus, half of the number of sequences is given. In a study on Heron Island, males of the same age cohort were found to share more syllables than other males, and it appears that the complex song repertoire of the Silvereyes is established by the first breeding season, after the birds have ranged widely throughout the island and learned a wide range of syllable types in largely the same acoustic environment. The complexity of a song may be influenced by low visibility of the species, sexual indistinguishability, intensity of competition, and low complexity of the community, but the song is subject also to temporal variation caused by change in song motivation, the time of the day and the stage of the dawn chorus. None of these explains the complexity very satisfactorily, but more research on the combined effect of these factors and possibly others throughout this speciose family may provide a useful indicator of a species’ overall ecology.

Flocking calls of Silvereyes in flight sound like “cli-cli-cli...”, and commonly a rather plaintive “cree” or thin peevish “psee” is heard. Equivalent calls of Cape White-eyes are a short “pee”, a longer, downslurred “pee-u”, a double “pee-u-pew”, an upslurred “tu-tsee” and a harsh “pik” or “tip”; excitement calls of individuals flying in follow-my-leader fashion from bush to bush are “krrreee”. The contact calls of Silvereyes differ according to sex. In field studies and studies of captive, as well as studies of individuals being released, the so-called “Variable call”, one of the species’ three types of contact call, was given by males only. Moreover, recognition of mates by voice has been demonstrated, this being the first evidence of vocal mate recognition by a species that maintains pair-bonds in mobile foraging flocks. At least three calls are used for mate recognition: male-specific linear

and variable calls, carrying over long distances, and a soft contact call, which is the main vocalization in close contact and easily pinpointed.

Among *Zosterops* species, flocking calls typically sound very like the calls of newly hatched domesticated chickens, “chew”, “chee” or the like, but Lemon-bellied, Sri Lanka and Solomon White-eyes are known also to utter a “shilp” like that of a House Sparrow. The Mauritius Olive and Reunion Olive White-eyes have a metallic and clipped “plik plik” or “chip chip” contact call which they share with the Seychelles Grey White-eye. In contrast, the Bridled White-eye commonly gives a whining call when in flocks, the same whining call being used also in agonistic interactions, such as intraspecific chases or the mobbing of a presumed predator. During incubation, the change-over calls of the Seychelles Grey White-eye, given when one partner leaves or arrives at the nest, are series of three or four notes, or occasionally warbling notes, the volume of which depends on the identity of the individual. In excitement the Cape White-eye emits a “krrreee” call, and two individuals in excitable mood may utter a tripping stutter, “k,r,r,r,eee”; this species’ alarm call is a harder and louder version of the “krrreee”. Among other vocalizations of this family are the searching call of a solitary bird that has lost sight of its companions, that of the Slender-billed White-eye having been described as a very loud “kyeeéé...kyeeéé...”, similar to the corresponding call of the Oriental White-eye and some other zosteropids; when Oriental White-eyes have found each other again, they utter an excited double “kia-kie” or “tia-tüih”. Special Silvereye calls, modifications of the “cree” call, are given during incubating, brood-feeding and feeding of fledglings, and as a threat call. The characteristic begging call of the juvenile Silvereye after leaving the nest is “ee-chéeta”, while a begging call of young Lemon-bellied White-eyes sounds like “chee-chee-chee-chee”.

White-eye alarm calls seem to be universal within the family, and similar calls are described for various species. The Oriental White-eye utters, with hardly opened bill, a “trrr-rt” or “deerrreet”, causing panic and fleeing reactions among conspecifics, whereas fledglings crouch and freeze upon hearing this call, their own alarm sounding like “scheep”. Christmas White-eyes emit a “tsirr...tsirr...” as an alarm and agitation call, and a high “cheeuw...cheeuw...cheeuw...” when scolding an

Australasian Goshawk (*Accipiter fasciatus*). The Seychelles Grey White-eye gives specific alarm calls on sighting a low-flying *Pteropus* fruit bat, a loud single “chewick” causing the group to scatter; human observers elicit thin “whee” calls. The nest-alarm call of the Silvereye is a grating or nasal “swang”, rarely heard except in the breeding season, but liable to be used if a kingfisher, owl or cat is nearby. When a Silvereye is actually flushed from the nest, this call is modified to “swang di-di-di-di”. Another alarm is described as “wee-ee-ee-ee-ee”, and a whinnying call of alarm and agitation sounds like “ti.hi.hi.hi.hi”.

Finally, Cape White-eyes have been reported as making clicking, possibly non-vocal, sounds when momentarily hovering in search of food items trapped in spider webs, for instance. The African Yellow White-eye, too, makes clicking noises, perhaps with the wings, during mutual chases. The wings of the Mountain Black-eye produce a thrumming “brtp brtp” noise in flight. Bill-clicking is a feature of aggressive encounters by Silvereyes, which produce this sound from an age of 25 days and older.

Food and Feeding

The diet of white-eyes seems to consist mainly of insects, but fruits, berries and nectar constitute a large proportion. Buds and seeds are taken sporadically, and capillary suckers of sugary plants and insect secretions are sometimes consumed. The morphology of the intestine and gizzard of the Silvereye, for example, is typical of that of facultative frugivores, being intermediate between the internal morphology of insectivores, in which the dimensions are similar, and that of specialist frugivores, which have a substantially larger gizzard. This plasticity in diet and the ecological adaptations of the Zosteropidae have resulted in a diversity of foraging behaviour. The generalist nature of these birds made them successful colonizers of oceanic islands. In Hawaii, the introduced Japanese White-eyes were found to spend 9% of their foraging time on fruits, 26% in feeding on flowers, 38% in foliage-gleaning, 16% in foliage-probing, 4% in bark-gleaning and 4% in bark-pecking.

The main feeding strategy, as described for the Abyssinian White-eye, is what is known as the “trap-line” method. The birds

systematically investigates the vegetation, taking the same route daily around the home range; they then appear at a given tree at the same time on successive days. On Palau, such a fixed foraging circuit of Citrine White-eyes included the edge of a woodland, bushes in gardens and taller trees in an adjacent mangrove swamp; the flock made the rounds here about once every hour, but at one time the birds interrupted their foraging in order to rest silently for half an hour in a large tree in a swamp. A neighbouring flock of Grey-brown White-eyes had about the same circuit, but the two species remained independent, their paths crossing occasionally as if by accident, at which time they would forage in the same tree. In the case of Mauritius Olive White-eyes, the home ranges appeared to be extremely variable, and, depending on food availability, ranged from 2 ha in areas rich in flowering plant species to 20–30 ha in others, where the birds could be seen to make long flights of up to 500 m to reach nectar sources.

In the search for arthropod prey, white-eyes employ four major foraging actions. These are that of gleaning, whereby prey is removed from a surface while the bird is perched; probing, in which the bill is thrust into a crevice, fruit or flower; hovering while removing an item from a surface; and sallying, in which the white-eye captures aerial prey on the wing in flycatcher-like fashion by darting from a perch. The foraging behaviour of *Zirkeln*, or open-bill probing (see Morphological Aspects), well described for the Common Starling (*Sturnus vulgaris*), is often practised by white-eyes, too. Crevices and holes are inspected in this way, and attention is paid especially to places where leaves are affixed to the stem, where tiny insects hide, and to cracks in palm stems, which are favourite places for scale insects (Coccoidea), including mealy bugs (Pseudococcidae). The African Yellow White-eye inserts its bill into crevices in bark and twigs, rolled-up leaves and flowers, and then, by opening the mandibles, prises apart the edges of the crevice or vegetation and peers inside. White-eyes also probe with considerable force into relatively firm plant and food parts without existing holes, such as grapes, nearly spikeless cactuses and the like, and then open them by opening the bill in order to gain access to the juicy parts.

Some species, such as the Cape White-eye, take flying insects in short, purposeful hawking flights reminiscent of those made by other sallying songbirds; upon discovery of a prey item, the bird stiffens and makes twitching movements, before striking, the prey then being killed and swallowed, after which the bird usually shakes its feathers. Not all insects are taken immediately; when insects are flying at a distance, the birds fix on the prey, following it with their eyes, while staying put. Insects flying within a short distance, however, are seized immediately. Flies (Diptera) and moths and butterflies (Lepidoptera) are skilfully caught in this way.

Inspecting of other birds' nests in the search for insects has been observed. This can lead to excessive behaviour, such as the feeding of the nestlings of the other species, and on Lord Howe Island the extinct Robust White-eye was even reported as “sucking” the eggs of other birds.

Although zosteropids are regarded as purely arboreal birds, there are observations of Oriental White-eyes occasionally flying down to the ground, even to a gravel path in a garden. Some members of the family can regularly be seen to potter about on the ground, working among dead leaves, a common habit of, for example, the Slender-billed and Christmas White-eyes. The African Yellow White-eye can progress for a metre or two by hopping, but these birds are able to walk, too. Although a very skilful climber, the Bonin White-eye, with its long tarsi and strong toes and claws, is well adapted to foraging on the ground, where it uses a thrush-like hopping mode, without walking or scratching and gleaning food with the bill. The Lemon-bellied White-eye is sometimes seen perched on the bark of a tree, with the tail held against the bark in woodpecker (Picidae) fashion, and with the head tending backwards, apparently to get a better view; it moves upwards in small leaps, everywhere searching for insects with great precision. This species often hangs upside-down in the manner of a nuthatch (Sittidae), sometimes from one foot only, but it never moves downwards head first. On Buru, the Rufous-throated White-eye is even further specialized in bark-feeding (see Systematics). White-eyes are able to jump from one branch

White-eyes need to take in water as well as food. A groove-shaped tongue assists them with drinking, as it means that they can suck up water without needing to tip the head back. The African Yellow White-eye flicks out its tongue a millimetre or two to draw water into its mouth. This white-eye also readily drinks from puddles and uses its tongue to lap up water from the surface of leaves. Populations of certain species living in seasonally arid regions exploit alternative water sources. In Western Australia, for example, the Silvereye (*Zosterops lateralis*) extracts water from the nectar of marri (*Eucalyptus calophylla*) or from grapes.

[*Zosterops senegalensis anderssoni*, Stone Hills Game Sanctuary, Zimbabwe. Photo: J. R. Peek]

White-eyes are monogamous and solitary breeders, and some species, such as the **Oriental White-eye**, have pair-bonds lasting several years. Breeding responsibilities are shared, with both sexes building the nest, incubating, brooding and feeding the offspring. The nest is typically suspended between twigs or forked branches in a shrub or bush. The height of the nest above ground varies among species and among individual pairs; Oriental White-eyes tend to nest in the first few metres above ground, but occasionally breed as high as 18 m up. The nest itself varies little across the family and is part of the justification for including monotypic genera such as *Chlorocharis* with *Zosterops*. The typical white-eye nest is a small, open, fairly deep cup. That of the Oriental White-eye is rather delicate and thin-walled, measuring just 6–7 cm in diameter and 3 cm in internal depth. Plant fibres, tendrils and grass constitute the basic building materials, and these are woven together and strengthened with spider web, moss and animal hair. Construction usually takes the Oriental White-eye pair 4–6 days, which is rather shorter than other congeners for which data are available. New nests are built for each brood.

[*Zosterops palpebrosus auriventer*, Singapore.

or twig to another without using the wings, bridging distances of up to 50 cm.

A favourite food for most, if not all, white-eyes is aphids (Aphidoidea), which are gleaned from stems. Caterpillars, taken from leaves, are also frequent items in the diet. Invertebrates found in the stomachs of, for instance, African Yellow White-eyes included spiders, both homopteran and heteropteran bugs, lacewings (Neuroptera), beetles (Coleoptera), ants (Formicidae) and caterpillars. When dealing with larger prey, the bird removes the wings by taking the item in its bill and rubbing it against a branch. Young white-eyes very soon display their inborn insect-catching skills. Grubs, caterpillars and similar items are taken by the head and beaten against a branch, and then squeezed through the bill several times, before being swallowed. Cape White-eyes soften some insects by nibbling on them before ingestion. Several white-eyes have been observed to make use of their feet to hold food or nesting material.

Fruits form an important part of the diet of this family. Nestlings of at least some species are at a certain stage even fed exclusively with fruits (see Breeding). In experiments with captives and observations on wild Silvereyes, this species showed a preference for fruit that is accessible, and the birds avoided "hanging" in order to obtain fruit, but they did not exhibit any preference for "picking" over "reaching up". The foraging methods are, however, likely to vary according to the species of fruiting plant and its morphology, including the branching pattern, the perch stability and the position of the fruit. In other experiments, captive Silvereyes showed a strong preference for red fruits, both artificial and natural ones, regardless of the spatial format of presentation, but the preference was based on selection of hue, rather than brightness, although some individuals selected for particular brightness levels within the same hue. This would be consistent with the hypothesis that fruit colour is related to avian frugivory, and would suggest that birds can act as strong selectivity agents with regard to fruit colour. It has also been demonstrated experimentally that green fruits are preferred if their sugar concentrations are twice those of red or white fruits; it appears that the birds are able rapidly to judge the fruit's nutritional quality, and thus its maturity, by taste. Further, in the same study, large fruits, those more than 4 mm in size, were preferred over

small fruits of 2 mm; large fruits contain more pulp, and the white-eyes, by consuming them, will maximize energy intake, provided that the fruits are not so large that they incur high handling costs.

When fruits are too big, the white-eye, using the bill, pierces them and pecks away the flesh from around the seed. This is how the Silvereyes, for instance, dealt with 6-mm olives (*Olea*), but the same olives were swallowed without difficulty by the much larger White-chested White-eye. Cape White-eyes swallow fruits whole, but they peck holes in olives, and they feed on oranges through natural cracks or splits or when these fruits have fallen to the ground and become rotten; large oranges hollowed out by other birds were entered by the white-eyes. One of the ways in which the Black-fronted White-eye breaks down fruits is by holding the fruit in the bill and beating it against the perch, a treatment sometimes referred to as "thrashing".

Fruits of the native rubiaceaceous shrub *Coprosma quadrifolia* are frequently eaten by Silvereyes, and experiments on the passage time of this fruit through the gut showed rates of six to 28 minutes, fastest when fed to birds with empty guts, and significantly slower when food had already been consumed. No difference whatsoever in seed viability was found between the two treatments, although the viability of seeds that had passed through Silvereye guts was significantly lower than that of fresh seeds. Disadvantages to seed viability may thus be countered by advantages in longer dispersal distances. During a study of a temperate Australian woodland, it was established that Silvereyes were the dominant frugivores, and 90% of their faecal material contained the seeds of fruiting plants. They were able to consume up to 40 fruits per visit, each of which lasted for only about a minute, after which they would fly towards canopy trees. With a gut passage rate of about 30 minutes, the seeds would be dropped away from the parent plants; despite the high viability of seeds recovered from the droppings, 94.4% for *Rhagodia* and 100% for *Hymenanchera*, the density-dependent seed mortality is nevertheless also high because of the large number of seeds per dropping. Experiments with captive Silvereyes revealed that the time taken by fruit with one large seed to pass through the gut, 22 minutes, is significantly shorter than that for fruits with three small seeds having the same total volume, which is 28 minutes, and that the birds consume significantly more large-seeded fruits than small-seeded ones. Apparently, the birds compensate for the costs of seed ingestion, increased ballast load, by a rapid passage rate through the gut and hence an increased rate of fruit consumption. Observations on wild Silvereyes feeding on fragrant saltbush (*Rhagodia parabolica*) showed that the birds prefer fruits with small seeds, as opposed to those with large seeds; in experiments with captives in which artificial fruits with many seeds were used, the ingestion of seeds was avoided, suggesting that Silvereyes are inefficient dispersers for plant species with large fruits containing many small seeds. Secondary metabolites in ripe fruit, such as tannins, alkaloids and saponins, serve to deter consumers that do not disperse viable seeds, and it has been suggested that they promote the movement of frugivores from the parent plant after consuming only a few fruits, and shorten the time of retention of the seed in the gut. It has been shown that Silvereyes consume tannin-rich artificial fruit if they can swallow it whole, but avoid a tannin-rich aqueous cereal diet. Rather than depending on a morphological adaptation, although the species' relatively large liver (5.48% of the body mass) may suggest otherwise, the consumption of secondary metabolite-rich fruit by wild Silvereyes is more likely to depend on food availability, nutrient content of the fruit, and the degree of dietary mixing.

White-eyes play their part in plant pollination. More than once in the past, specimens of the Cape White-eye the yellowish-green throat of which had become bright orange through aloe (*Aloe*) pollen have made their observers believe that they had discovered a new species of white-eye. Typical differences between American flowers, those visited by hummingbirds (Trochilidae), and Asiatic bird-flowers, typically visited by sunbirds and white-eyes, is that the former are situated such that they can be reached by hovering hummingbirds from the air, whereas the latter are in such positions that they are within reach of birds sitting in the foliage. White-eyes cling to the flowers, with the feet held wide apart, in a horizontal to perpendicular

The breeding season of the Cape White-eye varies geographically. In the south-west of its range, in southern Africa, it nests between August and April, whereas in the north-east it starts and ends two months earlier. During the laying period, white-eyes appear to lay one egg per day, around sunrise. Incubation often starts once three eggs have been laid. The incubating individual keeps as much of its body as possible within the nest cup, often with just the head and tail protruding above the rim. Cape White-eyes incubate for 10–12 days; judging from the limited data available, this period appears to be at the lower end of the white-eye range.

[*Zosterops pallidus virens*, Eshowe, KwaZulu-Natal, South Africa.

Photo: Guy Upfold]

stance and with the neck stretched forward and bent a little to the side; they work each flower only briefly. During visits by African Yellow and African Montane White-eyes to flowering silky-oaks (*Grevillea robusta*), only ten flowers per raceme are worked, while the birds usually remain in the same position and probe within a relatively small area of open flowers, staying for an average of only 20 seconds. Although the tongue of these species is adapted to nectar-feeding, the short bill makes them flower-robbers and thus not important pollinators, and not an example of close co-evolution. A study of pollination of *Grevillea* flowers in Kenya, however, showed that both of these *Zosterops* species brushed the bill and head against the flowers' stigmas, so that pollen removal and deposition on stigmas seemed highly probable. Their effectiveness as pollinators was supported by the absence of fruit-set in flowers that had been bagged to exclude visiting sunbirds and white-eyes. Frequency of visits to *Grevillea* flowers in Kenya corresponds with the times when the measured nectar concentration and volume are high, between 08:00 and 10:00 hours. In addition, low flower density greatly influences the visitation rate, and this may be affected by the availability of other food sources. Flower-visiting seems to follow the same pattern of sustained exploration of the environment as that used in inspection of branches, twigs and foliage. Tiny, inconspicuous flowers, as well as striking ones, are visited by Cape White-eyes, which suggests that these birds, unlike hummingbirds and sugarbirds, are not guided by colours. In the Mascarene Archipelago, it has been found that *Angraecum striatum*, which belongs to a subtribe of orchids specialized mainly for moth pollination but which differs from others in the group in being unscented and in having short-spurred flowers, is pollinated only by the endemic Mascarene White-eye.

Oriental White-eyes take the nectar of *Hibiscus* flowers by piercing the base of the calyx. Similarly, the corollas of *Watsonia* and *Tecomaria* are damaged by Cape White-eyes in their attempts to reach nectar, and the flowers of mistletoe (*Loranthaceae*) are exploited in the same "illegitimate" way. The petals of, for example, *Feijoa* flowers are torn up and the pieces swallowed. Abyssinian White-eyes, after having fed at flowers, often have a distinct dusting of yellow or cinnamon pollen on the

forehead. Oriental White-eyes of the Sumatra highland subspecies *buxtoni* feed in flocks at *Erythrina subumbrans* flowers, into which they insert the head and neck, and are therefore one of this plant's most important pollinators. However, this *Zosterops* takes nectar from the sides of *Erythrina orientalis* flowers, and cannot therefore be reckoned among its pollinators. Mountain Black-eyes push the head deep into the pink to deep red and purple corollas of rhododendron (*Rhododendron*) flowers with tube lengths of 15–20 mm, about the same as the bill length of this species; some birds show a yellow-stained forehead afterwards. They may also pierce the sides of the tubes in order to obtain the nectar. The robust flowers are placed in umbels at the ends of small branches, with up to ten flowers together, and with convenient leaf and flower stalks on which the black-eyes can perch.

The groove-shaped brush-tipped tongue of white-eyes enables them to suck up fluids, and saves them the effort of drinking in small amounts and having to raise the head each time. The tactile tongue of the African Yellow White-eye can be flicked out to a distance of 1–2 mm to draw water, exudates and liquid nutrient into the mouth by capillary attraction; this species also drinks water from puddles, and sucks with the tongue while foraging in damp forest. During drinking, the tongue in the half-open bill moves rapidly with long up-and-down strokes, very much like the action of the honeyeaters. When water is less available, and slightly saline, Silvereyes in Western Australia are dependent on the nectar of marri (*Eucalyptus calophylla*) as a source of water and carbohydrates. Only when marri nectar, too, is in short supply do the Silvereyes turn to the less favoured substitute of ripe grapes in vineyards, then becoming pests. The grapes alone are not, however, sufficient to meet the Silvereyes' needs for water, as vineyard birds appear to be dehydrated, having a total body-water content measured at 69.4%, as opposed to a "normal" value of 78.3 %.

Feeding trials with captive Cape White-eyes indicated a high sucrose activity, as absorption efficiencies of the three nectar sugars sucrose, glucose and fructose were close to 100%. A fourth nectar sugar, the pentose sugar xylose, a major constituent of the nectar of *Faurea* flowers, which are known to be visited by Cape

There is no published information on the breeding biology of the **Yap Olive White-eye**, which is endemic to the small island of Yap in the Caroline Islands. Judging from this photograph, however, it would seem likely that both sexes participate in the breeding responsibilities, in common with other family members. The nest of the Yap Olive White-eye appears to be a deeper and larger cup than in many *Zosterops* species, which is perhaps not entirely unexpected for a relatively large white-eye.

White-eyes in South Africa, had an absorption efficiency of 61%, and was rejected in the trials; it is not clear whether the sugar is utilized. Of the three other sugars, sucrose was preferred over the hexoses glucose and fructose, even though most fruits are hexose-dominant. Cape White-eyes resemble the specialized southern African nectarivores in their responses to nectar sugars.

Generalists' diets of fruit, nectar and insects vary considerably in nutrient content, and therefore require different digestive processing. Feeding trials in which transit times and assimilation efficiency of captive Cape White-eyes were measured indicated that body mass was lost when fruit was fed, but was maintained when nectar was fed, and mass was gained with mealworm diets. Assimilation efficiency was highest for nectar and lowest for mealworms. It was further shown that the white-eyes selected the most efficiently digested and energy-rewarding diet. Moreover, they regulated their daily energy intake by adjusting the transit time, rather than by maximizing assimilation efficiency; by maximizing the rate of energy gain per gram of food, they were able to maintain the energy balance.

Artificial food is occasionally eaten by the Zosteropidae. Cape White-eyes take jam and sugar from garden tables, and the Silvereye is commonly fed with fat, fruit, sugar, honey, syrup, jam and bread. In captivity, white-eyes thrive on a mixture of minced hard-boiled eggs or grated cheese, grated carrot or chopped chickweed, sweet biscuits, seaweed tablets, alfalfa tablets and soya meal, made crumbly and moist with honey and marmite, porridge, tomatoes, peaches and peanut butter; fruits taken include, among others, banana, apple, grapes, orange, tinned peaches and, especially, pear. Mealworms and spiders appear to be preferred above all other foods offered.

Gastroliths are small pebbles or similar items which an animal, and especially a bird, intentionally ingests, as an aid in the process of digestion. Sand has been reported as a gastrolith for Cape White-eyes, and grass seeds were found in the stomachs of Black-capped White-eyes during an *El Niño* drought.

Nestlings of the African Montane White-eye are fed with small spiders and numerous tiny caterpillars; tiny nymphs of long-horned grasshoppers (Orthoptera), however, were rejected by Abyssinian White-eyes as they were too large. Cape White-eyes feed their young with insects, small fruits and pieces taken from

larger fruits. Oriental White-eyes have been seen feeding their fledglings with the orange, fleshy arils of earleaf acacia (*Acacia auriculiformis*). Parents have also been observed to feed their nestlings with liquid; whether this was nectar, or water to facilitate the swallowing of large insects, was unclear.

Although the diets of the Zosteropidae show much similarity, there are some specialists. The Javan Grey-throated White-eye and perhaps other mountain-dwelling species appear to be more vegetarian than other members of the family. The two olive white-eyes on Mauritius and Réunion are, to a greater degree than other white-eyes, nectar specialists. Nectar-feeding by these species takes place from a perch, on which remarkable gymnastics are performed in order to reach the nectar sources in awkwardly positioned flowers; one individual of a pair pierced the corolla of *Trochetia* flowers up to half-way, a process sometimes known as "cheating", while its partner always used the direct method, suggesting specialization.

The acquisition of foraging skills by Silvereyes has been investigated by comparing foraging efficiency, measured in terms of captures per unit time and captures per unit energy, in three age groups. First-year and second-year individuals are less efficient foragers than are older birds. Breeding, however, is not delayed until adult levels of foraging efficiency have been attained, as some second-year Silvereyes attempt to breed. Both learning and selection effects, such as food shortages in winter, may have been involved in causing the age-related differences.

Breeding

In New Britain, Black-headed White-eyes breed in the early wet season and again in the latter part of the wet season. This is in contrast to some other parts of the tropics, for instance Java, where Oriental White-eyes breed mainly in May–June, the beginning of the dry season. The same pattern is found for Flores, in the Lesser Sundas. Within its tropical range the Australian Yellow White-eye breeds throughout the year, with a possible peak in September–October, the late dry season.

The breeding cycle of the Silvereye in New Zealand has been summarized as follows. In July, when the pairs still wander as members of foraging flocks, the male starts to make dawn visits to one particular tree, which could be his nesting tree of the previous season, and here he warbles briefly before joining the flocks later in the morning. His visits become gradually longer, and only females that enter his territory are tolerated, as they incite him to sexual displays and whisper songs (see Voice). Soon, the male follows and accompanies one particular female, and spends long periods in sitting next to her, allopreening and attacking any newcomers. In September the pair-bond is definitive, and the pair-members feed together, and spend much time in the territory tree, busily engaged in courtship activities such as mutual preening, whisper song, and posturing. In late September, one branch or twig in the territory tree has become the favoured site, and the male starts to sing his challenge song at a vantage point nearby. In early October, the female begins the task of nest-building, rarely accompanied by the male, but greeted with intense sexual displays on returning to the site with material. The eggs are laid daily, and the partners now forage singly, taking turns to incubate the eggs and to feed and brood the young; soon, however, they feed together as before. After fledging, the adults and young spend less than a day in the territory tree before the family wanders widely through the territories of aggressive neighbouring white-eyes. At the end of November the pair returns to its territory to start a second nest, and a third brood may be completed in March.

With the African Yellow White-eye, courtship is commenced by the male, which stands high on his legs, with the crown feathers or, when more intense, more feathers fluffed, and the half-open wings held horizontally, with wingtips quivering; rarely, the wings are fully opened. The female can react by flying away, or by pecking towards the male's neck and body in a half-hearted and hurried manner. If the male accepts the female's advance, the pecking becomes allopreening and pair formation has occurred.

The Dusky White-eye, endemic to the Palau Islands, is a good example of a white-eye restricted to a small island group and about which very little is known. No information has been published about its breeding biology, so this photo provides a start. The nest appears to be larger, deeper and somewhat less neat than that of a typical Zosterops. The two nestlings visible within the normal clutch size for the family of 2–3. Caterpillars are fairly typical items for an adult white-eye to feed to its offspring.

[*Zosterops finschii*, Ulong Island, Rock Islands, Palau. Photo: Mandy Etpison]

White-eyes are cautious parents, not leaving the nest unattended for the first few days following hatching. Studies of the **Silvereye** reveal that breeding success is correlated to the length of time that pairs spend at the nest. Young Silvereyes are provisioned with grubs, caterpillars and fruits such as ripe figs. On occasion, parents return to the nest with spiders (Araneae) or adult insects, including moths (Lepidoptera). The adults consume any item that is too large for the nestlings to swallow. Some Silvereyes produce up to five clutches in a single breeding season, but only a quarter of individuals survive from year to year.

[*Zosterops lateralis lateralis*,
Christchurch,
New Zealand.
Photo: Don Hadden]

False feeding as part of courtship has been described for, among others, the Oriental and Cape White-eyes; even false nest-building, without nesting material, has been reported for some species. In contrast to the situation with many other bird species, this behaviour has only an appeasing function, and does not serve to strengthen the pair-bond. When a female threatens a male, she offers her open bill to him, and he then puts his bill partly inwards from the side, repeatedly touching the inner side of her bill with his tongue.

Wing-quivering, which often takes place shortly before and during the first stages of nest-building, is a means of pointing out the definitive nest-site, and the male performs it also while delivering nest building materials. Wing-whirring by the female is nearly always followed by copulation. In this, the male hops around the female and, after having vigorously preened the neck and cheeks that she offers to him, he mounts her. The male Seychelles Grey White-eye has been seen to peck at the female's white eyering before copulation. Copulation frequency of Silvereyes in the Capricorn Islands is low; only 14 such instances were recorded during 199 hours of observation of eleven pairs during the fertile period of the females.

Males of the Lemon-bellied White-eye prefer to sing from posts in a high branch of the nesting tree, actively singing especially at the onset of the breeding season, but more or less ceasing when they have young to attend. The Bonin White-eye has a very simple courtship display, which consists mainly of chases and mutual bowing, while singing is very rare.

Nests of the Zosteropidae are strikingly uniform throughout the family, and even the most atypical species, such as those in the genera *Heleia* and *Chlorocharis*, build typical white-eye nests. The work of building is undertaken by both members of the pair, although the female does most of the work in some cases and the male in others. It takes the Abyssinian White-eye 7–8 days to construct the nest, and some fine fibres are added after the first or second egg has been laid. Other construction periods reported are 5.5–11 days for the Cape White-eye and 7–10 days for the African Montane White-eye. During observations on the Seychelles Grey White-eye, it was found that one individual arranged the nest material, in this case bark strips, brought in by both partners from a source 60 m away. Both sexes of the Oriental White-

eye brought in material and manipulated this, without any obvious division of tasks. The stealing of nest material is common. The construction of the nest by the African Montane White-eye takes place in the following sequence: first, one end of the material is worked around the arm of a twig, and then the other end is secured to the opposite arm; long strands of moss are laid on the resultant sling, and finally strands of material are worked into a U-shape and gradually into a bowl.

A typical white-eye nest may be described as a small open, delicate but durable cup or hammock, fairly deep, and firmly attached between two horizontal arms of a forked twig or two parallel thin petioles, so that the rim of the nest is at same level as the supports. It is made from plant material, mainly tendrils, pieces of beard lichen (*Usnea barbata*), plant stems, and fine strips of bark from creepers, bound together with spider web and often decorated externally with spider cocoons, and lined with woolly vegetable down and sometimes one or two feathers. Occasionally, nests may incorporate other material, and one was made from pieces of string and threads, with cobweb, and lined with plant down topped with coir from a doormat. Material from an earlier nest is sometimes used. The nests of Golden White-eyes are exceptional, as they are not lined with any soft material. Nests of a largish species, such as the Seychelles Grey White-eye, have an external width of 6.7–8 cm and height of 5.7 cm, with an internal width of 5 cm and interior depth also of 5 cm. The nests of a smallish species, such as the African Yellow White-eye, are 5.2–5.5 cm in external diameter and 2.8–3.6 cm in height, and have an internal width of 4.4–3 cm and depth of 2.4–2.7 cm. Nest dimensions can vary considerably within one taxon.

Nests are typically suspended between twigs at varying heights above the ground, but those of the Citrine White-eye and of the Pohnpei subspecies *ponapensis* of the Grey-brown White-eye are reported as being sometimes placed on thick branches. The nest is usually sited away from the prevailing wind in a thick terminal clump of vegetation, sheltered from wind, rain and sun. Cape White-eye nests are typically placed at the end of branches of a leafy sapling in shady undergrowth, or hung in a spray of branches a metre or so above the ground in a gully. Rarely, an exposed site may be chosen, as illustrated by Oriental White-eye nests found in the side of a road cutting in south India, and nests

of Citrine White-eyes are frequently in very exposed locations, such as some 45 cm from the ground and without concealment or covering leaves in an isolated low roadside shrub. On Réunion, Mascarene White-eyes camouflage the nest in accordance with the environment, using green moss when the nest is placed in foliage and grey-white material when it is in more exposed sites. This tactic is apparently effective against predation by avian predators, such as the local race of the Madagascar Marsh-harrier (*Circus maillardi*), but much less so against predation by black rats (*Rattus rattus*) and the introduced snake *Lycodon aulicus* and oriental garden lizard (*Calotes versicolor*).

For each subsequent brood Oriental White-eyes build a new nest. Old nests are sometimes demolished, most likely so that the material can be used for building a new one. In addition, when eggs or whole clutches are lost, a new nest is built in a new location. African Montane White-eye nests are constructed in the very same site season after season. In the North Marianas, Rota White-eyes were not seen to reuse nests, but the recycling of nest material in the construction of a new nest certainly occurred. Fidelity to the breeding area is strong among African Yellow White-eyes, and a male of this species is believed to have occupied the same territory for at least eight seasons.

Clutch size of the Zosteropidae is normally two or three eggs, and sometimes five. The geographical rule that clutch sizes are larger in temperate regions, having seasonal food abundance, than they are in the tropics is generally applicable to the white-eyes, although not very prominently so. Clutches of two eggs are found in most populations near the equator, and the Oriental White-eye always lays two eggs in Java, but clutches of the Malaysian race of this species contain three or four eggs; clutches laid by Silvereyes in New Zealand likewise consist of up to 3–4 eggs. Some longitudinal differences exist, for instance among Cape White-eyes, with an average of two eggs in the south-west of its range but three eggs in the south-east. The Chuuk subspecies *owstoni* of the Citrine White-eye lays only a single egg, as do so many passerines of the Pacific islands, and this is explained by some authors as “a remarkable preventative of a too rapid multiplication”.

For those members of the family for which the relevant information is available, the eggs are laid early in the day, before 08:00 hours, just before or just after sunrise, one daily on con-

secutive days. They have a very fine texture and those of the Slender-billed White-eye are slightly glossy. The eggs are typically pale blue, but white eggs have been found in the nests of a number of species, either as complete clutches or, more rarely, as one white egg in a clutch of pale blue ones. Blue or creamy-white eggs have been found in nests of Oriental Mountain White-eyes, and white and blue eggs are equally common in Lemon-bellied White-eye nests. Although apparently dichromatic, these eggs appear, on closer inspection, to be subject to variation, as the colour shade varies from blue to very pale blue, approaching white. Further, in the Cape White-eye, the subspecies *capensis* has white eggs, whereas those of other races are pale blue to greenish-blue. With Japanese White-eyes, the eggs may vary in colour with age, white eggs being at first more transparent pinkish, and becoming darker to even bluish before hatching; sometimes the air cell is visible, and this can be used to estimate the age of the egg. White eggs are not uncommon among other *Zosterops* species. Speckled or spotted eggs are laid by several distantly related members of the family, having been documented for the Crested White-eye, the Golden White-eye and the Yellow-spectacled White-eye, and very faintly brown-spotted eggs are reported for the Seychelles Grey White-eye. In Sri Lanka, the eggs of the Sri Lanka White-eye are rather longer and less broad than are those of the co-existing Oriental White-eye.

Incubation generally begins after the third egg. Typically, the incubating bird sits deep inside the nest cup, with the back hidden, but with the tail and head above the nest rim so that it can keep watch on the immediate vicinity of the nest. There appears to be little uniformity in the duration of the incubation period, but the shortest documented period is about ten days. More precisely, the shortest time measured for the Cape White-eye was 10 days and 12 hours. At the other extreme is the Seychelles Grey White-eye, with incubation times of 13–15 days, and the Christmas White-eye, with an exceptionally long incubation period of 15–16 days and, moreover, a fledging period of 17 days or longer. Small tropical white-eyes, such as the Oriental White-eye, may have slightly shorter incubation periods than that of the large southern Silvereye in a much cooler climate. Captive Oriental White-eyes held in outdoor aviaries in Europe had an incubation of 12–13 days, but about ten days was reported for the same species in the wild. The longer incubation of the “European” birds is undoubtedly due to the colder climate, but also to the accumulative effect of interruptions inherent in a life in captivity.

Incubation by Oriental White-eyes normally starts immediately after the laying of the first egg, whereas Silvereyes begin after the second egg and, consequently, the young hatch at intervals of up to one day. Although the two parents share nest duties, incubation is done mainly by the female, and during the first days she is relieved only when she leaves the nest to forage. Change-over takes place at irregular intervals, every 20–30 minutes on average but the time ranging from 15 to 60 minutes, and at higher frequency during bad weather; the eggs are covered for 70–100% of the time. In the case of the Golden White-eye, the task of incubation is shared nearly equally between the sexes. In studies of this species, it was found that, at change-over, the approaching individual usually called and the sitting bird would leave the nest moments before its partner arrived. No observations of the feeding of a female by a male were made during the entire incubation period. During the night the female broods alone, while the male roosts on a perch in the immediate vicinity of the nest. Incubating Abyssinian White-eyes sit very tight, and will even allow the human observer to touch them without leaving the nest. Hours before hatching, the parents become extremely nervous, and search for live insects only.

Pipping of the egg starts up to 24 hours before hatching. On the day of hatching, the adults take the empty eggshells from the nest and drop them well away from it. African Yellow White-eyes and Abyssinian White-eyes hatchlings are naked and pink, except for a patch of whitish down above the eye; the bill, mouth and tarsus are yellow, and the gape-flanges creamy. Golden White-eye nestlings have a yellow skin on hatching, and those of Silvereyes have a bright orange or yellow tinge to the pinkish skin and have the gape-flanges bright yellow.

In white-eyes, both sexes feed the nestlings, and over the first few days the parents take it in turns to brood or forage. African Montane White-eye nestlings are fed with spiders and small caterpillars for the 15 or so days before leaving the nest. One or two prey items are brought to the nest every few minutes. African Montane White-eyes are considered diligent parents, cooling their offspring by shading them from the sun. The species does not appear to be particularly territorial as pairs often nests close to one another.

African Yellow White-eye chicks hatch pink-skinned and almost entirely naked, but they rapidly grow feathers during the two-week nestling period. Both parents feed the nestlings with a variety of small arthropods and, in the case of this well-grown nestling, a spider's egg sac. Breeding seasonality in the African Yellow White-eye varies considerably across its large range, probably depending on local climatic patterns; in many areas, breeding has been recorded throughout the year. This species demonstrates high levels of site-fidelity, one male having been recorded using the same territory for eight consecutive years.

[*Zosterops senegalensis anderssoni*, Stone Hills Game Sanctuary, Zimbabwe. Photo: J. R. Peek]

For the first 3–4 days one of the adults stays on the nest with the young, as the two are never away and foraging at the same time. When an adult arrives at the nest with food, the sitting partner leaves, making way for the arriving mate. On the arrival of a Mauritius Olive White-eye at the nest, the adults call with a soft “pip”, which is immediately followed by begging of the nestlings; one adult feeds the young and broods them until the next feed. After 3–4 days the parents forage together, without attending the nestlings continuously. From day nine or ten the chicks are brooded only irregularly, and not at all during the night; the adults roost together outside the nest on the two nights before the young finally leave the nest.

Nestlings of the Cape White-eye are fed by both parents, which forage together and make an average of 16 food deliveries per hour throughout the breeding period, but with the visits more clumped and with longer intervals between them later in the season. The feeding frequency of Mauritius Olive White-eyes increased after seven days and reached a peak of 19 visits per hour on the eleventh day. For the Seychelles Grey White-eye, the hourly rate of food deliveries varied between seven and 16. Abyssinian White-eyes feed their young continuously from dawn to dusk, but they ease off for two hours during the midday period. In studies of Japanese White-eyes, observers recorded 1–2 feeds per chick per hour on the first two days, and up to 14 feeds at fledging; several young may be fed on each visit. African Montane White-eyes are very attentive parents. When the nest is exposed to the full sun, one of the adults has been seen to stand above the chicks to provide them with shade. Every few minutes, food found among the leaves around the nest is brought in, one or two items at a time; rather than creeping in a roundabout way before delivering food to the nest, the adults of this species bring it directly to the nest. This attentiveness is in contrast with the inattentiveness of the birds during incubation, notably at times of heavy rain, which often causes nest failures.

Nest sanitation is generally undertaken by both parents. Adult Japanese White-eyes wait for the chicks to produce faecal sacs after each feeding session. The Rota White-eye swallows the chicks' faecal sacs, but the two parents do not simultaneously take part in nest sanitation. When the young are 5–6 days old, the parents remove the faecal sacs and drop them some distance from the nest, or, rarely, stick them to a branch. Dead chicks several

days old, and even considerably large young of up to eight days in age, are also removed from the nest and taken up to 2 m or more away from it.

Nestling white-eyes are fed with insects, and any of these which, having been offered, appear to be too large to be swallowed by the young are eaten by the adults. Young Abyssinian White-eyes are fed exclusively with insects on the first and second days, but after day six only fruits were presented to them. In observations on captive Oriental White-eyes, it was seen that larger prey items were fed to the young, while the smaller items were eaten by the parents themselves; at an age of 5–6 days each of the young consumed per day about 30 prey items, consisting of mealworms, butterflies and grasshoppers, and it would take a chick about 20 seconds to swallow the larger ones among these.

For the Cape White-eye, hatching takes place over a period of 12 hours, and the development of the chicks is described as follows. On the fourth day the quills of the wing-coverts and alula emerge, followed on day five by the quills of the tertials, back, rump, flanks, breast and belly, including the tibiotarsus feathers. On days 5–6 the eyes open, and on day six the quills of the forehead, chin and ear-coverts emerge, while those of the primaries and secondaries start to break open. On the eighth day most other quills are open. The growth and development of the feathers proceed very rapidly, but much depends on food availability and quality and on the intensity of parental attendance. Young Oriental White-eyes are fully feathered after 12 days, except for the upper thigh, the underwing-coverts and the throat, the throat acquiring its yellowish feathers at an age of 17 days. In the race *egregius* of the Oriental White-eye, the nestling plumage is similar to that of the adults but less intense, and the eyerings are not acquired until 24 days after the chick has left the nest; the white feathers constituting the eyering start to emerge on its fifth day out of the nest, coinciding with the time when it becomes capable of flying. Japanese White-eyes weigh 1.1 g on the day of hatching, gain about 1 g per day during the first week, and then 1 g or so until they fledge, at a weight of 8.3 g.

Nestling periods of zosteropids vary from 10 to 16 days, being longer in poor weather, as documented for Abyssinian and African Yellow White-eyes. A period of 11–14 days is reported for captive Oriental White-eyes, and of up to about 16 days for

Nest sanitation is an integral component of a breeding attempt, and both white-eye sexes rid the nest of faecal sacs excreted by their offspring. This **Malagasy White-eye** will probably fly a safe distance away from the nest prior to either dropping the gelatinous sac on the ground or smearing it onto a branch. Either way the desired result is the same: a nest free both from disease and from conspicuous white splashes that could catch the attention of potential predators. The nest of the Malagasy White-eye is comparatively deep and wide for the genus *Zosterops*, and is lined with soft material to provide comfort and warmth.

[*Zosterops maderaspatanus maderaspatanus*, Madagascar. Photo: Dominique Halleux/Bios]

The nestling period of most white-eyes is roughly 14–16 days, but parental care continues after the young have left the nest. Recently fledged **African Yellow White-eyes** beg for food from their parents by fidgeting their wings and imitating the contact call uttered by their parents. While brood parasites tend not to use white-eyes as hosts, the African Yellow White-eye is parasitized by two species, Klaas's Cuckoo (*Chrysococcyx klaas*) and the Eastern Green-backed Honeyguide (*Prodotiscus zambesiae*). The annual mortality rate in this white-eye is roughly two-thirds, but birds can live up to seven years.

captives kept in outdoor conditions in the UK. Short nestling periods of 10–12 days have been reported for Golden White-eyes. Young of, for example, Cape White-eyes and Silvereyes are more prone than are chicks of other bird species to leave the nest prematurely, at an age of just nine days. When undisturbed, young leave the nest and immediately scramble into the surrounding branches, where they wait, bunched together on a perch, to be fed; on the appearance of the parents, they break apart, approach, and quiver the wings while emitting hunger calls. Nestling Mauritius Olive White-eyes were watched as they were being enticed from the nest on day 13, the parents not feeding them but, on three occasions in the afternoon, calling from a perch 2 m from the nest, each time for three minutes. This behaviour was repeated in the morning, when a chick moved from the nest and was preened by one of the parents. The young stayed within 5 m of the nest on the first day.

Newly fledged African Montane White-eyes can fly very short distances, and they hide in leafy vegetation while waiting for the parents to feed them. At night the parents sleep with the fledglings, huddling close, one on each side of them, and they never return to the old nest. The young, clambering about, are guided into safe cover by continuous call notes from the adults, the latter often with food in the bill. Very young fledglings may fall to the ground and, because they cannot yet fly, they sometimes have to stay there for a while; it has been observed that one of the parents, despite a dislike of being on the ground, will then keep the youngster company during the night, while the other parent looks after the other young. Young African Yellow White-eyes, when out of the nest, solicit food from the parents by quivering their wings and giving a shrill call resembling the parental contact call. After fledging, the young of Abyssinian White-eyes are accompanied and fed for some days by the parents. They are duller above and below than the adults, and have a lax plumage, a thick yellow gape, a pinkish bill, and wispy white down at the rear end of the superciliary stripe. For about one week after fledging they cannot fly, but instead they hop and cling to branches. Similarly, Japanese White-eyes do not fly until one week after leaving the nest.

As already discussed, both sexes are involved in nest-building, incubation, brooding and feeding of the young, this having been observed for many well-studied white-eye species, such as the

Silvereye and the Cape, Oriental, Japanese and Rota White-eyes. Likewise, during the 2–3 weeks in which fledgling Silvereyes are dependent, no lasting brood division by the adults has been observed, although some unequal investment by male and female parents occurs. When renesting for a subsequent clutch, however, there is variable parental investment but no obvious transfer of responsibility within the Silvereye pair. Except for the laying of the eggs, by the female, and the territorial advertisement, by the male, the parental responsibilities of the two sexes seem to overlap completely. The development of brood division, in which fledglings accompany one particular parent away from the territory for prolonged periods, is precluded by the tendency among Silvereyes for young sibling fledglings to come together when unattended by the parents, as well as by the strong pair-bond between the adults, and also by the small brood size of two or three chicks. This brood size is similar to a single family unit in a large divided brood, as, for instance, that of Song Sparrows (*Melospiza melodia*) and Prairie Warblers (*Dendroica discolor*).

The strong motivation of parent birds to satisfy the demands of fledglings is illustrated by a case in which a male Silvereye lost both his mate and two fledglings. This male subsequently adopted two unrelated fledglings of similar age from a neighbouring nest; unaided, he raised these to independence, while the biological parents deserted their own young and renested. In captivity, a similar case of feeding assistance was observed in which an immature Japanese White-eye 56 days old fed two 22-day-old young as soon as they were put together in a cage; a fourth, recently fledged individual placed in the cage two weeks later was fed by the three older white-eyes until he became independent; and finally, one month later, a fifth fledgling was fed by the four older birds, after some conflict had developed and then been settled again. The feeding of parentless fledglings of the Japanese White-eyes by older white-eyes has been observed, and several cases of interspecific feeding assistance have been described for white-eyes (see General Habits).

In captivity, Oriental White-eyes begin the construction of a second nest when the young of the first brood have fledged only several days before, or, in exceptional cases, when they are still in the nest. Even so, the young are still fed intensively. At this stage the male takes the greater part of the feeding duties, although food is also delivered regularly by the female; the female

incubates more persistently and for longer periods than the male. After 26–28 days young Oriental White-eyes are independent, but they continue to beg for food for much longer. It is quite possible that the young of a subsequent brood have hatched by then, and that the parents are caring for two broods. The cohesion among the parent birds, the first brood and the second brood remains strong, and all individuals roost together in one row. Third broods are also included in the assembly, although less prominently. This has to do with the formation of natural flocks, including different families. In Nairobi, in Kenya, the African Montane White-eye is double-brooded in a long season, and third breeding attempts are undertaken when two earlier ones have failed. Up to five clutches per season are produced by the Silvereyes of the islands in the southern Great Barrier Reef.

The Oriental White-eye is, at best, an unusual foster parent of cuckoos. For the South-east Asian population of the nominate race, three cases of parasitization by the Common Cuckoo (*Cuculus canorus*) are known, and one each by the Asian Lesser Cuckoo (*Cuculus poliocephalus*) and the Plaintive Cuckoo (*Cacomantis merulinus*). None of the cuckoos in Java is known to parasitize white-eyes. In eastern and southern Africa, *Zosterops* species such as the Abyssinian and African Yellow White-eyes are the principal hosts for the Eastern Green-backed Honeyguide (*Prodotiscus zambesiae*); another Afrotropical brood parasite is Klaas's Cuckoo (*Chrysococcyx klaas*), which lays in nests of African Yellow White-eyes. Young of the Shining Bronze-cuckoo (*Chrysococcyx lucidus*) have been successfully raised in Silvereye nests, but for the large Pallid Cuckoo (*Cuculus pallidus*) and the even larger Long-tailed Koel (*Eudynamis taitensis*) no satisfactory white-eye host can be established, solely because the nest of the white-eye could not hold a full-grown cuckoo chick.

Breeding success among the members of this family is known only for some well-studied local populations. In a Lemon-bellied White-eye population on Sulawesi, 24 nests had a success of only 33%, and many nests remained empty. For Cape White-eyes, 50–57% of nestlings survive to the fledging stage, against an average adult mortality of 35%. During a 1972–1973 study of the Japanese White-eye in Hawaii, where this species is introduced, the proportion of hatched eggs that produced fledglings was 58.6%, resulting in a recruitment of 5.52 young per pair per year. In the case of the Abyssinian and African Montane White-

eyes it appears that few clutches are successful, as the eggs and young are heavily preyed on by shrikes, rats, mongooses and snakes, or the nests parasitized by the Eastern Green-backed Honeyguide, which may replace up to two of the white-eye's eggs with its own, one at a time.

Annual survival rates of Silvereyes are low, with a mean survival of 25%; in the African Yellow White-eye an annual survival rate of almost 34% was found. In the Heron Island population of Silvereyes in the southern Great Barrier Reef, difference in breeding success between dominant and lower-ranking pairs occurs when food supply, principally figs and arthropods, is poor. Because pairs that spend longer periods at the nest rear their nestlings better, and as successful defence of food resources near the nest probably means that more time can be allocated for attending chicks, dominant pairs raise heavier young. It was also shown that breeding success, expressed as the number of successful nests, depends on the behaviour of the birds in the previous non-breeding season. Solitary or paired foragers may be more specialized feeders or highly skilled foragers, not benefiting from flocking, and holding small ranges; this may, if enough food can be obtained, allow them to stay close to their summer territories and to start nesting early. Dominant first-year males may defend feeding territories more efficiently than subordinate birds, but, if such a male is paired with a less dominant female, the latter's submissiveness may mitigate the disruptive effects on breeding of the male's territorial fights. Finally, areas with *Pisonia* trees offer experienced birds, rather than unskilled ones, good-quality food, in the form of large insects, and also the most suitable nest-sites. In an earlier study of the same Silvereye population, it was shown that the greatest survival rate of young was in those derived from parents of intermediate dominance in a year with high population density; in other years with high population density, such a relationship between offspring mortality and the dominance status of parents has not been confirmed. There are more dominant individuals among young born early in the season than among those born later, and these dominant birds survived better in the austral winter months of May–August. No such dominance-related survival was found for adults. Although an individual's weight did not determine survival in either first-year or adult birds, large size may be selected for; its effects on dominance fluctuate over time with density and food availability.

The race *tephropleurus* of the **Silvereye** has often been treated as a distinct species. This is a restricted-range taxon, given that it is endemic to Lord Howe Island, which is just 17 km² in area. Having not been seen since 1914 and consequently feared extinct, it was rediscovered in 1963. It had managed to avoid the fate of another white-eye endemic to Lord Howe Island, the Robust White-eye (*Zosterops strenuus*). It had earlier succumbed following predation by ship-borne black rats (*Rattus rattus*).

White-eyes are generally monogamous, solitary breeders. The pair-bond in Oriental White-eyes is known to be long-lasting, and Silvereyes remain paired outside the breeding season, while divorces are rare. In eleven pairs of Silvereyes in which both members survived, no change of mate occurred from one breeding season to the next. Mates are often selected soon after becoming independent. In a study of 23 pairs of Capricorn Silvereyes on Heron Island, ten pairs suffered the loss of one member, and the remaining adult remated in the following season; no extra-pair paternity was detected in DNA-fingerprinting studies among 122 offspring from 53 broods, despite high breeding densities and a synchronous start of breeding. Neither mate-guarding nor frequent intra-pair copulation explain this result, but it is consistent with the hypothesis that, with low levels of genetic variation in fitness, and thus variation in male quality, on small islands, sexual selection for good-quality males is reduced. The avoidance of pairing with siblings is the only mechanism for maintaining heterozygosity in Capricorn Silvereyes. A possible case of bigamy has been reported for captive Oriental White-eyes. One pair and a single female of this species both had nests in which young hatched, but in this case the possibility that clutches in both nests were laid by the mated female could not be excluded. The later recapturing of a possible pair of Cape White-eyes may suggest some level of monogamy in a species regularly occurring in flocks. DNA analysis indicates that flocks of this species form cohesive groups, with little gene exchange between populations.

Observations at nests of the Seychelles Grey White-eye have revealed co-operative breeding in which non-breeders help with nest-building, incubation and rearing duties, relative contributions of the individuals being similar. Nests with up to eight eggs have been found. This phenomenon indicates a saturated breeding habitat and could be the result of food limitation, which may restrict breeding opportunities and result in a lack of population growth. Helpers have been found also at Mascarene White-eye nests, but this strategy has not been confirmed for other species of white-eye.

Hybridization in the wild has been documented for a number of species. Silvereyes and Slender-billed White-eyes reportedly interbred on Norfolk Island in 1913, after the former had colonized, but subsequent studies showed no noticeable effect on the population of the latter species. Interbreeding between subspecies is more widespread. Examples can be found, for example, on

Kangaroo Island, in South Australia, where Silvereyes of the subspecies *pinarochrous* and *chloronotus* intermix, or in the hills in central-west Java, where Oriental White-eye subspecies *buxtoni* and *melanurus* occur in close contact. In captivity more instances of interbreeding are known, and may in fact be numerous.

African Yellow White-eyes and Silvereyes are known to breed at the age of 12 months, and this is probably applicable to most, if not all, members of the family.

A remarkably long lifespan has been documented for white-eyes, and the record seems to have been achieved by a captive male Oriental White-eye which was reportedly still in good condition when nearly 24 years old. Such a long lifespan is not unusual for birds having small clutch sizes and often rather indifferent breeding success, as is demonstrated by the Lemon-bellied White-eye. In the wild, ages of 5–7 years have been attained by African Yellow White-eyes, and for Silvereyes ringed in Australia ages of 7–8 years are not unusual, while Silvereyes up to 11 years old have been recorded on the Capricorn Islands. During a study of nine species of white-eye ringed in South-east Asia and East Asia, totalling 4272 individuals, only 23 birds of five species were recovered, none of which was older than 25 months, but this sample is insufficient to indicate survival in the wild.

On the islands of Saipan, Tinian and Aguijan, in the Northern Marianas, Bridled White-eyes reach what are among the highest densities ever reported for landbirds. On Saipan, the population has been estimated to occur at approximately 5950 individuals/km². Silvereyes have been found to have 3.4–8.7 breeding territories per 10 ha in suburban areas. Much higher densities, however, were found near food sources for Japanese White-eyes, with 11–30 pairs/ha in urban O'ahu, in the Hawaiian Islands, where the smallest successful territory was of 0.12 ha, nests were 15–854 m apart, and songposts were on average 91 m apart. Lemon-bellied White-eyes, too, breed in high densities. No territoriality or nest defence is known for the Mascarene White-eye, which sometimes nests in loose semi-colonial groups.

Movements

White-eyes are generally highly sedentary, yet there is the contradictory tendency for flocks to disperse over considerable distances. One of the most extraordinary examples is that of the Silvereye,

The propensity of white-eyes to colonize small islands and subsequently speciate means that three-quarters of zosteropids are classified as restricted-range species with a distribution of less than 50,000 km², a remarkably high proportion for a family containing so many species. The **Louisiade White-eye** falls into this category, its distribution spanning two Endemic Bird Areas: the Louisiade Archipelago; and New Britain and New Ireland. This species is common to abundant on most islands within its range, probably being the commonest species on Nissan Island, and is not at present at risk.

[*Zosterops griseotinctus eichhorni*, Nissan Island, Papua New Guinea. Photo: Don Hadden]

The **Yellow-spectacled White-eye** inhabits several islands in the Lesser Sundas, the largest of which are Sumbawa, Flores and Sumba. It is a restricted-range species, occurring in both the Sumba and Northern Nusa Tenggara Endemic Bird Areas. It is generally common throughout its range, with the population on Sumba thought to exceed 400,000 individuals. This relatively large population and the species' preference for forest edge and degraded habitat have led to its conservation status being listed as of Least Concern.

[*Zosterops wallacei*, Flores, Lesser Sundas.

the commonest bird in New Zealand, after it invaded in the 1850s from Australia, from which New Zealand is separated by 2000 km of sea. Many islands had double invasions of white-eyes, and Norfolk Island was invaded three times, resulting in the evolving of two different species, the Slender-billed and White-chested White-eyes. Tasmanian Silvereyes are known to cross Bass Strait and spend the winter in south-eastern Australia, some individuals migrating in some years but not in others. Moreover, it is not only the juveniles that migrate but also older birds. In late March and early April, up to 26% of the total Silvereye population in central Victoria is made up by the Tasmanian race.

Four white-eye taxa are known to migrate long distances. These are the Chestnut-flanked White-eye, the nominate race and the subspecies *simplex* of the Japanese White-eye, and the nominate race of the Silvereye. It is not surprising that the first, which lives at the highest latitude, is the most strongly migratory. In the Japanese White-eye, it is not the entire populations of the two races that migrate, but most likely the northern breeders do so, over distances of several thousands of kilometres, whereas the southern population is sedentary; *simplex* is more strongly migratory than the nominate race, and its more pointed wing is significant in this respect.

There is much to be learned about the movements and the non-breeding areas of the migratory white-eyes. The study is a very difficult one, because of the low recovery rates of ringed individuals. For example, during a ringing study in 1977–1985 of Silvereyes in Western Australia, 13,870 individuals were ringed, of which only 15, or 0.11%, were recovered, only four of these having travelled 100 km or more. In eastern Australia a recovery rate of just 0.075% was found for 100,000 Silvereyes ringed in a ten-year period. Higher recovery rates were found in southern Africa, where an estimated 15,000 ringed white-eyes in the 1970s and 1980s produced a recovery rate of 0.25–0.36%.

In experiments with captive Silvereyes, migratory restlessness, or *Zugunruhe*, develops in some individuals, whereas others develop restlessness only in the presence of actively "migrating" individuals. Whether or not a bird migrates, however, appears to have a genetic basis, and there seems to be an endogenous programme that determines the timing and direction of migration. Such a programme is present in migratory subspecies of Silvereyes: during experiments over 14 months with two closely related subspecies, the migratory nominate race and the non-migratory *cornwalli*, the first showed significant directional preferences during the spring and autumn migration periods, whereas the other did not. In the migration season, the birds are

most restless in the period between two hours before and four hours after sunrise, which is consistent with field observations. Vocalization has an important function in pre-migratory flocking, and food availability, weather conditions and various social stimuli also play a role. The switch from migratoriness to sedentariness takes place in young and old Silvereyes, and in both sexes.

In Silvereyes, it has been found that haematocrit, a measure of the relative volume of red blood cells as compared with total blood volume, and frequently used as an indicator of condition of wild birds, is low in March but high in September. Migration by Silvereyes takes place, as intimated in the preceding paragraph, during the two hours before sunrise and the four hours after; on the wintering grounds diurnal activity increases in relation to winter movements. Migratory movements by Silvereyes involve the combination of short journeys through vegetation, the choice of which is dependent on the availability of flowering trees, the presence and abundance of other Silvereyes, and visibility, and longer flights. Migrants exhibit more nocturnal restlessness than residents in winter, and in the autumn and spring migration seasons.

The pre-migratory lipid reserve of Silvereyes is equivalent to that of a short-distance migrant, and is consistent with the over-water distance to be covered of about 250 km between Cape Liptrap, on the coast of south Victoria, and Tasmania. Assuming an air speed of 6 m/sec for a 12-g bird, and that 1.5 g of lipid is enough for a distance of 570 km, Silvereyes should be able to cross the Bass Strait in about eleven hours in calm weather, during which only about 0.6 g of mobilizable fat is required of the 0.56–3.74 g found in the birds. The leaner individuals may stop over on islands along the migration route, whereas the fatter ones may fly non-stop. Any excess in the fat reserve may be viewed as a precaution against unpredictable weather in the Bass Strait, including changing cloud density and wind direction. Silvereyes are known to fly at altitudes of between 200 m and 600 m; through gaining favourable wind by altering their flight altitude, they would be able to reduce the flight time and energy expenditure. The overnight energy requirement and expenditure of the Silvereyes, and also the mean fat content of 8% of body weight, equivalent to 1 g for a 12-g bird and sufficient for one overnight fast, are generally less than found in northern passerines. This may be explained as being an adaptive response to long-term winter temperatures at low elevations, which are less severe than those in northern temperate regions. Moreover, the effects of a

The **Mascarene White-eye** is a restricted-range species that occurs in the two Endemic Bird Areas that cover the islands of Réunion and Mauritius. It is common on both islands, with local densities on Mauritius estimated to reach 150 pairs per square kilometre. Its large population and tolerance of a wide range of habitats, including man-made ones, mean that this it is not considered threatened. The species is unusual within its family in having a contrasting white rump, which is thought to act as a signal to encourage flock movement, along the lines of "follow-my-leader".

[*Zosterops borbonicus mauritanus*, Mauritius.
Photo: Roland Seitre]

low ambient temperature are mitigated by the Silvereyes' behaviour of huddling in groups and controlled hypothermia.

Interestingly, the lipid content accumulated in the late afternoon in order to survive through the night was the same for migrants at Armidale, in New South Wales, and for residents on Mount Nelson, in Tasmania, places with very similar temperatures. This makes one wonder why the birds should migrate at all. Better food conditions, higher daytime temperature and a longer daylength available for foraging may play a role. Various hypotheses can be put forward to explain the choice by Silvereyes to migrate or not to migrate. Only the "genetic" hypothesis can explain the phenomenon of partial migration, as some individuals migrate automatically, while others migrate only if stimulated to do so in the presence of other, already "migrating" individuals. The other possibilities are the "social-dominance" hypothesis, namely that unsuccessfully competing birds, that is females and juveniles, migrate; the "body-size" hypothesis, that smaller birds, females, migrate, having lower resistance to cold conditions; and the "arrival-time" hypothesis, that the sex-class or age-class responsible for establishing breeding territories is less migratory. These last three, however, are not consistent with the Silvereye's natural history and with observations made in the field.

Celestial clues, such as the patterns of polarized light at sunset, and magnetic clues are used by migratory birds for orientation. Experiments with Tasmanian Silvereyes suggest the existence of a hypothetical magnetite-based receptor in the head, serving as a navigational "map". This allows the migrating birds to measure local values of magnetic gradients, and provides them with information on their geographical position. These studies showed also that high-intensity pulse magnetization disrupts the orientation of adult birds with migration experience, but not that of inexperienced juveniles. Apparently, the juveniles make use of an innate magnetic compass, which is more robust than the map with regard to detection of small changes of intensity and inclination. Other experiments revealed that under red light, with a wavelength of 633 nanometres (nm), both age-classes are disoriented, but neither class is affected under white and green light, suggesting that light-dependent processes also are involved in the birds' magnetic compass. In experimentally generated conflicting situations, the white-eyes recalibrate the celestial clues on the basis of the altered magnetic field.

Migration on a more local scale is known for a much larger number of species. In north-west Bali, the Lemon-bellied White-eye makes seasonal movements between the mainland and its breeding sites on the offshore island of Menjangan, and similar

seasonal shifts have been noted on Bawean. Seasonal movements downslope and upslope are reported for Oriental White-eyes in India. As a further example, movements covering 164 km are recorded for Cape White-eyes in southern Africa, and seasonal immigration and emigration is suggested by the varying reporting rates within some western parts of this species' range.

In Hawaii, some juvenile Japanese White-eyes return to their natal territories, whereas most pairs return in the second year to breed either on their previous breeding territories or within 0.4 km of that; during breeding birds were observed up to 0.8 km from their territories visiting fruiting trees.

Relationship with Man

Because of their delightful personalities, their adaptable and inquisitive natures, a high degree of intelligence, hardiness, and their easy maintenance, white-eyes are popular as cagebirds. These birds seem to become accustomed to a life in captivity without any special problems, and they readily take food items previously unknown to them. In 1874, the first white-eyes were brought into the European bird trade by the wife of the animal-trader and zoo-owner C. Hagenbeck. First successful breeding was reported in 1910 or thereabouts, in England. Even in unheated large cages or aviaries in temperate countries white-eyes are easily persuaded to breed, and they seem extremely persistent in their attempts if circumstances are adverse; five or six nesting attempts in a single breeding season have been reported.

By far the most abundant member of this family in captivity is the Oriental White-eye, closely followed, according to 1980s figures for the UK, by the African Yellow White-eye and the Chestnut-flanked White-eye. The origin of many imported white-eyes, however, is difficult to ascertain because of the similarity of many of the species; moreover, their identity is often further obscured by a loss of yellow pigments, although these are easily restored by a diet of various plant extracts containing carotenoids. The Japanese White-eye is very popular as a cagebird in Japan, and is also a familiar image in art, usually depicted alongside camellia (*Camellia*) blossoms; in the Japanese language there is even an expression *mejro-oshi*, meaning "white-eye huddle", which indicates the familiarity of the people with this bird. Oriental White-eyes are popular with the ethnic Chinese inhabitants in Singapore, where this species is one of the five most popular cagebirds and may in fact be the most numerous one. The Singaporeans hold social gatherings at specific display grounds where the white-eyes are kept in small, narrow, bell-shaped cages, often richly ornamented with boxwood and ivory carvings that are traditionally auspicious. Formal birdsong contests began there in 1964. Among other criteria, loudness of volume and clarity of the individual's song are taken into account, as also is its variety; although rarely, as many as 20 varied tunes can be heard. A high-scoring white-eye song, which is short, has many rapid short notes joined together to form a tune, as a continuous flow of sound, but these are not always repeated in sequence; it has an opening consisting of a series of high-pitched sounds, and repetition of the same tune may occur, but other tunes must follow without too long a pause. The most sought-after white-eyes come from Johore, in Malaysia, and these can produce notes that rise to a strong staccato sound. Although white-eyes are kept in Hong Kong, China and the Philippines, it is in Singapore that they are most popular.

Captive white-eyes, because of their confidence with humans and their adaptability to life in an aviary or cage, have long been favoured as research subjects. The nominate race of the Japanese White-eye has been a favourite object for endocrinological studies in Japan; since the 1930s, but especially the 1960s, numerous papers have appeared on the relationship between daylength, activity of the neurosecretory cell groups of the hypothalamus and gonadal development. In Australia, experiments with captive Silvereyes have yielded much insight into the biology of migration (see Movements), but also other varied information, including fruit choice, and the predation of jumping spiders by Silvereyes.

Several white-eye species have been subject to intensive field studies. As they are readily baited and trapped, and common in certain areas, the colour-marking of individuals is not a problem.

For a family strongly represented in nearby Indonesia, there are remarkably few species of white-eyes in the Philippines. These include the **Black-masked White-eye**, endemic to submontane and montane forest on Mindanao, within the Mindanao and Eastern Visayas Endemic Bird Area. This restricted-range white-eye is locally common or not uncommon at 1250–2400 m. Moreover, high-altitude forest on Mindanao is relatively secure, so the species is not considered globally threatened.

[*Lophozosterops goodfellowi* goodfellowi, Baracatan, Davao, Mindanao, Philippines. Photo: Doug Wechsler/VIREO]

The **Crested White-eye** occurs only in the Northern Nusa Tenggara Endemic Bird Area. While locally common in primary forest at 700–1000 m, this restricted-range species is fairly intolerant of degraded habitat. Lowland forest is being destroyed rapidly in the zone, and this species cannot retreat upslope, as it is apparently outcompeted by the congeneric Yellow-browed White-eye (*Lophozosterops superciliaris*) at higher altitudes. These factors may justify upgrading the Crested White-eye's conservation status from of Least Concern to Near-threatened.

[*Lophozosterops dohertyi subcristatus*, Flores, Lesser Sundas. Photo: Morten Strange]

In the 1940s, the New Zealand Silvereye was therefore selected for a special study; this had been preceded in 1939–1940 by C. A. Fleming's ringing study of Silvereyes, 470 individuals in total, the first published ringing study of an Australian species and one that revealed much of its life history. Famous indeed are the Silvereyes of the 17-ha Heron Island, in the Capricorn Group of the southern Great Barrier Reef, off the Australian mainland, the ecology and biology of which have been studied by J. Kikkawa and his colleagues since 1965; the majority of the population has been colour-ringed for individual recognition.

In many areas white-eyes frequent birdtables, especially during the winter months. In New Zealand, a study of the energy needs of some 7500 Silvereyes showed that the natural population obtained at least one-third of its total calorie expenditure from artificial food, suggesting that artificial feeding had an important role.

The Oriental Mountain White-eye, the Oriental White-eye, the Sri Lanka White-eye and many other members of the family, apparently in Africa in particular, are strikingly confident with humans, and are approachable to within two metres or so in field conditions. Foraging flocks of Cape White-eyes will approach observers quite closely, but they retreat to the other side of the tree if themselves approached by the observer. The African Montane White-eye lives in gardens and is so accustomed to people that incubating individuals can be stroked without being disturbed; similar tameness is reported for the Abyssinian White-eye. The Japanese White-eye in Hawaii is easily attracted by an observer making squeaking sounds. Where birds are persecuted by people, they are, not surprisingly, much shyer. For instance, the Large Lifou White-eye of Lifou Island, in the Loyalty Islands, is reported to be shy. In the Caroline Islands, the Citrine White-eye is wary and easily frightened away by the shooting of a gun; on the other hand, the bird-collector W. F. Coultas reported from Pohnpei that the Long-billed White-eye was not in the least disturbed by the noise of a gun, and remained long enough for long series of specimens to be collected. Museum collectors in the early twentieth century reported that Oriental Mountain White-eyes were so tame that they had to be captured with a butterfly net, as they were too close to be shot with a gun. In the eighteenth century, a special relationship with humans was reported for Mascarene White-eyes on Réunion. The habit of these birds of mobbing ground animals such as the introduced partridges (Phasianidae), lagomorphs and cats, and giving a characteristic, very piercing, mobbing call on detecting them, gave the game away to local hunters. Apparently, the white-eyes are now accustomed to the animals, as this habit died out.

In New Zealand, Silvereyes have been called "Blight Birds", because of their effective destroying of the "American blight",

the aphid *Schizoneura lanigera*. Silvereyes in Western Australia make themselves useful to humans in summer because they devour large quantities of larvae of the potato moth (*Phthorimaea operculella*). Moreover, their mobility and the fact that they exist in large numbers make them potential vectors of a granulosis virus that controls the potato moth.

Not only their insect diet but also their nectar-eating and the consequent cross-pollination of a wide variety of flowers make the Zosteropidae potentially beneficial for agriculture. Indeed, studies in Kenya on the pollination of the exotic silky-oak, a popular tree for farm-planting, indicated an important role for the African Yellow White-eye and African Montane White-eye, even though these birds' habit of piercing the calyx bases would seem to diminish their usefulness as pollinators (see Food and Feeding). Any suspicion that they may fertilize flowers of mistletoe, which is regarded as a pest, is removed by the observation that white-eyes squeeze the flowers at the base of the corolla lobes to get at their nectar.

The Oriental White-eye is reported as becoming a pest locally in orchards, such as mango (*Mangifera*) and guava (*Psidium*) farms, and in vineyards. Cape White-eyes are more widely regarded as a pest, as they feed on small soft fruits by pecking and taking small amount of flesh from many fruits in turn, which are then prone to rot; one farmer claims to have shot 500 individuals of this species with an air-gun in one season. Similarly, Silvereyes are notorious pests of vineyards in Australia, where they are sometimes referred to by the name of "Grape-eater". Here, the broadcasting of sounds that totally envelop the frequency range of the Silvereye's contact calls, 4–5 kHz, have proved effective in encouraging the birds to move, as they were unable to hear their mates and this prompted them to avoid the vines. The Japanese White-eye is not considered a pest in Hawaii, although there is controversy because its dramatic increase contrasts with the simultaneous decrease of native bird species. In south-western Australia, the berries of the introduced bridal creeper (*Asparagus asparagoides*), an unwelcome environmental "weed", are mostly eaten by Silvereyes and thereby dispersed.

The only known reference to white-eyes being taken for human consumption comes from New Zealand, where the Maoris process these relatively newly arrived birds for food, but this is not significantly different from their behaviour in processing other small birds. Apparently, the small size of white-eyes and

Some 13 members of Zosteropidae are listed as Near-threatened on a global level. One such is the **Biak White-eye**, a restricted-range species endemic to two islands within the Geelvink Islands Endemic Bird Area, off the north-west coast of New Guinea. In recent surveys, only low numbers at best were recorded, which causes some concern for the species' survival. Nevertheless, its toleration of degraded forest and the existence of a relatively large protected forest on one of the islands suggest that it is not at immediate risk of extinction.

[*Zosterops mysorensis*, Biak Island, Geelvink Bay, New Guinea. Photo: Tony Tilford]

the difficulties in netting large quantities of them preclude the exploitation of them for mass human consumption, for instance in Japan, but in most of the family's range the occasional white-eye killed by slingshot or air-rifle generally disappears in the cooking pot. No special importance is known of white-eyes in human traditions, even in South-east Asia, where numerous illnesses are, according to local beliefs, cured by diverse parts of various bird species.

Many tribes have specific names for white-eyes, especially in places where the members of this family are among the most abundant species in the immediate surroundings of houses. Where they are not abundant, or where they co-exist with many other, similar-looking fine-billed birds, no specific names are given to them, as they are mostly united with sunbirds. On Muna and Butung, off south-east Sulawesi, where white-eyes are the most common birds, they are called "tomi-tomi", and names for the flowerpeckers and sunbirds are derived from this. The Duri people in south Sulawesi appear to have different names for the Lemon-bellied and Black-ringed White-eyes, calling them "cilele" and "läuelen", respectively.

Tribal names for birds are often descriptive, and the names for white-eyes are no exception. Names are given after their voices, morphology, nest shapes and habitat, but, strangely enough, rarely after their white eyering. On Flores, in the Lesser Sundas, Manggarai names refer to the shape of the white-eye's nest, such as "cik lékép", meaning "bird with cup-shaped nest", and "cik lewo lentap", meaning "bird with nest that is open above"; or to the bird's eyes, such as "cik mata mbé", the "goat-eye bird". The west Javan name for the Oriental White-eye, "éséngka" or "sikinangka", refers to this species' likeness to the yellow fruit parts of the jackfruit tree (*Artocarpus*); the Javan names of "pleci", "pêci", "prece" and the like describe its piercing contact calls. Similarly onomatopoeic names can be found in tribal nomenclature in Africa, where "siiriri" refers to the African Yellow White-eye on Bioko Island, and on Mauritius, where "oiseau pit-pit" is the name given to the Mauritius Olive White-eye. There are many other examples. Finally, colloquial names for white-eyes are sometimes derived from their food, such as "Cherrypicker" and "Grape-eater" for the Silvereye in Australia, or their habitat, such as the "oiseau manioc" for the Mascarene White-eye, indicating the latter's more artificial habitat compared with that of its olive congener.

Status and Conservation

A great many zosteropids are restricted to small islands, or are otherwise confined to a very small area, such as a mountain range, or coastal habitat. These species, having a very small global range of fewer than 500 km², are prone to extinction because additional threats may easily upset the balance of these often very small populations. Indeed, all 20 species and three distinct subspecies, which are sometimes treated as full species, that are globally threatened are inhabitants of small islands, mountain tops, or even mountain tops on small islands.

The largest concentrations of threatened zosteropids are in tropical and subtropical Africa, with eight species and three subspecies, and Oceania, with eight species. Near-threatened species also occur in these zones, with respectively one and six species. The Robust White-eye of Lord Howe Island became extinct in the early decades of the twentieth century, whereas at least some surviving species, such as the Giant White-eye, had larger ranges than they have at present, the consequence of pre-historic human activity.

One of the few fossil records of white-eyes is a femur of an Oriental Mountain White-eye, found at a cultural site of the Tarung-tung cave, on the Philippine island of Palawan, in a layer younger than 11,000 years before present (bp), and possibly indicative of human consumption. The site is at 250 m, considerably below the 1000 m above which the species is found nowadays, which may suggest a much wider distribution when the Palawan forests were still intact. Other zosteropid fossils found include a pre-human record (more than 3000 years bp) of now extinct white-eyes on 'Eua, in the Tonga Islands; and bones from Bridled and Golden White-eyes and from an unidentified white-eye have been found in a number of caves with deposits of up to 2500 years old on Tinian, Rota and Aguijan, in the Northern Mariana Islands. The Bridled White-eye is still found on these islands, but the Golden White-eye has disappeared from the first two.

Of the 98 species presently included in the family, no fewer than 20, more than one-fifth, are globally threatened. Six of these are categorized as Critically Endangered, these being the Rota White-eye, Sangihe White-eye, White-chested White-eye, Mauritius Olive White-eye, Faichuck White-eye and Golden White-eye. Each of these species is confined to one or a few small islands. In the next category, Endangered, are a further five species, namely the Bridled, Splendid, Slender-billed, Seychelles Grey and Rufous-throated White-eyes, each again restricted to one or two small islands. In the last threatened category, Vulnerable, are nine species, namely the Christmas White-eye, the Ranongga White-eye (*Zosterops splendidus*) and the Samoan White-eye (*Zosterops samoensis*), the Principe and Annobon White-eyes, the Mount Karthala White-eye, the Bonin White-eye, the Bioko Speirops (*Speirops brunneus*) and the Mount Cameroon Speirops. Apart from the last-mentioned species, in West Africa, these Vulnerable zosteropids are, once again, restricted to small islands, in one case to a single mountain on the island of Grand Comoro, off south-east Africa. A further 13 species are currently considered to be Near-threatened, and one species, the White-throated White-eye, is a Data-deficient species. Yet again, all of these have in common the fact that they are confined to one or a few islands.

The main cause of decrease in population size to dangerously low numbers is the removal of original habitat on which a certain bird species is dependent. It is believed that many islands in Oceania have lost species in this way, but in addition the Seychelles Yellow White-eye disappeared from Marianne following the wholesale destruction of that island's original vegetation. Other threats to extremely small islands, those smaller than 10,000 ha, and to small populations are climatic fluctuations; the rise in sea-level which is predicted to occur during the twenty-first century would have as yet unknown effects on the available habitat for a number of species. Hurricanes can have a disastrous impact on the vegetation, in particular flowers, and on smaller islands, especially, they may seriously disrupt the food availability of certain nectar-dependent species, such as the Reunion Olive White-eye. The Mount Karthala White-eye has its entire range

More than one-fifth of all the white-eyes are considered globally threatened. Six species are listed as Critically Endangered, five as Endangered and nine as Vulnerable. The last group includes the **Christmas White-eye**. This restricted-range species is naturally endemic to Christmas Island, in the Indian Ocean, but was introduced to Horsburgh in the Cocos Islands in the late nineteenth century. While still abundant on Christmas Island, its tiny range and increasingly threatened habitat justify its designation as globally threatened.

[*Zosterops natalis*,
Horsburgh Island,
Cocos Islands.

on the slope of an active volcano, where volcanic gases adversely affect leaf survival and reduce flowering activity in heavily damaged areas. In north Kenya, the distinct race *kulalensis* of the African Montane White-eye, sometimes regarded as full species, is believed to be threatened by, among other factors, the gradual disappearance of natural glades, a favourable habitat created naturally by large mammals such as buffalos and elephants, which have disappeared since the 1970s.

Four zosteropid taxa are now known or presumed to have become extinct. The Seychelles Yellow White-eye was restricted to an island of less than 100 ha in extent, where it was still present in 1890, but it seemed to have gone in 1940; although next to nothing is known about the ecological changes on the island, it can be assumed that the species' extremely small range and the clearing of the forest for coconut trees had a major influence on its presumed disappearance. The Robust White-eye was confined to Lord Howe Island, where it had been common until at least 1914; it is believed to have been extirpated by black rats, which swam ashore from a wrecked ship in 1918. The nominate race of the Bridled White-eye, found only on the island of Guam, in the Northern Marianas, has dwindled in numbers to almost certain extinction since the arrival on the island of the exotic brown tree-snake (*Boiga irregularis*). Finally, the nominate race of the Bonin White-eye, which inhabited the northern group of islands in this north-west Pacific archipelago, is believed to be extinct; it had disappeared from Nakôdo-jima by 1930, in which year the last specimens were taken on Muko-jima, and it appeared to have gone from the latter by 1941.

So, rats are known to have played a major role in the demise of the Robust White-eye on Lord Howe Island, and an introduced tree-snake has probably wiped out the nominate race of the Bridled White-eye on Guam. On islands elsewhere, the introduced Red-whiskered Bulbul (*Pycnonotus jocosus*) appears to be the major nest predator of the native Reunion Olive White-eye, which has not yet adapted its nesting strategy to counter this. Just to the north of Guam, on Rota Island, the introduced Black Drongo is known to prey on and harass small passerines of the size of the Rota White-eye, and possibly caused a decline of 89% of this Rota endemic in the 13 years since 1982.

Avian malaria and bird pox can also be serious problems (see General Habits), and avian malaria may already be determining

the distribution of olive white-eyes in the Mascarene Islands. Studies on Mauritius showed that introduced honeybees (*Apis mellifera*) could be interfering with interactions between the two endemic *Siderox* species and the Mascarene and Mauritius Olive White-eyes. This could have an impact on the island ecosystems, because the honeybees are less efficient pollinators of the two plant species, and may have strong competitive effects on the white-eyes.

In Hong Kong, where 100,000 or more birds are sold annually on the local market, the Japanese White-eye is one of the three most popular songbirds. In Japan, too, white-eyes were continuously supplied to local pet shops, without serious decreases in their abundance, until at least the 1950s. In South-east Asia, Oriental White-eyes are popular only in Singapore, where the subspecies *auriventer* is in most demand; it is imported in large numbers from the neighbouring Malaysian state of Johor, where it is protected, and from Indonesia. White-eyes are rarely bred in captivity as they are relatively inexpensive to purchase. During 211 surveys in 1991–1993, the 10,800 individuals counted in markets represented 8.4% of the total number of birds in the Singapore retail trade, and they were sold in 41 of 47 trade localities. Nevertheless, bird-capturing and hunting cannot so far be blamed for the demise of any single species of white-eye, although the local Singapore population of Oriental White-eyes has surely disappeared into the bird trade. If any of the latter do remain in the wild, the release of previously captured but unmarketable white-eyes, represented by females and silent males, may have an impact on the native avifauna. The Singapore race *auriventer* of the Oriental White-eye is likely to be mixed with the introduced subspecies *siamensis*, from Thailand and south Myanmar, *williamsoni*, from the northern part of the Malay Peninsula, and *buxtoni* and *melanurus*, from Sumatra and Java. White-eyes are much less popular as cagebirds in Indonesia and Vietnam, but the possible consequences should any of the many Indonesian endemic white-eyes suddenly become popular with bird-fanciers cannot be ignored. Even once common bird species have almost disappeared from many localities, and at least one species, the Straw-headed Bulbul (*Pycnonotus zeylanicus*), has already become extinct in much of its former range; more species may follow before too long.

In many aspects, being confined to a single mountain is similar to occurring only on a single island. The tiny global range constrains the species' population size, while dispersal possibilities may be negligible, so additional threats render the species more susceptible to extinction. One such threatened single-mountain endemic is the **Mount Cameroon Speirops**, which is restricted to a narrow altitudinal band on Mount Cameroon. While the species remains common, any increase in pressures could result in its conservation status being upgraded from Vulnerable.

[*Speirops melanocephalus*, Mann's Spring, Mount Cameroon, Cameroon.
Photo: Doug Wechsler/VIREO]

The high proportion of globally threatened species among the Zosteropidae reflects the frequently precarious conservation status of small-island endemics. The nominate race of the **Bonin White-eye**, endemic to the northern Bonin Islands, was last seen in 1941 and is probably extinct. The southern race *hahasima* is extant, but apparently occurs at a maximum of five sites in a total range of less than 100 km²; its current population is just a few thousand birds. Continued pressure from deforestation and perhaps from introduced mammals have led to the species being listed as Vulnerable.

A population viability analysis on the Capricorn subspecies *chlorocephalus* of the Silvereye was carried out in order to assess its extinction risk. This white-eye has its largest population, of about 375 individually colour-ringed birds, on Heron Island, and the analysis was based on 26 years of monitoring of this intimately known population, a comparative wealth of data. It is predicted that this small Silvereye population will be at risk of extinction within the next 100 years, threatened by the introduction of predators or diseases, inbreeding and storms but much less so by moderate loss of habitat, half of which has already been modified. The Silvereye has much smaller populations on islands near Heron Island, and movement or dispersal between these has a mitigating effect, although the smaller populations require unrealistically high immigration rates to enable them to remain viable in the long term.

Extreme weather, particularly heavy storms, and events determined by the El Niño Southern Oscillation are likely adversely to affect the survival chances of isolated populations. The effects of El Niño in 1991–1992 on the Japanese White-eye population of the Hawaii Islands were considerable, with significant decreases in mean monthly capture rates of the species, as well as noticeable reductions in fat scores of the individual birds.

Although only three, or possibly four, extinct white-eye taxa may seem to be a low number for a family with so many vulnerable species, there is no reason for complacency. A great number of white-eye taxa are restricted to small islands; indeed, a large proportion of all white-eye species are considered restricted-range species. There are still quite a few populations of otherwise wide-ranging and secure species which are confined to very small islands, and for which little information has been published. In the Philippines, the two subspecies *richmondi* and *meyleri* of the Golden-green White-eye have not been observed since they were initially described, at the beginning of the twentieth century. A large *Rukia* species is known to have become extinct on Saipan Island. During recent years, however, surveys of some of the most remote islands have “rediscovered” a number of supposedly lost taxa. For example, the nominate race of Everett’s White-eye (*Zosterops everetti*), restricted to the Philippine island of Cebu, was thought to be extinct because of the total deforestation of its native island, and because of a lack of observations since 1906, despite recent visits by ornithologists; in the 1980s, however, it was rediscovered on Cebu, where it has since been seen on sev-

eral occasions. Similarly, the Seychelles Grey White-eye, believed possibly extinct in the middle of the twentieth century, was subsequently rediscovered. Recent surveys in the Talaud Islands, north of the Moluccas, found the “lost” subspecies *babelo* of Everett’s White-eye to be still common. In an adjacent island group the Sangihe White-eye was likewise refound, but it appears to be very rare and is now listed as Critically Endangered. Its rediscovery also yielded new insight into its taxonomic status, which was upgraded to that of a full species.

Although most white-eyes are common where they occur, however restricted their range may be, some, such as the Sangihe White-eye, are exceptionally thinly distributed, and only very few records exist. Furthermore, because of their extreme mobility, lack of territorial displays and often secretive behaviour, white-eyes are not always easy to census. Sometimes indications of changing numbers may be found in the data on observed flock sizes. For the nominate Guam race of the Bridled White-eye, flock sizes appear to be related to population density: flocks of 10–20 individuals were reported at the beginning of the twentieth century, and of up to at most 15 in the 1970s, but in the 1980s parties held only 3–8, subsequently falling further to 3–6 birds.

Predictions on the vulnerability of woodland birds to local extinction in fragmented box-ironbark forest in Australia suggested intermediate risk values for Silvereyes, these values being based on mobility, population density and habitat specificity. This is in accord with findings for Oriental White-eyes, which, in a study in a number of Javan forest fragments, had a similar, more or less intermediate position. Whether this may be extended to the numerous white-eyes restricted to islands where the original vegetation is becoming increasingly fragmented merits investigation.

A few conservation programmes have been targeted at white-eyes. A scheme to eradicate the Black Drongos that threaten the endemic Rota White-eyes was temporarily mounted in 1991, and in eight mornings of shooting 1100 drongos were killed, while a captive-breeding programme for the white-eye was initiated in 1993, but with little success so far. The Critically Endangered White-chested White-eye has been included in Appendix I of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). The inclusion of the Oriental White-eye on CITES Appendix II (or at least on Appendix III) by some of the species’ range states, as well as documentation of trade levels and assistance for Malaysian efforts to stop illegal exports,

is required in order to control local extirpations of this popular cagebird; the encouragement of captive-breeding at commercial levels may also be worth consideration.

Reintroduction of extinct populations should be preceded by studies to determine the likely influences that interactions with existing species may have. Genetic studies indicate that, so long as the brown tree-snake can be controlled on Guam, reintroduction from the closely related and formerly interchanging population on Tinian or Saipan is warranted. The translocation in 2001 of Seychelles Grey White-eyes to the predator-free island of Frégate has proved successful. In translocation experiments with Japanese White-eyes on Hawaii, survival was good, but weight loss, food consumption and faecal production needed to be monitored individually.

Until its discovery on the tiny island of Conception in 1997, the **Seychelles Grey White-eye** was thought to occur only on Mahé. Following successful translocations to predator-free islands of other threatened Seychelles endemics, most famously the Seychelles Magpie-robin (*Copsychus sechellarum*), this white-eye was introduced to the island of Frégate in 2001. Further introductions were made to Cousine and North in 2007, by which stage the population of Frégate had risen to about 100 birds. In 2006, the species was downgraded to Endangered.

[*Zosterops modestus*, Cousine Island, Seychelles.

Photo: Jock Henwood]

The **Rufous-throated White-eye** is a highly distinctive white-eye in its own genus. Endemic to the island of Buru, in the Moluccas, the species is known only from two or three localities, and there have been only two records since the species was discovered in the 1920s. It is unclear whether it is very elusive or highly localized, or occurs at low densities. Despite the fact that Buru's montane forest is probably safe from destruction, this species is listed as Endangered on the basis of its apparently very small population and range.

[*Madanga ruficollis*, Buru, Moluccas.

Subfamily ZOSTEROPINAE

Genus ZOSTEROPS Vigors & Horsfield, 1827

1. Chestnut-flanked White-eye

Zosterops erythropleurus

French: Zostérops à flancs marron

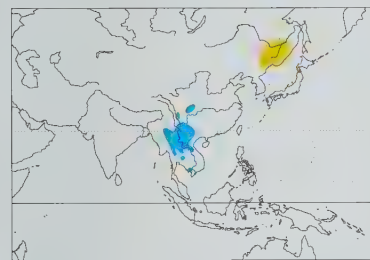

German: Rostflanken-Brillenvogel

Spanish: Antejitos Flanquirrofo

Other common names: Red-flanked/Chinese White-eye

Taxonomy. *Zosterops erythropleurus* Swinhoe, 1863, northern China = Shanghai and Tientsin. Presumably most closely related to either *Z. palpebrosus* or *Z. japonicus*. Monotypic.

Distribution. Breeds extreme SE Russia (E Amurland, Ussuriland) and NE China (Heilongjiang), possibly reaching extreme N Korea; non-breeding S China, Myanmar, Thailand, NW Vietnam, Laos and S Cambodia.

Descriptive notes. 10.5–11.5 cm; 10–13 g. Male has black lores, olive side of the head, well-developed white eyering broken at front; olive-yellow above, rump and uppertail coverts more yellow; closed wings like back; tail greyish-brown, feathers edged olive; throat bright lemon-yellow, clearly demarcated from pale grey side of breast, centre of underparts white, flanks chestnut (sometimes rather faint); iris dark brown; bill brown above, bluish below; legs greyish. Female is like male, but lores dusky, chestnut of flanks often very faint, sometimes no more than a faint pinkish suffusion. Juvenile undescribed. **VOICE.** Loud song.

Loud piercing, monosyllabic “tsee” (“lost-chick” call), or “tseeplee”.

Habitat. Breeding habitat includes groves, bushes, poplars (*Populus*), alder (*Alnus*) thickets, willow (*Salix*) jungles along riverbanks, streams and lakes. In non-breeding area deciduous or broadleaf evergreen forest, secondary growth; from foothills to 2590 m, most often above 800–1000 m.

Food and Feeding. Feeds on insects. Usually in flocks, sometimes mixed with other small passerines, e.g. Northern Long-tailed Tits (*Aegithalos caudatus*).

Breeding. Little known. Season probably end May to Aug; fledglings found in Aug, also four fledglings attended by three adults in elm (*Ulmus*) woodland in Jun. Nest in tree; clutch 5–6 eggs. No other information.

Movements. The most migratory species in family. Leaves breeding grounds in Sept, main stream of migrants passing S (mainly W of Korea) through S Gansu and E Sichuan; normal wintering areas include S China (Sichuan, Yunnan), W, C & E Myanmar (Nov–Apr), Cambodia, N & C Laos (regular visitor), N Thailand (fairly common), and N Vietnam (W & E Tonkin, where seems to prefer mountains). Small numbers sometimes found during summer in winter quarters. Accidental in coastal areas and islands in Sea of Japan (records in Oct, Nov, Feb, and May), but may prove to be a rare but annual migrant there. Distances flown, twice a year, up to 3500 km; one in Bokor (S Cambodia) would have migrated 5000 km from breeding area.

Status and Conservation. Not globally threatened. Fairly common locally; not numerous on its breeding grounds. Large numbers seen in China, where many captured for food and cagebird trade. Recorded as a migrant in Pangquangou National Nature Reserve, in China (Shaanxi).

Bibliography. Brazil (1991), Carey *et al.* (2001), Cheng Tsohsin (1987), David & Gosselin (2002b), Deignan (1963), Duckworth *et al.* (2002), Evans (2001), Flint *et al.* (1984), Inskipp *et al.* (1996), King (1989b), Kontorschikov (1997), Lekagul & Round (1991), Lethaby (1998), Li Guiyuan *et al.* (1982), MacKinnon & Philipps (2000), Mees (1957, 1969), Melville & Round (1984), Meyer de Schauensee (1984), Robson (2000b), Thomas & Poole (2003), Tomek (2002).

2. Japanese White-eye

Zosterops japonicus

French: Zostérops du Japon

German: Japanbrillenvogel

Spanish: Antejitos Japonés

Other common names: Dark Green/Chinese White-eye

Taxonomy. *Zosterops japonicus* Temminck and Schlegel, 1845, Decima, Nagasaki, Japan.

Forms a superspecies with *Z. meyeri* and *Z. palpebrosus*, and sometimes considered conspecific with either or with both, but all appear morphologically distinct; hybrids with *Z. palpebrosus* found in S China and N Vietnam; sometimes only N race *batanis* of *Z. meyeri* placed within present species. Affinity to *Z. erythropleurus* unclear. Geographical variation possibly partly clinal, as N races large, dark and with somewhat brownish or buffy flanks, whereas smallest and brightest races occur in S of range (Hainan I); curiously, races on small islands surrounding Japan (*insularis*, *stejnegeri* and *alani*) are larger and have longer, broader bill than average-sized nominate in mainland Japan; further study required. Races *stejnegeri* and *alani* interbreed in Bonin Is (where both were introduced); hybrids named as *boninsimae*. Other proposed races are *yessoensis* (described from Muroran, on Hokkaido), which is synonymized with nominate, and, in S Ryukyus, *iriomotensis* (from Iriomote) and *yokakuni* (Yonaguni-jima), which are subsumed in *loochooensis*. Eight subspecies recognized.

Subspecies and Distribution.

Z. j. japonicus Temminck & Schlegel, 1845 – S Sakhalin I, Japan (including Sado, Oki, Tsushima, Iki, and Goto Is) and coastal S Korean Peninsula.

Z. j. insularis Ogawa, 1905 – extreme N Ryukyu I (Tanegashima I, Yakushima I and Kume-jima).

Z. j. loochooensis Tristram, 1889 – Ryukyu Is (except extreme N) S to Yonaguni-jima.

Z. j. daitoensis Nagamichi Kuroda, 1923 – Borodino Is (Kita-daito-jima and Minami-daito-jima).

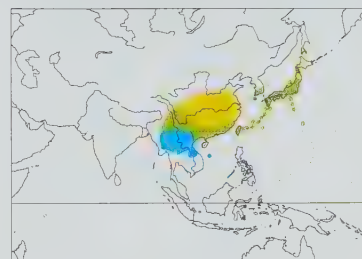

Z. j. stejnegeri Seebohm, 1891 – O-shima (Izu Is) S to Tori-shima (Nanpo Archipelago).

Z. j. alani E. J. O. Hartert, 1905 – Volcano Is (Kita-iwo, Iwo-jima).

Z. j. simplex Swinhoe, 1861 – breeds E China (extreme S Gansu E to Jiangsu, S to Sichuan, E Yunnan, Guangxi, Guangdong and Fujian) and Taiwan and extreme NE Vietnam (E Tonkin); non-breeding SE China S to Thailand and C Indochina.

Z. j. hainanus E. J. O. Hartert, 1923 – Hainan I.

Introduced on all main islands of Hawaii (nominate) and in Bonin Is (*stejnegeri* and *alani*).

Descriptive notes. 10–11.5 cm; 7.5–13.9 g. Male nominate race is olive-green above (without yellow on forehead or over lores), white eyering of average width interrupted at front by blackish spot (rarely absent), black lore line continuing under eyering; throat and upper breast lemon-yellow, rest of underparts pale grey, mostly buff to tawny-olive on flanks and often whole undersurface, except for whitish centre of belly; undertail-coverts pale lemon-yellow; iris brown or yellowish-brown; bill slate-grey; legs grey. Distinguished from *Z. palpebrosus* mainly by darker crown and upperparts and lack of yellow ventral stripe.

Sexes alike. Juvenile is like adult, but eyering greyer at first. Races differ mainly in colour depth and pattern, also in size: *insularis* is similar to nominate, but bill larger, and yellow colours often slightly richer, probably heightened by asymmetrically distributed rusty patches on head, nape and throat; *stejnegeri* is similar to nominate but slightly larger, and bill much larger; *alani* resembles nominate but slightly larger, less brownish on flanks, larger and broader bill; *loochooensis* is very like nominate, but underparts pure pale grey, little or no buff on flanks; *daitoensis* is very similar to previous but slightly larger, and has yellow patches above lores; *simplex* also is very similar, but has distinctly yellow forehead and supraloral region; *hainanus* is like last but distinctly smaller in size, has head and mantle slightly more yellowish. **VOICE.** Song of nominate race high-pitched and squeaky, but complex, resembling in pattern song of House Finch (*Carpodacus mexicanus*), often including mimicry of other species; song in Taiwan (race *simplex*) not so attractive as nominate, given from top of tall tree early in morning. Call notes (nominate) include high-pitched “tee” and nervous twitter, noticeably different from other races; *simplex* calls tiny staccato chirps, “tsip-tsip-tsip”, “chi-i, chi-i”, “jeet, jeet”; also trill like that of a cicada (Cicadidae).

Habitat. Deciduous or mixed forests, thickets, open woodland, secondary growth, also cultivated areas (e.g. urban parks, gardens, farmlands, groves, orchards); also tall forest trees in winter. Breeds mainly in lowlands, but occurs at up to 800 m in S China and c. 1000 m in Japan; to 2590 m in SE Asia non-breeding areas. Introduced population in Hawaii in wet to very dry habitats, from sea-level to tree-line, but less common in relatively undisturbed native forest.

Food and Feeding. Small insects, soft fruits and nectar. In Japan very fond of persimmons (*Diospyros kaki*), and in late winter and spring attracted to blossoms particularly of the Japanese apricot (*Prunus mume*), camellia (*Camellia japonica*), broad-leaved mangrove (*Bruguiera gymnorhiza*) and similar. Switches food sources often, and may prefer different fruits seasonally. In Hawaii more than 30 tree species visited for fruits, including exotic plants such as lantana (*Lantana camara*), banana poka (*Passiflora molissima*), firetree (*Myrica faya*), and raspberries and blackberries (*Rubus*), and nectar; native Hawaiian plants such as *Metrosideros polymorpha* and *Sophora chrysophylla* visited mainly for insects and nectar. Robs *Hibiscus* flowers of nectar by splitting corolla base. Efficient disperser of fruit seeds in Japan. Forages at all heights in vegetation, but particularly in forest subcanopy. Wanders about in flocks associated with tits (Paridae), Old World warblers (Sylviidae), Goldencrests (*Regulus regulus*) and Pygmy Woodpecker (*Dendrocopos kizuki*). In Hawaii, joins mixed-species flocks in winter (Jul–Feb) of up to 200 or more individuals.

Breeding. Season Mar/Apr–Aug; two broods in Japan, with eggs as late as Aug, probably two broods in subtropical part of range, but up to three (usually two successful) reported for Hawaii. Nest, constructed in 7–10 days, a solidly built cup-shaped structure, cup 56.2 mm in diameter and 41.7 mm in depth, of fine grasses woven together with spider web, exterior decorated with spider cocoons, bits of coloured string and paper, lined with moss, lichens and/or mammal hair, placed in fork of twigs of tree, mostly exotic banyan (*Ficus microcarpa*) or haole kow (*Leucaena leucocephala*) in Hawaii, or in bush or bamboo, usually 1–5 m (occasionally below 1 or above 30 m) above ground; smallest territory in Hawaii 0.12 ha. Clutch 2–6 eggs, usually 3–4, pale blue to greenish-blue, sometimes pure white, dimensions 15.5–16.3 × 12–13.5 mm; incubation period 11 days; nestling period 10–12 days, fledging period 15–20 or more days. Reported as host of Himalayan Cuckoo (*Cuculus saturatus*). In Hawaii, nests preyed upon by cats, mongooses (Herpestinae), lizards and House Sparrows (*Passer domesticus*).

Movements. Some N populations migratory; non-breeding range of race *simplex* includes C, S & E Myanmar, N & E plateaus in Thailand, Indochina (S to Viangchan, in Laos, and C Annam), Hainan I. and Parcel Is (S China Sea). Taiwan population possibly augmented in winter by visitors from mainland China; large flocks found during last days of Oct in lower Yangtze basin, apparently preparing to move S. In Japan, usually a post-breeding movement to open country and woodlands at lower levels, and frequently visits suburban and urban parks and gardens. Nominate race recorded as migrant in the Izu I and Ryukyu Is. On Hawaiian Is (introduced), individuals remain generally within 8 km of breeding territory, but sightings of birds flying over water indicate occasional dispersal attempts; juveniles may range farther during winter.

Status and Conservation. Not globally threatened. Common in most of range. The most common bird species in secondary forest of Hong Kong, with mean density of 12.4 birds/ha, accounting for 33% of total avian community; one of the three dominant species in Taipei Botanical Gardens, in Taiwan. Introduced in Bonin Is, where a hybrid population of races *alani* and *stejnegeri* survives; no information on numbers. In Hawaiian Is, nominate race introduced on Oahu in c. 1930 and became established in 1933; by late 1950s had spread throughout main islands, where it became the most abundant, widespread and omnivorous forest passerine, with 1.3 million individuals counted in 1980s on main island of Hawaii alone; it has been seen as far S as Johnston Atoll; 82 pairs/50 ha in urban Oahu. May play potential role in depressing populations of native Hawaiian bird species such as Elepaio (*Chasiempis sandwichensis*), Iiwi (*Vestiaria coccinea*), Hawaii Amakihi (*Hemignathus virens*) and Akikiki (*Oreomystis bairdi*), but convincing evidence lacking; moreover, has been suggested as being important agent of dispersal of exotic plants, in particular firetree, which readily invades open-canopy forests and alters the ecosystem. Possibility of these intro-

On following pages: 3. Lowland White-eye (*Zosterops meyeri*); 4. Oriental White-eye (*Zosterops palpebrosus*); 5. Sri Lanka White-eye (*Zosterops ceylonensis*); 6. duced birds also acting as reservoirs for disease (avian malaria, bird pox) has been raised. One of the most popular cagebirds in China. Individuals of this species occurring regularly in Singapore are imported birds released at religious festivals (suspected breeding once recorded).

Bibliography. 3. Lowland White-eye

Zosterops meyeri

French: Zostérops des Philippines **German:** Luzonbrillenvogel **Spanish:** Antojitos Filipino
Other common names: Luzon/Philippine White-eye

Taxonomy. *Zosterops meyeri* Bonaparte, 1850, Luzon, Philippines.

Forms a superspecies with *Z. japonicus* and *Z. palpebrosus*, and sometimes considered conspecific with either or with both, but all appear morphologically distinct; sometimes only N race *batanis* is placed within *Z. japonicus*. In Philippines, birds of this species recently discovered on Mindoro of uncertain racial identity, provisionally included in nominate; birds from Marinduque described as race *gilli*, and formerly placed with *Z. montanus*, but now regarded as a synonym of nominate race of present species. Originally named as *Dicaeum flavum*, but that name preoccupied. Two subspecies recognized.

Subspecies and Distribution.

Z. m. batanis McGregor, 1907 – islands of Lan Yü and Lü Tao, off SE Taiwan, and Batan Is, in extreme N Philippines.

Z. m. meyeri Bonaparte, 1850 – Calayan, Luzon, Lubang, Verde, Mindoro, Caluya, Marinduque and Banton, in N & NC Philippines.

Descriptive notes. 10.2–12 cm; one female 10 g. Nominative race has forehead lemon-yellow, crown and upperparts yellowish-green; white eyering interrupted at front by blackish spot, darkish loreal line; throat and upper breast lemon-yellow, rest of underparts pale grey except for rather faint yellow longitudinal streak over centre, pale lemon-yellow undertail-coverts; iris yellowish-brown to stone-grey; bill blackish to horn-brown, bluish at base, or black above and bluish-horn below; legs slaty brown or lead-blue. Sexes alike. Juvenile undescribed. Race *batanis* is larger than nominate, brighter yellow, and has more yellow on forehead.

Voice. Male described as “an excellent songster”, singing frequently near nest. Call “swit” or “swit-tee”, varying to more complicated series of twittering and wheezy notes, lasting 5–6 seconds.

Habitat. Forest, forest edge, scrub, bamboo thickets, gardens, cultivated areas, and other places near open country in lowlands; on Mindoro, absent from plantation areas and cultivated lands. Altitudinally segregated from *Z. montanus*, which occurs above 1000 m.

Food and Feeding. No details on diet. Forages in groups and mixed flocks, associating with eight or nine other species.

Breeding. Season Apr–Aug, occasionally from Jan. Nest said to be typical of genus, placed a few metres above ground in small tree. Clutch 3–4 eggs, occasionally 5, pale sky-blue or white, 15 × 12.1 mm. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Common in lowlands. Race *batanis* widespread in Batan Is, where present on Batan, Sabtang and Y’ami, and recently discovered also on Ivojos and Itbayat. Nominative race only recently found on Caluya and Mindoro. A common cagebird locally in Philippines, e.g. Manila (Luzon).

Bibliography. Dickinson *et al.* (1991), Gonzales (1993), Hachisuka (1930), Inskipp *et al.* (1996), Kennedy *et al.* (2000), McGregor (1909), McGregor & Gardner (1930), Mees (1957, 1969), Meyer de Schauensee (1984), duPont (1971b), Sibley & Monroe (1990), Wolfe (1938).

4. Oriental White-eye

Zosterops palpebrosus

French: Zostérops oriental **German:** Gangesbrillenvogel **Spanish:** Antojitos Oriental
Other common names: Indian/Ceylon Small/Ceylon (Hill)/Sri Lanka(!) White-eye; Yellow-bellied/Siamese White-eye (*siamensis*); Hume’s White-eye (*auriventer*)

Taxonomy. *Sylvia palpebrosa* Temminck, 1824, Bengal, India.

Forms a superspecies with *Z. japonicus* and *Z. meyeri*, and sometimes considered conspecific with either or with both, but all appear morphologically distinct; interbreeding with *Z. japonicus* occurs in S China and N Vietnam. Was formerly considered to form a species complex with *Z. salvadorii* and *Z. everetti*; in that arrangement, race *siamensis* treated as a full species, *auriventer* (together with race *tahanensis* of *Z. everetti*) as another species, *melanurus* and *unicus* then constituting a third species, and remaining races of present species (together with *Z. salvadorii* and remaining races of *Z. everetti*) forming the fourth species. *Z. salvadorii* and *Z. e. everetti*, however, now believed to be more distantly related to present species. Otherwise, populations in neighbourhood of Mt Pangrango, in W Java, are intermediate between races *buxtoni* and *melanurus*. Races *egregius* and *salimalii* possibly better subsumed in nominate. Birds of this species recorded in Cambodia of uncertain racial identity, provisionally included in *williamsoni*; those in Andaman Is currently included in *nicobaricus*, but possibly represent an as yet undescribed race. Proposed races *joannae* (described from SE Yunnan, in China) and *occidentis* (Shimla, in N India) are synonymized with nominate, and *amabilis* (Kathiawar Peninsula, in W India) is merged with *egregius*. Eleven subspecies currently recognized.

Subspecies and Distribution.

Z. p. palpebrosus (Temminck, 1824) – SE Arabia (Mahawt I, in Oman); NE Afghanistan, Pakistan and N India E to S China (SE Xizang, SW Sichuan and Yunnan E to SW Guangxi) and Myanmar (except S & E).

Z. p. nilgiriensis Ticehurst, 1927 – S Western Ghats (hills of S Karnataka and W Tamil Nadu), in SW India.

Z. p. salimalii Whistler, 1933 – S Eastern Ghats (Shevaroy, Chitteri, Seshachalam, Nallamalai), in SE India.

Z. p. egregius Madarász, 1911 – lowlands of India, Laccadive Is and Sri Lanka.

Z. p. siamensis Blyth, 1867 – S Myanmar (Pegu, Kayah, Kayin), N, E & SE Thailand and NW Indochina.

Z. p. nicobaricus Blyth, 1845 – Andaman Is and Nicobar Is (except S).

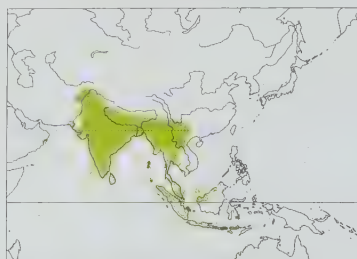

Z. p. williamsoni Robinson & Kloss, 1919 – Gulf of Thailand coast (from Bangkok S to Pattani) and W Cambodia.

Z. p. auriventer Hume, 1878 – extreme S Myanmar (S Tenasserim), W coast of S Thailand, W & SE Peninsular Malaysia (including islands of Ra, Libong, Pinang, Kelang estuary Group and Pisang off W coast, and Tioman off E coast), Singapore, E coastal areas of Sumatra, Riau Is (Kundur), Bangka I, S Natuna Is and Borneo (W Sarawak, Brunei).

Z. p. buxtoni Nicholson, 1879 – highlands of Sumatra, and extreme W Java (Bantam and Bogor).

Z. p. melanurus Hartlaub, 1865 – Java and Bali.

Z. p. unicus E. J. O. Hartert, 1897 – Lesser Sundas (Sumbawa and Flores).

Descriptive notes. 9.6–11 cm; 5.6–11 g. Nominative race has forehead and supraloral region yellowish, black loreal line extending to halfway under white eyering, latter broken at front by blackish spot; crown and upperparts olive-green, rump more yellowish; flight-feathers and tail blackish-brown, the former edged with olive-green; chin, throat, upper breast and undertail-coverts yellow, remainder of underparts pale greyish-white, sometimes with yellow mesial longitudinal streak over abdomen; iris yellowish-brown or brown; bill dark brown to black, bluish-grey base of lower mandible; legs slate-coloured or plumbeous.

Differs from *Z. japonicus* in having brighter yellow-green upperparts and uniformly yellow-green crown, more extensive yellow on forehead, grey and yellow of underparts paler. Sexes alike. Juvenile is like adult but duller. Races differ mainly in colour tone, in colour pattern of underparts and in biometrics, also SE races tend to have more blackish primaries and rectrices without greenish edges, relatively short tail and darker grey flanks than W races: *nilgiriensis* is largest, has relatively longest tail; *salimalii* is very bright yellow above, yellow mesial streak below present but rather weak, bill finer than that of others; *egregius* is close to nominate, but slightly less green, more yellowish, upperparts, generally lacks yellow mesial streak on abdomen; *siamensis* is similar to nominate, but entire underparts yellow; *nicobaricus* is very like nominate, but larger bill; *williamsoni* is close to nominate, but has brighter yellow supraloral region, similar also to following race but has more yellow above lores, slightly paler throat and undertail-coverts, mid-ventral stripe less distinct or lacking; *buxtoni* is smallest, generally slightly darker and greener above than nominate, with very distinct yellow median streak on underparts; *auriventer* is similar to previous but slightly larger, with paler underparts and more yellowish upperparts; *melanurus* also is similar but slightly larger, and has entire underparts yellow; *unicus* is very similar to last, but has slightly yellower lower back. **Voice.** Song, heard only in breeding season, short, thin and wispy, of slurred call notes, that of race *egregius* described as a rather feeble tinkling jingle beginning almost inaudibly but growing louder and soon fading; lasts 4–5 seconds, starts with some melodious rising and falling whistles followed by some querulous notes, uttered in continuous accelerating and decelerating strophes, “qwee-qwoor-quawarr tu-cheer-tu-cheer-cheer, tu-cheer-cheer-tu-cheer-cheer”. Flock-members call persistently; usual call a repeated, monotonous querulous sibilant “jieww” or “cheuw”, or “(tu) cheer) cheer cheer cheerr” like cheeping made by a day-old domestic chick; a series of weak sibilant high-pitched, rapidly twittering notes (0.7 seconds) repeated at intervals of 1–2 seconds; also an unobtrusive yet distinctive nasal, raspy, gradually downslurred guttural “djééééé”. **Habitat.** Deciduous forest, broadleaf evergreen/semi-evergreen forest and swamp-forest, also forest edge, secondary growth, woodland, farmland, thickets, all zones of mangroves (mature and regenerating), scrub and wooded cultivation (orchards, parks, gardens, cardamom plantations); also open strand woodland, especially with stands of casuarinas (*Casuarina*), and coastal scrub of all kinds. From plains to 2500 m, in Himalayas to 4000 m; generally 200–1600 m but locally in true lowlands in Java; from 850 to 1730 m on Sumbawa and above 500 m on Flores. In Borneo restricted to mangroves, swamp-forest and non-forest (edges of wet rice fields and scrub along riverbanks), mainly adjoining coastal areas. Along Gulf of Thailand coast confined to belt of mangroves and scrub; frequents mangroves also in Malay Peninsula, where race *auriventer* occurs also 15–45 km (to an extreme 80 km) inland in gardens and rubber plantations in SW part of peninsula. In Sumatra, *auriventer* is a coastal race in mangroves and other low forests, rubber plantations and gardens, whereas *buxtoni* occurs on higher ground inland in primary and secondary forests, tall turpentine trees in hills, plantations and gardens in villages and towns at 400–1400 m. This species is apparently the only passeriform found in the mangroves of the Sind coast (Pakistan).

Food and Feeding. Omnivorous. Vegetable matter includes small buds, seeds, fruits and nectar; animal food mostly insects. Fruits taken include those of the trees *Trema orientalis*, *Trema cannabina*, *Elaeocarpus sphaericus*, *Ficus religiosa*, of the shrubs *Rhamnus*, *Vaccinium variegatum*, the liana *Zizyphus oenopia*, and the exotic shrub *Lantana camara*; reported also as swallowing unexpectedly large fruits of the introduced *Cordia cylindrostachya*. Nectar taken from *Erythrina subumbrans*, *Erythrina orientalis*, *Elaeocarpus grandiflorus* and *Madhuca* trees, *Woodfordia* shrub, flowering coconut and mangrove trees (including *Sonneratia alba* and *Bruguiera*), strandline bushes (e.g. *Hibiscus tiliaceus*), the mistletoe *Dendrophloe pentandra*; also from the exotic *Grevillea robusta*, *Bombax* and eucalypt (*Eucalyptus*) trees, *Holmskioldia sanguinea* and *Calliandra haematocephala* shrubs, and *Euphorbia pulcherrima* hedge plants. Especially favours the exudation of petioles of banyan trees and ripe peepul figs (*Ficus religiosa*). Seen to take fleshy arils of *Acacia mangium* fruits and to feed fledgling with those of *Acacia auriculiformis* fruits. Animal food includes praying mantis larvae (Mantodea), weevils (of genus *Tanymecus*), stick-insects (of genus *Phyllium*), predatory bugs (Anthocoridae), the ants *Camponotus compressus*, *Pheidole malinsi* and *Polyrhachis simplex*, caterpillars (bagworms and other moth larvae, possibly tiny moths), flower-bugs, and small *Drosophila*-like flies, also spiders (Araneae) and mites (Acarina). In a study in India in Feb–Mar and Oct–Nov, only five out of 15 stomachs contained insects (including small weevils, ants and small caterpillars), but also held buds and small leaves; the remaining ten had only seeds, *Ficus* fruits and small buds, but no trace of insects. Highly gregarious, in flocks of 3–30, and flocks of more than 100 have been seen; often a member of mixed-species foraging flocks, e.g. in Sumatra seen with nuthatches (*Sitta*), tits (Paridae), Old World flycatchers (Muscicapidae) and minivets (*Picrocotus*). Where there is an abundant food supply may be encountered in foraging flocks of 40 or more individuals, but in less favourable (e.g. drier) habitats parties of 4–6 birds more usual. Often forages by hover-gleaning, and generally found high up in tree canopy. In Java, the exotic *Sesbania grandiflora* is favourite tree for insect-hunting.

Breeding. Season Feb–Sept in Indian Subcontinent, mainly Mar–Jun in Pakistan but extending right up to outbreak of monsoon (to as late as Aug), and mainly Mar–May in S India; Dec–Sept in SE Asia; Dec–April in Borneo, Jan–Oct (peak May–Jun) in Java and May–Oct (peak Apr/May–Jun) on Flores; often two or more broods. Pair-bond long-lasting. Nest built by female, or by both sexes, taking c. 4–6 days, a delicate-looking, thin-walled tiny cup 5 cm high, 6–7 cm wide and 3 cm deep, woven from vegetable floss (grass, plant fibre and bryophytes), strengthened with spider webs, moss, animal hair and fine grass strips, sometimes only willow (*Salix*) and poplar (*Populus*) seed floss or jute (*Corchorus*) cord used; suspended from bifurcating (nearly) horizontal twigs, or even leaf petioles at end of twig, and often small enough to hang between two adjoining leaves, usually not very high up (1–2 m in Pakistan, 1–6 m in India) but sometimes up to 18 m above ground in small bush, shrub or bamboo thicket. Clutch 2–4 eggs, most commonly 3 in N Punjab, almost always 2 in Java, initially turquoise-blue (fading to pale blue) to greenish-blue, in Lesser Sundas (race *unicus*) very pale blue to white, average dimensions 15.5 × 11.6 mm (*egregius*), 15.2 × 11.4 mm (*willamsoni*, *buxtoni*/*melanurus*), 15.5 × 11.5 mm (*unicus*); incubation by both sexes, period 10–11 days; fledging period 10–11 days; care of young by both parents, fledglings totally dependent on parents for 10–14 days.

Movements. Mostly resident, but continental races (especially nominate, *salimalii* and *nilgiriensis*) subject to some seasonal (winter) movements. In NE Pakistan, many make post-breeding descent to Punjab, where common Oct–Mar. In W Borneo, after breeding in mangroves of R Sarawak, moves farther inland (even into centre of Kuching city) from Jul to Dec, but returns in flocks each night to roost in mangroves. Single individual found on Rakata I (Krakatau Is), W of Java, suggests capability of crossing extensive waterbodies.

Status and Conservation. Not globally threatened. Generally or locally common to very common throughout range. In Pakistan appears to be gradually spreading S into N Sind with the spread of irrigation, and to be more sedentary in N plains regions. Locally common in Thailand, where roost of 750–1000 individuals recorded on small island of Hard Toop (Trang Province, in SW peninsula) in Oct 1986; presence of a population in Khao Yai National Park requires confirmation. Scarce in parts of N Vietnam (E Tonkin and N Annam). In gardens of Penang I, in NW Malaya, increase in numbers and an outward expansion from its original mangrove habitat was reported in 1950s. Widespread and abundant on 39 of 45 surveyed islands of Andaman Is. Scarce in Borneo. In W Java, now locally common in Jakarta, where formerly absent; race *buxtoni* a relatively recent arrival from Sumatra, and interbreeds with *melanurus*. Excessive capturing for cagebird trade eliminated the species in Singapore, where last breeding record in 1944; began to be reported again in 1970s, but still very scarce, and present population probably originates from captivity; also, especially by late 1980s, there may have been confusion between this species and feral *Z. japonicus*. Recently colonized Mahawt I, off Oman; whether this a genuine W expansion of 1000 km or the result of human actions (bird trade) requires investigation. Considered a pest locally; reported as causing damage to ripe mangoes (*Mangifera*) and guavas (*Psidium*) by piercing holes in order to reach the juice.

5. Sri Lanka White-eye

Zosterops ceylonensis

French: Zostérops de Ceylan **German:** Ceylonbrillenvogel **Spanish:** Antojitos Cingalés
Other common names: Sri Lanka Hill/Ceylon (Hill)/Large Sri Lanka White-eye

Taxonomy. *Zosterops ceylonensis* Holdsworth, 1872, Nuwara Eliya and on the upper hills, Sri Lanka.

Closest to *Z. palpebrosus*, and may have originated from ancestors of latter following their double colonization of Sri Lanka. Morphologically (long tail and bill, large wing, greener upperparts) and ecologically (restricted to hills) apparently closest to race *nilgiriensis* of *Z. palpebrosus*. Monotypic.

Distribution. Hills and mountains of Sri Lanka.

Descriptive notes. c. 11 cm; one female 12.6 g. Male has top of head and upperparts between olive-green and dark citrine; lores and streak under eye dusky grey, some grey also on ear-coverts; white eyering of average width, interrupted at front by dark grey spot continuous with lores; flight-feathers and tail feathers blackish-brown with broad dark greenish margins; greenish-yellow throat and breast, becoming greenish towards margins, undertail-coverts pure yellow, remainder of underparts greyish-white, darker on flanks, usually a trace of yellow streak over belly; iris light brown; bill blackish above, bluish-grey below; legs

dark greyish. Differs from *Z. palpebrosus* in somewhat larger size, much duller and greener plumage, yellow extending over whole breast, and longer bill, tarsus and tail. Female is like male, but less dark on forehead. Juvenile is slightly paler above than adult, and has narrower eyering, and slightly brighter yellow on throat and breast. **VOICE.** Jingling song, heard before sunrise, reminiscent of sound made by shaking bunch of keys, repeated 8–9 times; described also as fairly prolonged, syncopated strophe of short, sharp couplets or triplets, roughly alternating in pitch but at constant tempo, e.g. “chik chik chuk chik chuk-chuk chik”. Common call note “cheep”, like the chirp of a sparrow (*Passer*), or a slightly downturned short reedy chirp, “chisip”, stronger, deeper and less nasal than that of *Z. palpebrosus*.

Habitat. Forest, forest edge, low isolated bushes, tea plantations, *patna* jungle, and gardens; above 1000 m, sometimes as low as c. 450 m in SW (e.g. Sinharaja), and with mountain tops as upper limit. Overlaps locally with *Z. palpebrosus*.

Food and Feeding. Nectar, berries, and insects; insects include tiny moths and small caterpillars (Lepidoptera), in particular those of the tea tortrix (*Homona coffearia*). Outside breeding season forages in flocks of 10–15, sometimes of hundreds; also in mixed flocks, including *Z. palpebrosus* where the two species co-occur. At lower elevations of its distribution (at 450–600 m), is an alternative nuclear species in flocks where both nuclear species Orange-billed Babbler (*Turdoides rufescens*) and Greater Racket-tailed Drongo (*Dicrurus paradiseus*) are absent; here it occurs in 19% (dry season) to 31% (wet season) of mixed-species flocks.

Breeding. Feb–Jul, with peak in Apr, and renewed activity in Aug–Sept, occasionally in other months. Nest built by both sexes, a small deep cup made from green moss, rootlets, fine grass and fibres, lined with rootlets, suspended by rim in slender fork 1–7 m (mostly 2–4 m) above ground among foliage of tea bush (*Camellia thea*), often in *Grevillea robusta* (a shade tree in tea plantations), or in bushy sapling or bush at forest edge, or in fir tree (*Abies*), often in comparatively low shrub or tree growing in open; more often a lower site is selected than those chosen by *Z. palpebrosus*. Clutch 2 eggs, occasionally 3, pale bluish-green, 16.5 × 12 mm; care of young, probably also incubation, by both sexes; no information on duration of incubation and nestling periods.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Sri Lanka EBA. The most common bird species in higher parts of Sri Lanka.

Bibliography. Grimmett *et al.* (1998, 1999), Henry (1955, 1998), Inskipp *et al.* (1996), Kotagama & Goodale (2004), Legge (1874, 1983), Mees (1957, 1969), Phillips (1951), Rasmussen & Anderton (2005b), Ripley (1949), Ripley & Beehler (1990), Stuart Baker (1926).

6. Rota White-eye

Zosterops rotensis

French: Zostérops de Rota **German:** Rotabrillenvogel **Spanish:** Antojitos de la Rota

Taxonomy. *Zosterops semperi rotensis* Takatsukasa and Yamashina, 1931, Rota Island, in Northern Marianas.

Forms a superspecies with *Z. conspicillatus*, *Z. semperi* and *Z. hypolais*; all formerly considered conspecific, but differ in plumage, vocalizations and behaviour, and treatment as separate species supported by DNA–DNA hybridization and analyses of mitochondrial DNA. Monotypic.

Distribution. Rota I, in Northern Mariana Is.

Descriptive notes. 10 cm; 10 g. Has top of head and upperparts greenish-yellow, forehead and supraloral region tinged bright yellow, narrow white eyering; auriculars concolorous with upperparts; remiges and tail feathers blackish-brown with light yellowish-green edges; chin, throat and entire underparts yellow; iris olive; bill light brown above, light yellowish-brown below; legs light brown to yellow-orange. Differs from similar *Z. conspicillatus* mainly in having brighter coloration above, yellower lores, uniformly yellow throat and underparts. Sexes alike. Juvenile undescribed. **VOICE.** Reported as having complex

song, but no further details. Calls with rolling chirps, similar to but higher-pitched than call of Eurasian Tree Sparrow (*Passer montanus*); harsh, rolling, low-pitched “tsheip”, buzzy “zee-zee-zee-e-e”, and less buzzy “see-tseep”.

Habitat. Wet native forest of primarily tall trees at c. 400–490 m (occasionally down to 200 m) on Sabana Plateau; ranging from stunted open forest on plateau summit to closed mature forest on upper slopes. Dominant trees include *Elaeocarpus joga*, *Hernandia labyrinthica*, *Ficus prolixa*, *Intsia bijuga*, *Guettarda speciosa*, *Psionia umbellifera*, *Claoxylon marianum*, and *Pandanus* species; found breeding also in *Merrilliodendron megacarpum* and (introduced) *Acacia confusa* forests.

Food and Feeding. Insects. Forages mostly on small branchlets in outer tree crown; gleans insects from leaves. Lives in family groups or extended families in isolated flocks within home range.

Breeding. Breeds Dec–Aug, in both dry and wet seasons, thus possibly throughout year. Nest cup-shaped, mean external height 40 mm, diameter 59 mm, internal diameter 46 mm, depth 28 mm, constructed from woven grass and *Pandanus* fibres, *Asplenium* rootlets, spider webs, and a yellow cottony material, covered with moss, the inner cup composed of *Pandanus* fibres and woven grass, suspended at 3.3–14.6 m (average 10.3 m) between branch and branchlet/leaf petioles, occasionally from ferns below branches, in native *Elaeocarpus joga*, *Hernandia labyrinthica* or *M. megacarpum* tree, or in introduced *Acacia confusa*. Clutch 1 or 2 eggs, light blue, 17.1 × 13 mm; incubation period 10–12 days; nestling period 10–12 days; post-fledging dependence at least 8 days.

Movements. Relatively sedentary.

Status and Conservation. **CRITICALLY ENDANGERED.** Restricted-range species: present in Mariana Islands EBA. Confined to Sabana Plateau region of Rota I, where once (e.g. 1945) common and widespread, but considered uncommon by 1960s; population declined from 10,763 individuals in 1982 to 300–1500 in 1991, a reduction of 87% in period of ten years. Most recent surveys, in 1995 and 1999, yielded 1167 and 1100 individuals, respectively. Maximum flock sizes dropped from 23 in 1988 to about ten in 1991, which can be linked to population decline. Black Drongo (*Dicrurus macrocercus*), introduced in 1935, very likely implicated in this decline, as the drongos became abundant in 1960s, which coincided with decrease of present species; latter’s very small size and its habit of feeding in exposed micro-habitat make it susceptible to predation. Programme to eradicate the drongo was mounted in 1991, and a captive-breeding programme for present species initiated in 1993. Predation by rats, both Polynesian rat (*Rattus exulans*) and introduced Tanezumi rat (*Rattus tanezumi*), an additional threat. Typhoons of common occurrence in Northern Marianas, and known to damage forest habitat; a single event can have severe adverse impact.

(2004, 2007n), Baker (1948, 1951), Butchart & Stattersfield (2004), Collar *et al.* (1994), Craig (1999), Craig & Taisacan (1994), Engbring *et al.* (1986), Fancy & Snetsinger (1996), Lusk & Taisacan (1997), Mees (1969), Pratt *et al.* (1987), Slikas *et al.* (2000), Stattersfield & Capper (2000), Yamashina (1932).

7. Bridled White-eye

Zosterops conspicillatus

French: Zostérops bridé **German:** Guambrillenvogel **Spanish:** Antojitos Embridado
Other common names: Marianas Bridled/Spectacled White-eye; Saipan Bridled White-eye (*saypani*)

Taxonomy. *Dicaeum conspicillatum* Kittlitz, 1833, Guam, Northern Mariana Islands.

Forms a superspecies with *Z. roseni*, *Z. semperi* and *Z. hypoleis*; all formerly considered conspecific, but differ in plumage, vocalizations and behaviour, and treatment as separate species supported by DNA–DNA hybridization and analyses of mitochondrial DNA. Race *sapayni* sometimes treated as a full species, but this not supported by mtDNA data, although differs vocally from nominate; further study required. Two subspecies recognized.

Subspecies and Distribution.

Z. c. sapayni A. J. C. Dubois, 1902 – N Northern Mariana Is (Saipan, Tinian and Aguijan).

Z. c. conspicillatus (Kittlitz, 1833) – Guam.

Descriptive notes. 10 cm; 7.9–10.5 g. Male nominate race has forehead and supraloral region yellowish-white, crown and upperparts greenish, often with greyish tinge, uppertail-coverts very slightly brighter; dark grey line from gape to below eye, where ends in black blotch, white eyering of average width, greyish cheek; flight-feathers and tail blackish-brown with broad greenish margins; throat pale yellowish, underparts amber-yellow; iris light amber, outer ring white; bill yellow, upper mandible with black-brown tip; legs dark olive-green. Distinguished from all others of genus by combination of pale throat and yellow

underparts. Female is like male. Juvenile is similar to adult. Race *sapayni* is slightly smaller than nominate, has narrower supraloral line, green cheeks (like mantle), uniform pale buffish-yellow underparts but citron-yellow undertail-coverts, and darker bill. **Voice.** Song of nominate race a lilting series of buzzy notes, “zeeep-zee-zee-zoo-zip”, and calls a buzzy chirp “cheep” or “tszeep”, lacking high-pitched calls of *sapayni*. Race *sapayni* has higher-pitched, less buzzy calls, with chirps often rapidly uttered and organized into loose song; “confusion” chorus described. Calls of both races, especially in flight, sound like those of House Sparrow (*Passer domesticus*); in flocks a series of “chit-chit” notes, and whining vocalizations, which used also in agonistic interactions.

Habitat. Nominat race found in all habitats from beach strand to disturbed habitats; edges of forest, grasslands in hills, secondary growth (rather than true forest). Race *sapayni* in sugar-cane fields, common in casuarina (*Casuarina*) stands and semi-wooded hillsides, gardens and shrub in villages.

Food and Feeding. Seeds, nectar, flowers and fruit of 22 vine, tree and herb species; also insects, small snails. Recorded as taking fruits of the vines *Momordica* (also seeds), *Passiflora*, and *Jasminum* (also flowers), and the trees *Premna* (also nectar), *Ficus*, *Melanolepis*, *Artocarpus*, *Pipturus*, *Lantana*, *Carica* and *Muntingia*; nectar and/or flowers of the vines *Mikania*, *Operculina*, the trees *Pisonia*, *gulos* (*Cynometra ramiflora*), coral tree (*Erythrina variegata*), *Psychotria*, *Morinda*, *Hibiscus*, *Albizia* and *Leucaena*; seeds of the herb *Bidens*. Insects include, among others, caterpillars and ants (Formicidae), rarely grasshopper (Orthoptera) parts. Versatile in its foraging, including every micro-environment from ground to treetops, but primarily in canopy, shows marked preference for small leaves and leaflets in trees and bushes, using smaller perches of taller trees, especially *Cynometra ramiflora*. Nominat race was usually encountered in flocks of 10–40 individuals, and flocks of 100 observed; sometimes in (non-territorial) pairs away from flocks; forages by gleanings, probing, hovering and sallying, principally on outer crown of trees and shrubs; favourite foraging sites are the small *Linovia trifolia* bushes growing by roadside and waste places throughout Guam. Race *sapayni* found typically in flocks of 10–40 birds, and up to 50 at flowering and fruiting trees, throughout year, even when some are nesting. One observation of an individual following a foraging Rufous Fantail (*Rhipidura rufifrons*).

Breeding. Mostly Jan–Oct (race *sapayni*); bred throughout year on Guam (nominate). Not territorial except near nest, but birds remain in home range. Nest of nominate race a fairly deep woven cup of fine grass and roots, with cobwebs, wool and cotton wool on outside (all identifiable material from introduced plants), external diameter 40–50 mm (occasionally to 80 mm), height 48 mm, internal depth 25 mm, suspended in fork of branch 1–4 m above ground in *Leucaena leucocephala* or *Pithecellobium dulce* tree; nest of race *sapayni* similar, external diameter 55–65 mm, height 40–55 mm, internal diameter 40–45 mm, depth 25–30 mm, placed at 2–6 m in *Pithecellobium* or *Casuarina equisetifolia* tree, or in reeds (*Phragmites karka*). Clutch of nominate race usually 2 eggs, sometimes 3, pale blue, 16.9 × 12.9 mm, of *sapayni* 1–3 eggs, 15.2 × 11.4 mm; no information on incubation and nestling periods. Collared Kingfisher (*Todiramphus chloris*) possibly a regular predator, has been observed to take a probable fledgling from a branch.

Movements. Sedentary. Many ringed individuals known to stay for up to 14.5 months in study area (radius 300 m).

Status and Conservation. ENDANGERED. Nominat race of Guam almost certainly Extinct. Restricted-range species: present in Mariana Islands EBA. On Guam, nominate race reported by early visitors as being fairly common and widespread in 1828, but more restricted in distribution in middle of 20th century; by 1945 still a few in S Guam, and in 1981 an estimated 2200 remained in 2% of known historical range in N Guam and none in former range in C & S Guam. Most recent observation in Jun 1983 in Pajon Basin; a few individuals may survive in forests near Ritidian Point. Reasons for sudden decline unclear, but most likely became a victim of introduced brown tree-snake (*Boiga irregularis*). Saipan race (*sapayni*) was fairly common to abundant in 1887 and first half of 20th century on Saipan and Tinian; numbers estimated at 229,138 individuals in 1982; population extremely dense, and likely at saturation point. Reintroduction of species to Guam, using this race, should be considered, but only when brown tree-snake eradicated or under control, and when extinction of nominate confirmed beyond doubt.

Bibliography. Amidon *et al.* (2004), Anon. (2007n), Baker (1951), Butchart & Stattersfield (2004), Craig (1989, 1990, 1996, 2002), Craig & Beal (2001), David & Gosselin (2002b), Downs (1946), Engbring & Ramsey (1984), Engbring *et al.* (1986), Fancy & Snetsinger (1996), Hartert (1898b), Jenkins (1983), Marshall (1949), Martin & Kremer (2006), Mayr (1945b), Mees (1969), Owen (1977), Pratt *et al.* (1979, 1987), Scale (1901), Slikas *et al.* (2000), Stopplet (1946), Stott (1947), Wiles *et al.* (2003), Yamashina (1932).

8. Citrine White-eye

Zosterops semperi

French: Zostérops de Semper **German:** Semperbrillenvogel **Spanish:** Antojitos de las Carolinas
Other common names: Caroline (Islands) White-eye

Taxonomy. *Zosterops semperi* Hartlaub, 1868, Palau Islands.

Forms a superspecies with *Z. roseni*, *Z. conspicillatus* and *Z. hypoleis*; all formerly considered conspecific, but differ in plumage, vocalizations and behaviour, and treatment as separate species supported by DNA–DNA hybridization and analyses of mitochondrial DNA. Geographical variation minimal, but races separated by large geographical distances. Three subspecies recognized.

Subspecies and Distribution.

Z. s. semperi Hartlaub, 1868 – Palau Is.

Z. s. owstoni E. J. O. Hartert, 1900 – Chuuk (high islands within the atoll: Weno, Udot, Fefan, Fana, Dublon, Uman and Fanabeguets), in E Caroline Is.

Z. s. takatsukasai Momiyama, 1922 – Pohnpei I, in EC Caroline Is.

and having paler yellow underparts, darker upper mandible and legs. Sexes similar. Juvenile undescribed. Race *owstoni* has darker olive and less yellowish-green upperparts and duller yellow underparts than nominate, also slightly more yellow on forehead; *takatsukasai* is similar to previous but slightly smaller, and brightest underneath of all races, also has brown eyes. **Voice.** No song described. High clear whistles “tee dee, tee dee, tee dee-dee-dee”, or squeaky, high-pitched contact call.

Habitat. Variety of forest and scrub habitats.

Food and Feeding. Small insects. Forages in pairs and small flocks, sometimes with *Z. finschii* or *Z. cinereus*. Seeks food in foliage of small trees, around yellow-flowering bushy trees. Fixed daily circuits described for nominate race in Palau.

Breeding. Breeds Feb–Mar in Palau (nominate race), and nests found throughout year in Chuuk (*owstoni*). Nest thinly woven of grass, small tendrils, pieces of dead leaves, plant down or cobweb, lined with fine soft grasses, placed 1.2–2.4 m above ground in bush, tree (e.g. *Hibiscus*) or reed (*Phragmites*) tangle, at edge of forest, in garden or close to house, frequently in extremely exposed location, e.g. low bushes adjoining roadway with no surrounding vegetation in Chuuk (race *owstoni*); nests in Palau (nominate) sometimes placed on thick branch, instead of suspended between twigs. Clutch in Palau 2 eggs, pale green; in Chuuk 1 egg, light blue, sometimes with more intense band of blue at widest point, 17.3 × 11.7 mm; on Pohnpei 1–2 eggs, glossy light blue, 17 × 13 mm. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Palau EBA and in East Caroline EBA. Widespread and common (but less common than *Z. finschii*) throughout main islands in Palau Is; common also in Chuuk and on Pohnpei. Nominat race uncommon in Palau in 1931; numerous on Peleliu I, where not found in 1945, when 25 individuals located on Ngergoi (Garakayo). On Pohnpei race *takatsukasai* rare in 1931; more recently, encounter rates (birds per hour) in Pohnpei forest above 200 m 6.1 in 1983 and 0.9 in 1994 (85% decrease), and below 200 m 10 in 1983 and 1.2 in 1994 (88% decrease).

Bibliography. Baker (1951), Brandt (1962), Buden (2000), Finsch (1880), Hartert (1900a), Marshall (1949), Mees (1969), Nehrkorn (1879), Owen (1977), Pratt, Bruner & Berrett (1987), Pratt, Engbring *et al.* (1980), Slikas *et al.* (2000), Yamashina (1932).

9. Plain White-eye

Zosterops hypoleis

French: Zostérops hypolaïs

German: Schlichtbrillenvogel

Spanish: Antojitos Liso

Taxonomy. *Zosterops hypoleis* Hartlaub and Finsch, 1872, Yap, Caroline Islands.

Forms a superspecies with *Z. roseni*, *Z. conspicillatus* and *Z. semperi*; all formerly considered conspecific, but differ in plumage, vocalizations and behaviour, and treatment as separate species supported by DNA–DNA hybridization and analyses of mitochondrial DNA. Monotypic.

Distribution. Yap I, in extreme W Caroline Is.

Descriptive notes. 10 cm. Rather nondescript white-eye with pale eye; crown feathers often ruffled, creating big-headed profile. Plumage is greenish-grey above, slightly more greenish on crown and uppertail-coverts; narrow dirty-white loreal line, very narrow white eyering, traces of dusky under eyering; remiges and rectrices blackish-brown with citrine outer margins; throat, upper breast, centre of belly and undertail-coverts yellow, flanks washed pale buff; iris white; bill fuscous, paler basal part of lower mandible; legs plumbeous. Sexes alike. Juvenile undescribed. **Voice.** Song of short, chirping phrases, “chee-twee-chulip...”

and so on, slower than those of related congeners. Calls with thin trilled “chee” notes, and buzzy “zee-up”.

Habitat. Wide variety of habitats, from forest canopy to grassy fields; at edge of jungle is usually confined to undergrowth.

Food and Feeding. No details of diet. Forages in small flocks, but not so conspicuous and noisy as other members of genus. Flocks often feed in grass less than 1 m tall. Movements slower and more deliberate than those of other white-eyes, e.g. *Z. conspicillatus*.

Breeding. One nest found, woven from grasses, suspended c. 3 m above ground in fork of tree at edge of dense forest. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Yap Islands EBA. Widespread and common on Yap, where 2–15 individuals found in every c. 100-m stretch of forest edge. Although not at any immediate risk, this species, because of its tiny global range, could suffer greatly from any adverse meteorological event or accidental introduction of predators.

Bibliography. Anon. (2007n), Baker (1951), Butchart & Stattersfield (2004), Fisher (1950), Hartlaub & Finsch (1872), Kuroda (1933b), Mayr (1945b, 1967), Mees (1969), Pratt *et al.* (1977, 1987), Sibley & Monroe (1990), Slikas *et al.* (2000), Stattersfield & Capper (2000).

10. Enggano White-eye

Zosterops salvadorii

French: Zostérops d'Enggano **German:** Salvadoribrillenvogel **Spanish:** Antojitos de Enggano

Taxonomy. *Zosterops salvadorii* A. B. Meyer and Wilesworth, 1894, Enggano Island.

Relationships unclear. Formerly considered conspecific with *Z. palpebrosus*, or united with race *auriverter* of latter in a separate species with race *tahanensis* of *Z. everetti*. Monotypic.

Distribution. Mega I and Enggano I (including tiny satellite island of Dua), off SW Sumatra.

Descriptive notes. 10 cm. Top of head and upperparts are olive-green; white eyering fairly wide, interrupted at front by blackish spot, broad blackish loreal line continuing as streak backwards beneath and to behind eye; primaries and tail feathers blackish-brown, edged olive-green; throat, upper breast, undertail-coverts and indistinct streak over centre of belly lemon-yellow; remainder of underparts pale grey, almost white on belly, darker on flanks; iris reddish-brown or yellowish-brown; bill black; legs leaden. Sexes similar. Juvenile undescribed. **VOICE.** Little information. Apparently similar to that of *Z. palpebrosus*.

Habitat. Coconut groves and other lowland wooded areas.

Food and Feeding. No information. Flock of six individuals seen on Mega I.

Breeding. No information.

Movements. No information; presumably sedentary.

Status and Conservation. Not globally threatened. Restricted-range species: present in Enggano EBA. Abundant in 1983. Confined to island of Enggano (444 km²), one of its satellite islets and the remote Mega I (c. 170 km NW of Enggano). Latest information available, from early 1990s, indicates Enggano still quite extensively forested; it contains a large hunting reserve, and it has been recommended that four small game reserves be established.

Bibliography. Gill (1969), Holmes (1994), Inskipp *et al.* (1996), Junge (1938), MacKinnon & Philipps (1993), van Marle & Voous (1988), Mees (1957), Ripley (1944), Salvadori (1892), Stattersfield *et al.* (1998), Stresemann (1931a, 1939).

11. Black-capped White-eye

Zosterops atricapilla

French: Zostérops à calotte noire **Spanish:** Antojitos Capirotado **German:** Schwarzstirn-Brillenvogel

Taxonomy. *Zosterops atricapilla* Salvadori, 1879, Mount Singgalang, central-west Sumatra.

Closely related to *Z. everetti*. An old species that must formerly have been more widespread in Borneo, as latter population not even racially distinct from that in S Sumatra; reasons for species' limited and patchy distribution not known. Two subspecies recognized.

Subspecies and Distribution.

Z. a. viridicatus Chasen, 1941 – N Sumatra (Leuser Mts, in Aceh; region of Berastagi, in Sumatera Utara).

Z. a. atricapilla Salvadori, 1879 – C & S Sumatra; N, NE & SE Borneo (Mt Kinabalu, Mt Mulu, Batu Patap, Ulu Sabai, Tutoh; upper Kayan region; Meratus Mts).

Descriptive notes. 9.5–10 cm; 8.5–11 g (*viridicatus*). N nominate race has forecrown, forehead, area around eyering, and submoustachial region black, white eyering of average width broken at front with black; rear crown to back olive-green, rump much yellower; flight-feathers and tail feathers blackish-brown, more or less edged with olive-green; chin, undertail-coverts and broad streak up to lower breast chrome-yellow, throat more greenish-yellow, remainder of underparts rather dark grey; iris yellowish-brown to hazel or orange; bill horn-black, base of lower mandible grey; legs feet slate-coloured, blue

or grey. Sexes alike. Juvenile is duller throughout, with almost no black on forehead and no white eyering, has greyish-brown iris, pinkish-grey bill and grey legs. Race *viridicatus* is very like nominate, but has slightly more greenish, less yellow, throat. **VOICE.** Loud twinkling series of calls (race *viridicatus*); nominate race has trembling call note, more like that of genus *Tephrozosterops* than voice of typical white-eye.

Habitat. Upper hill forest and lower montane forest, ascending into upper montane bush and alpine ericaceous meadows, where one of very few small bird species to be found. In Sumatra from 700 m up to 3000 m on Mt Leuser, but more restricted in altitudinal range and far less abundant where *Z. montanus* occurs at upper limit (e.g. 1300–2500 m on Mt Kerinci); in Borneo at 900–2100 m on Mt Kinabalu, where it meets *Chlorocharis emiliae* at higher altitudes, and mostly between 1200 and 1900 m elsewhere.

Food and Feeding. Mainly insects, grubs, fruits, nectar. Fruits taken include those of mistletoes (Loranthaceae), wild raspberry (*Rubus*), small purple figs (*Ficus*) 4 mm in size; nectar includes that of *Eugenia* species, and buds of *Homalanthus* also consumed. During drought in 1983, grass seeds found in stomachs of Bornean individuals. Young fed with grubs and smaller insects. Forages in small flocks of 4–12 individuals; associates in mixed flocks with minivets (*Pericrocotus*), Blue Nuthatch (*Sitta azurea*) and others in Sumatra. Flocks visit fruiting trees and forage through lower and middle storeys of forest, along shrubs at forest edge and among clumps of tall bushes and low trees. Gleans insects from outer foliage; probes among moss hanging from twigs and petioles.

Breeding. Birds in breeding condition recorded in Apr, adult carrying nesting material in May and fledgling in Jun in Sumatra; nest with young in early Mar and fledglings in Apr and Jul in Borneo. One nest known, built of fine roots, placed on moss-covered bough. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Bornean Mountains EBA and in Sumatra and Peninsular Malaysia EBA. Locally very common on high

mountain tops in Sumatra. Common at 1600 m in Meratus Mts, in SE Borneo, where found relatively recently; discovered recently in upper Kayan region (E Kalimantan).

Bibliography. van Balen (1997), Chasen & Hoogerwerf (1941), David & Gosselin (2002a, 2002b), Davison (1992, 1997a), Fodgen (1965), Holmes (1996, 1997), Inskipp *et al.* (1996), MacKinnon & Philipps (1993), van Marle & Voous (1988), Mees (1954, 1957, 1969), Meyer de Schauensee & Ripley (1940), Robinson & Kloss (1918, 1924), Sheldon *et al.* (2001), Smythies (1957), Smythies & Cranbrook (1981), Smythies & Davison (1999), Stattersfield *et al.* (1998), Strange (2000, 2001), Whitehead (1893).

12. Everett's White-eye

Zosterops everetti

French: Zostérops d'Everett **German:** Everettbrillenvogel **Spanish:** Antojitos de Everett

Taxonomy. *Zosterops everetti* Tweeddale, 1878, Cebu, Philippines.

Probably derived from *Z. atricapilla*. Proposed race *forbesi* (from Camiguin Sur, in SC Philippines) is lumped with *basilanicus*. Birds of this species found on Panay, in WC Philippines, possibly represent an undescribed race. Eight subspecies currently recognized.

Subspecies and Distribution.

Z. e. wetmorei Deignan, 1943 – NE & S Thailand (S to Trang); probably also S Myanmar (Tenasserim).

Z. e. tahanensis Ogilvie-Grant, 1906 – extreme S Thailand (Yala), Peninsular Malaysia, and Borneo (Sabah, and locally C, E & S Kalimantan).

Z. e. boholensis McGregor, 1908 – Samar, Calicoan, Biliran, Leyte and Bohol, in EC Philippines.

Z. e. everetti Tweeddale, 1878 – Cebu, in C Philippines.

Z. e. siquijorensis Bourns & Worcester, 1894 – Siquijor, in SC Philippines.

Z. e. basilanicus Steere, 1890 – Dinagat, Siargao, Camiguin Sur, Mindanao and Basilan, in S Philippines.

Z. e. mandibularis Stresemann, 1931 – Sulu Archipelago (Jolo, Tawitawi, Sanga Sanga, Bongao, Papahag).

Z. e. babelo A. B. Meyer & Wilesworth, 1895 – Talaud Is (Karakelong and Salibabu), S of Philippines.

Also (race unknown) on Panay, in WC Philippines.

Descriptive notes. 11–11.5 cm; 7.8–12 g. N nominate race has forehead and supraloral region yellow, lores dusky, white eyering of average width interrupted at front by dark spot and with black line underneath; crown and upperparts olive-green; chin to upper breast yellow, connected to yellow of undertail-coverts by broad yellow mesial streak, remainder of underparts pure grey, dark grey flanks; iris yellowish-brown or brown; bill brownish-grey to black; legs pale brown. Distinguished from similar *Z. palpebrosus* mainly by slightly darker grey side of breast and flanks, colder green upperparts (especially

crown and rump), yellow of throat more greenish-tinged, ventral stripe and undertail-coverts deeper yellow. Sexes alike. Juvenile is duller than adult, with paler, less pronounced ventral stripe and greener wing-feather fringes. Race *basilanicus* differs from nominate in having dusky (instead of black) line under eyering, and black bill, size rather variable, some of largest and, conversely, smallest populations in species; *boholensis* is close to previous, but has brighter, slightly more yellowish upperparts, and deeper yellow underparts; *siquijorensis* is brightest, similar to previous but more yellow on forehead and over pale yellow lores, eyering with pale yellow spot at front, paler yellow below, yellow ventral line narrower, flanks paler grey; *mandibularis* is very like smallest populations of *basilanicus* but with paler grey flanks; *babelo* also is similar, but is yellower above, has much paler bill and legs; *tahanensis* is likewise close to *basilanicus*, but has relatively short tail, rectrices without greenish margins, no yellow on forehead and over black lores, legs blue-grey; *wetmorei* is like last, but with slightly larger bill. **VOICE.** Song in Philippines a rather complex series of metallic whistles of 8–13 notes, loud and somewhat raspy, 1.5–2.5 seconds in duration, repeated two or more times per minute, that in S (*basilanicus*) as a clear pleasant, though rather weak, whistle; in SE Asia (*tahanensis*) described as a clear, pleasant sweet but rather weak series of twittering notes, thinner and higher-pitched than those of *Z. palpebrosus*. Calls include “tee-tee” metallic “sreet” or “peet” whistle while perched and when flying in flocks; high-pitched buzzing “dzee” and rather more musical, inflected “dzee-ap”, mainly in flight.

Habitat. Low thick brush, evergreen forest, forest edge on mountain slopes, also secondary growth and scrub, cocoa plantations; in remnants of upper hill dipterocarp forest mixed with secondary growth around villages, and at edges of clearings for cultivation (hill rice, *Albizia* and cocoa). From foothills to 1800 m in Thailand and to 2000 m on main range of Peninsular Malaysia; submontane resident at 130–1700 m, mainly 200–1100 m, in Borneo, where common at 1450–1700 m on Mt Kinabalu; sea-level to 1000 m in Philippines, and sea-level to 500 m in Talaud Is (Karakelong I). Overlaps locally in altitude at c. 1000 m with *Z. montanus*.

Food and Feeding. Generalist: eats fruits (e.g. of *Macaranga*), tiny insects, caterpillars (on *Albizia*) and nectar (e.g. of *Rhodamnia*). Gregarious, usually in single-species flocks of 5–20 individuals, sometimes up to 50 or more, and up to 100 in low montane forest; also joins mixed-species flocks, e.g. with tailorbirds (*Orthotomus*) and sunbirds (Nectariniidae). Forages in subcanopy, crown foliage, tree-fern fronds etc., and attracted to flowering crowns; recorded at mass fruitings of fig trees (*Ficus*), *Macaranga*, etc. Flocks flight up and down hillsides above treetop level. Feeds also in cocoa.

Breeding. Season Feb–Sept in Philippines (e.g. Jun on Cebu, Apr on Bohol, Sept on Jolo, Jul on Bongao), and Feb–Jul in Malay Peninsula; recently fledged juvenile begging for food in Oct in Talaud Is (Karakelong). Nest a delicate cup, slung from twigs of tree branch, sometimes in top of bamboo 13 m tall. Clutch 2 eggs, white, one egg 14 × 11.4 mm. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Uncommon in Thailand; fairly common and sufficiently abundant over a wide altitudinal stretch of montane forest in Peninsular Malaysia; common on Karakelong, in Talaud Is; locally fairly common in Borneo; locally common in Philippines, e.g. common on Bohol. N nominate race recently rediscovered on Cebu, where had been believed to be extinct; no observations since 1906 until seen again in 1985, since when it has been observed at various locations throughout the island. Occurs in several protected areas, e.g. Kaeng Krachan National Park, in Thailand, and Kinabalu Park, in Borneo.

Bibliography. van Balen (1997), Brooks *et al.* (1996), Coates & Bishop (1997), Curio *et al.* (2001), David & Gosselin (2002b), Davison (1997a), Deignan (1963), Dickinson *et al.* (1991), Dupond (1942), Hachisuka (1930),

13. Golden-green White-eye

Zosterops nigrorum

French: Zostérops jaunâtre **German:** Philippinenbrillenvogel **Spanish:** Antojitos Amarillento
Other common names: Philippine (Yellow)/Yellow/Yellowish/Golden-yellow White-eye

Taxonomy. *Zosterops nigrorum* Tweeddale, 1878, Valencia, Negros, Philippines.

Possibly closely related to *Z. everetti*. Race *imminatus* sometimes merged with *luzonicus*. Proposed race *sierramadrensis* (from Mt Cagua, in extreme NE Luzon) synonymized with *imminatus*. Eight subspecies recognized.

Subspecies and Distribution.

Z. n. meyeri McGregor, 1907 – Camiguin Norte (N of Luzon), in extreme N Philippines.

Z. n. aureilioris Ogilvie-Grant, 1895 – N & NW Luzon.

Z. n. imminatus Finsch, 1901 – NE & C Luzon.

Z. n. luzonicus Ogilvie-Grant, 1895 – SE Luzon (Mt Mayon, Sorsogon) and Catanduanes.

Z. n. mindorensis Parkes, 1971 – N Mindoro (recorded from N slope of Mt Halcon).

Z. n. nigrorum Tweeddale, 1878 – Cresta de Gallo, Masbate, Ticao, Caluya, Panay and Negros.

Z. n. richmondi McGregor, 1904 – Cagayan (Cagayancillo), in Sulu Sea W of Negros.

Z. n. catarmensis Rand & Rabor, 1969 – Camiguin Sur.

Descriptive notes. 10.8–12 cm; 6–9.2 g. Male nominate race has band on forehead and lores bright yellow; blackish spot (sometimes absent) in front of white eyering, narrow blackish line under eye; crown, upperparts, side of head and neck yellowish-olive; flight-feathers and tail feathers blackish-brown, edged yellowish-olive; chin, throat and middle of breast, belly and undertail-coverts lemon-yellow, merging into yellowish-olive (paler than upperparts) on side of breast and flanks; underwing white, washed yellow; iris greenish-white or brown; bill blackish above, bluish-grey below, lighter base; legs greyish-brown. Female is overall paler

than male. Juvenile is much duller than adult. Races differ chiefly in tone of colours, nominate race duller; *aureilioris* is very bright, has distinctly defined yellow area between crown and bill, is small in size; *luzonicus* is greener, less yellow, than previous, brighter on rump, uniformly yellow below; *imminatus* is similar to last but somewhat yellower above, rump more concolorous with back, has well-defined yellow forehead, and throat brighter and richer yellow than undertail-coverts; *richmondi* is largest race, also brightest, with deep yellow underparts; *meyeri* is similar to last, but has wider eyering, especially under eye; *mindorensis* is richest and deepest yellow of all races, both above and below, black mark under eye slightly more extensive, and white eyering slightly broader than in *aureilioris* and *imminatus*; *catarmensis* has larger bill than others. Voice. Series of “pi-it tit” or “sit-it si-it” or “sip-it sip-it”, some series lasting c. 1.5 seconds and given 5–10 times per minute.

Habitat. Forest, forest edge, second growth, clearings and lower storeys of dipterocarp forest, isolated growth in grassland areas. From sea-level mostly to c. 500–600 m, much less common to 900 m; rarely to 1250 m, but not in mossy forest. Locally overlaps with *Z. montanus* at c. 1000 m.

Food and Feeding. Small insects, and berries and other tiny fruits. Forages in flocks of up to 20 individuals; often one of the core species in mixed flocks with Flame-templed Babbler (*Dasyrotapha speciosa*), Arctic Warbler (*Phylloscopus borealis*), Blue-headed Fantail (*Rhipidura cyaniceps*), Elegant Tit (*Periparus elegans*) and Balicassiao (*Dicrurus balicassius*). Searches for food in lower storeys of forest. Foraging said to be accompanied by a great deal of singing.

Breeding. Birds with enlarged gonads in Jan on Negros and late Mar in S Luzon; also recorded in May, with no locality given. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Fairly common throughout most of range; common to abundant on Luzon. Status of races *meyeri* (confined to Camiguin Norte) and *richmondi* (Cagayan) uncertain; neither has apparently been observed since first described, in 1907 and 1904, respectively.

Bibliography. Danielsen *et al.* (1994), David & Gosselin (2002b), Dickinson *et al.* (1991), Goodman & Gonzales (1990), Inskipp *et al.* (1996), Kennedy *et al.* (2000), McGregor (1909), Mees (1957, 1969), Parkes (1971), Peterson (2006), duPont (1971b), Rabor (1977), Rand & Rabor (1969), Ripley & Rabor (1956, 1958).

14. Oriental Mountain White-eye

Zosterops montanus

French: Zostérops montagnard **German:** Gebirgsbrillenvogel **Spanish:** Antojitos Montano
Other common names: Mountain White-eye

Taxonomy. *Z[osterops] montana* Bonaparte, 1850, Mount Merapi, west Sumatra.

Montane sibling of *Z. palpebrosus*. Despite enormous number of proposed names and the isolation of many populations, hardly any constant geographical variation exists; some authors prefer to recognize only two races (nominate and *obstinatus*) in Wallacea, and some even include most or all of Sumatran, Javan and Philippine races in nominate. Race *pectoralis* seems to represent a population in transition from pale-bellied to yellow-bellied, but sufficiently homogeneous to justify own name. Birds of this species recorded on Panay (WC Philippines) may represent an as yet unnamed race; some differentiation exists among the various populations of nominate; further study required. Birds of this species in Sula Archipelago of uncertain racial identity, provisionally included in nominate. Birds from Marinduque (NC Philippines) described as race *gilli* and formerly placed with present species, but now regarded as synonym of nominate race of *Z. meyeri*. Otherwise, proposed Moluccan races *seranensis* (described from Mt Pinaia, on Seram) and *ternatanus* (Ternate) both synonymized with *obstinatus*; *sarasinorum* (Mt Klabat, in NE Sulawesi), *oriochares*

(Latimojong Mts, in SC Sulawesi), *origenes* (Wawa Karaeng, in S Sulawesi), *foghaensis* (Mt Madang, on Buru), *korinchi* (Mt Kerinci, in Sumatra), *sindorensis* (Mt Tjerima, in W Java), *minimus* (Mt Papandayan, in W Java), *neglectus* (near Tosari, in E Java), *floreus* (Geli Mutu, on Flores) and *steini* (Mt Ramelan, in E Timor) all subsumed in nominate; and, in Philippines, *finitimus* (Mt Cuernos de Negros, in S Negros) merged with *pectoralis*. Nine subspecies currently recognized.

Subspecies and Distribution.

Z. m. whiteheadi E. J. O. Hartert, 1903 – highlands of N Luzon, in N Philippines.

Z. m. halconensis Mearns, 1907 – Mindoro (NC Philippines).

Z. m. parkesi duPont, 1971 – mountains of Palawan, in W Philippines.

Z. m. pectoralis Mayr, 1945 – Negros (Canlaan Volcano, Cuernos de Negros), in WC Philippines.

Z. m. diuatae Salomonsen, 1953 – N & NW Mindanao (Diuata Mts, Mt Malindang, Civolig, Daggayan, Misamis Oriental), in S Philippines

Z. m. vulcani E. J. O. Hartert, 1903 – C Mindanao (Mt Kitanglad, Mt Apo).

Z. m. difficilis Robinson & Kloss, 1918 – Mt Dempo, in S Sumatra.

Z. m. montanus Bonaparte, 1850 – mountains in C Sumatra, Java (E from Mt Papandayan), Bali, Lesser Sundas (Lombok, Sumbawa, Flores, Timor), Sulawesi (including Taliabu, in Sula Archipelago) and S Moluccas (Buru).

Z. m. obstinatus E. J. O. Hartert, 1900 – Ternate and Bacan (off Halmahera) and Seram.

Also (race unknown) on Panay, in WC Philippines.

Descriptive notes. 11.5–12 cm; 9.4–12.6 g. Nominative race has forehead and supraloral region yellow, white eyering of medium width interrupted at front by blackish spot, black lores, black stripe under eyering; crown and upperparts olive-green, rump slightly more yellow; flight-feathers and tail feathers blackish-brown with greenish outer edges; throat, upper breast and undertail-coverts yellow, rest of underparts greyish-white, flanks sometimes washed buff; iris greyish or yellowish-white; bill horn-black, base of lower mandible grey; legs plumbeous. Sexes alike. Juvenile is duller than adult, with more greenish throat, forehead

less differentiated from rest of head, and brownish-ashy flanks not so well marked. Races differ mainly in colour tones, pattern of underparts and size: *whiteheadi* is smaller and greener above than nominate; *parkesi* is larger than previous and much yellower-tinged above, has forehead and face golden-green, eyering bolder, richer yellow on chin, throat and undertail-coverts; *vulcani* is close to nominate, but with less yellow on forehead; *diuatae* is very like previous but slightly yellower above; *halconensis* also is similar but perhaps larger than *vulcani*, and sometimes with weakly developed yellow median streak on belly; *pectoralis* differs from nominate in having broad yellow streak over underparts, and flanks more or less washed with yellow; *obstinatus* is yellow-bellied; *difficilis* is entirely yellow below, paler yellow on flanks. Voice. Song in Sulawesi a two-syllable “peet-peet” followed by light trill, in Sumatra low but melodious song on 3 notes, in Java a longer distinctive warble similar to that of Mountain Leaf-warbler (*Phylloscopus viriviratus*). Contact calls soft and high-pitched, with distinctive “elastic” quality, or somewhat metallic.

Habitat. Primary montane forest, moss forest and ericaceous shrubs, forest edge, secondary growth, and in isolated bushes almost to barren mountain summit, and as high as the fumes, fires and eruptions of volcanoes permit vegetation to approach; here it is often most numerous bird species. Also in casuarina (*Casuarina*) stands, pine (*Pinus*) forests on Timor, Java and Luzon, *Dodonaea* shrubs on Sumbawa, and wooded cultivation on Flores. Found no lower than 500 m, generally above 900–1200 m; above 1000 m in Philippines, 2200–3100 m in Sumatra, 1600–3300 m in Java, 1500–3500 m (occasionally down to 900 m) on Sulawesi; fairly common between 1000 m and 1300 m, common above 1000 m to at least 2300 m on Sumbawa, scarce at 2300 m on Seram. The lowest mountain on Java on which it is known to occur is Mt Papandayan (2660 m). Overlaps altitudinally with *Z. nigrorum* in N & C Philippines, *Z. everetti* in E & S Philippines, and with *Z. palpebrosus* in E Java and Bali.

Food and Feeding. Fruits and small insects. Recorded fruits include those of the tree *Myrica javanica*, the herb *Polygonum chinense*, and the shrub *Vaccinium varingaefolium*; nectar of *Gaultheria*, *Vaccinium forbesii* and other species, including century plant (*Agave americana*), also taken; one specimen with much pollen under chin, suggesting possible feeding on flowers of rhododendron (*Rhododendron*) and *Vaccinium*. Insects include small beetles (Coleoptera), moths (of family Noctuidae) and caterpillars, and “jumping plant lice” (Psyllidae). Gregarious, travelling in noisy, fast-moving, usually small flocks of 4–5 to a dozen or so individuals, often also in large flocks; often seen also in mixed-species foraging flocks, in Java and Bali with *Z. palpebrosus*, in many places with *Lophozosterops* species. Old World flycatchers (Muscicapidae) and whistlers (*Pachycephala*), in Philippines also with Elegant Tits (*Periparus elegans*), Red Crossbills (*Loxia curvirostra*), nuthatches (*Sitta*) and fantails (*Rhipidura*) when present. Frequents upper tree levels.

Breeding. Birds with enlarged gonads in Jan–May in Philippines, where also nest with two young ready to fly in Jan in N Luzon, and on Negros one nest with newly hatched young in Apr and another with eggs in Apr/May; breeding recorded Aug and Oct in W Java, Apr–Jun and Aug on Flores, and eggs in Aug on Sulawesi. Nest almost unknown, material said to include lichens and bits of seeding grass-heads; nests have been found in dense reeds outside forest on Sulawesi. Clutch 2 or 3 eggs, white or creamy, sometimes with faint suggestion of bluish tint, to pale blue (Sulawesi) or pale greenish (W Java), dimensions 17.5 × 12 mm on Negros, 17.2 × 12.7 mm in Java and 16.6 × 12.3 mm on Flores. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Common throughout range. Generally common to very common in Wallacea, but uncommon on Sumbawa; in Sulawesi rare in Mt Mengkoka and Mt Matinan, but recently discovered on Taliabu I (Sula Is), where common in montane forest. Occurs in several protected areas, e.g. Lore Lindu National Park, in Sulawesi.

Bibliography. Becking (1989), David & Gosselin (2002b), Dickinson *et al.* (1991), Docters van Leeuwen, H. (1929), Docters van Leeuwen, W.M. 15. Yellow-spectacled White-eye

Zosterops wallacei

French: Zostérops à lunettes jaunes

Spanish: Antejitos Ojigualdo

German: Gelbring-Brillenvogel

Other common names: Wallace's White-eye

Taxonomy. *Zosterops wallacei* Finsch, 1901, Flores.

Relationships uncertain; seems to be distantly related to *Z. atricapilla*, *Z. everetti*, *Z. nigrorum* and others. Very different from other members of genus in several features, e.g. wing formula (with short primary P2, as small as or smaller than P10), head pattern (trace of superciliary stripe) and speckled eggs. Although birds from Flores slightly smaller on average than those from Sumba, difference considered too trivial to warrant naming of geographical races. Treated as monotypic.

Distribution. Lesser Sunda Is: Sumbawa, Moyo, Komodo, Rinca, Sumba, Flores, Besar, Adonara, Lomblen.

Descriptive notes. 11.5 cm; male 11.1 g, female 10.6 g. Distinctive. Has orange-yellow forehead, traces of yellow supercilium; otherwise olive-green with brownish-yellow wash above, crown and nape more yellowish, more yellow on ear-coverts; yellow eyering, black spot in front of eye, anterior part of lores yellow; remiges and rectrices blackish-brown with broad greenish margins; chin, throat, upper breast and undertail-coverts yellow, remainder of underparts pure grey, with white longitudinal streak over belly; iris dark brown; bill dark greyish; legs greyish-blue. Distinguished from similar *Z. montanus* and *Z. citrinella* mainly

by yellow (not white) eyering, from *Z. palpebrosus* and *Z. chloris* also by lack of yellow on belly. Sexes alike. Juvenile has pale brown iris. **VOICE.** Song on Komodo a rapid series of 12 warbled notes starting with 2 short unmusical notes, then a single upslurred loud whistle and a jumble of fairly high-pitched sweet notes, the whole 3 seconds in duration; on Sumba a descending, tinkling warble, sometimes beginning with harsh notes; on Flores 2 indistinct short insect-like notes followed immediately by sweet warbled series of 10–14 rapidly ascending and descending notes, duration of whole 3–4 seconds. Contact call on Sumba a plaintive “chiuw”, also churring notes when agitated; also dreary whistled notes on Flores.

Habitat. Coastal savanna habitats, including cashew (*Anacardium occidentale*) and coffee plantations, under *Duabanga* forest, also dry scrub, low bushes, semi-open shrub country, light monsoon forest, forest edge, thickets of Siam weed (*Chromolaena odorata*), secondary growth, primary and secondary forest, heavily degraded forest, woodland, bamboo thickets, vine forest and lightly wooded cultivation; also tolerant of very dry habitat, and occurs in scrub away from main blocks of forest; on Adonara I, found in coconut plantations but unrecorded from closed-canopy forest. Sea-level to 800 m, locally to 1050 m. Sympatric with *Z. citrinella* on Sumba and with *Z. chloris* on Flores.

Food and Feeding. No details of diet. Visits fruiting and flowering trees and vines, mainly middle to upper tree levels, usually in outer foliage. Singly, in pairs and in flocks of 10–15 individuals, and sometimes up to 20 or more; sometimes in mixed-species foraging flocks with Old World flycatchers (Muscicapidae), monarch-flycatchers (Monarchidae), Sumba Myzomela (*Myzomela dammermani*) and Arctic Warbler (*Phylloscopus borealis*). Utilizes very similar habitats to those exploited by *Z. chloris*, but rarely mixes in flocks with latter species.

Breeding. Season Apr–Oct (peak Apr/May–Jul) on Flores. Eggs very pale blue, with numerous very small brown spots mostly concentrated near blunt end, 17.3 × 12.6 mm. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Nusa Tenggara EBA and in Sumba EBA. Generally common on larger islands of range (Sumbawa, Sumba and Flores); moderately common on Komodo and abundant on Besar; uncommon on Moyo. Population on Sumba estimated as exceeding 400,000 individuals. As a result of its preference for forest edge, dry forest and degraded habitat, present species is believed not to be at any immediate risk.

Bibliography. Butchart *et al.* (1996), Coates & Bishop (1997), Hoogerwerf (1955), Jones *et al.* (1995), Mayr (1965), Mees (1961, 1969, 2006), Pilgrim *et al.* (1997, 2000), Rensch (1931a), Stattersfield *et al.* (1998), Strange (2001), Trainor (2002a, 2002b, 2002c, 2003a), Verheijen (1964), Verhoeve & Holmes (1999), White & Bruce (1986).

16. Javan White-eye

Zosterops flavus

French: Zostérops flavescent

German: Horsfieldbrillenvogel

Spanish: Antejitos Amarillo

Other common names: Yellow White-eye

Taxonomy. *Dicaeum flavum* Horsfield, 1821, Java.

Sometimes united with *Z. chloris*, *Z. citrinella* and *Z. luteus*, but generally considered a well-marked species without certain close relatives. Monotypic.

Distribution. W & S Borneo, including Laut I (off SE Kalimantan); coastal N Java and Madura I.

Descriptive notes. 9.5 cm. Very small white-eye with relatively very short tail. Has frontal area yellow, crown and upperparts between pyrite-yellow and olive-green, rump more yellowish; lores pale yellow, white eyering of average width; primaries and tail feathers brownish-black, edged yellowish-green; entire underside yellow, on flanks and breast side merging into colour of mantle; iris bright yellowish-brown; bill dark horn above, plumbeous below; legs leaden blue. Differs from *Z. chloris* in lack of black on lores. Sexes alike. Juvenile has narrower eyering than adult. **VOICE.** No song known. Call notes “trrieew” and short, soft “trip”; alarm “wiwiwiwi”.

Habitat. In Borneo inhabits mangrove forest and dryland forest edge along coast, locally low waterside trees in small towns and nearby wet coconut groves upriver (up to 10 km inland), also

fledged young at end of Jul in W Java, and fledged young and juvenile in Aug in S Borneo. Small, neatly built nest of thin grass blades, lined with many fine stalks, and covered externally with much cobweb, placed 1 m above ground. Clutch 2–3 eggs, very pale blue, 15.4 × 11.4 mm.

Movements. Resident.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Javan Coastal Zone EBA and in Bornean Coastal Zone Secondary Area. Locally common. Moderate to large numbers recorded at night-time roosts, from which they disperse during day. In Java and on Madura I, this species' favoured habitat of mangroves is now much reduced and remains under continuous threat.

Bibliography. Allport & Milton (1988), Anon. (2007n), Bartels, M. (1931), Bartels, M.E.G. (1915–1930), Becking (1989), Butchart & Stattersfield (2004), Collar *et al.* (2001), David & Gosselin (2002b), Davison (1997b), Delacour (1947), Heath (1991), Hellebrekers & Hoogerwerf (1967), Holmes (1997), Holmes & Burton (1987), Hoogerwerf & Rengers Hora Sicama (1938), Inskipp *et al.* (1996), Kuroda (1933a), Kuschel (1895), MacKinnon & Phillips (1993), Mayr (1944a), Mees (1954, 1957, 1969), Milton & Marhadi (1985), Nash & Nash (1988), Rusila & Enis (1995), Smythies (1957), Smythies & Cranbrook (1981), Smythies & Davison (1999), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Sunarto & Melisch (1995), Telford (2003), Vorderman (1883).

17. Lemon-bellied White-eye

Zosterops chloris

French: Zostérops à ventre citron

Spanish: Antejitos Ventrilimón

German: Molukkenbrillenvogel

Other common names: Moluccan/Banda/Yellow/Yellow-bellied/Large Bridled/Mangrove White-eye; Pale White-eye (sometimes includes *Z. citrinella*)

Taxonomy. *Z[osterops] chloris* Bonaparte, 1850, Banda Archipelago, Banda Sea.

Forms a superspecies with *Z. citrinella*, and sometimes *Z. grayi* and *Z. uropygialis* included in same superspecies; relationship with *Z. consobrinorum* uncertain. Has sometimes been treated as conspecific with *Z. flavus*, *Z. citrinella* and *Z. luteus*. Described races *majauensis* (from Mayu I) and *tudjuensis* (Tujuh I) merged with nominate; *solombensis* (Masalembu Is), *zachlora* (Laut Kecil Is) and *periplectus* (Lombok) subsumed in *maxi*; and *sumbawensis* (Bima, in E Sumbawa) and *kalaotuae* (Kalaotoa I) synonymized with *intermedius*. In Sulawesi, racial identity of birds in NE arm of mainland, on Dodepo I (in N Tomini Bay) and on Kabaena I (off SE Sulawesi) unclear; all provisionally placed with *intermedius*, but those on Dodepo and Kabaena possibly represent undescribed races. Five subspecies currently recognized.

Subspecies and Distribution.

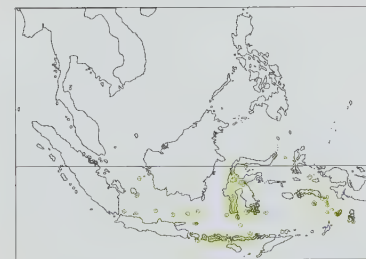

Z. c. chloris Bonaparte, 1850 – Mayu I (half-way between Sulawesi and Halmahera), Schildpad Is (N of Misool), Tjujuh (off N Seram), Banda, Manuk, Seram Laut, Tayandu, Kai, Taam (off Kai), and outliers of Aru Is (Babi, Karang, Enu).

Z. c. mentoris Meise, 1952 – NC Sulawesi.

Z. c. flavissimus E. J. O. Hartert, 1903 – Tukangbesi Is, off SE Sulawesi.

Z. c. intermedius Wallace, 1864 – E & S Sulawesi, Dodepo I, Kabaena, Muna, Butung (but not recorded from SE peninsula), small islands in Flores Sea (Tanakeke, Salayar, Tanahjampea, Kalao, Bonerate, Kalaotoa, Madu), and C Lesser Sundas (Sumbawa, Komodo, Rinca, Flores, Palu, Besar, Sabolan Besar).

Z. c. maxi Finsch, 1907 – Karimata Is (off W Borneo), islets S & E of Belitung, islands in Bay of Jakarta (Seribu Is), Karimunjawa Is, Gili (off Bawean I), Laut Kecil Is, Kangean Is, Menjangan (off NW Bali), Nusa Penida, and Lombok.

Descriptive notes. 11–12 cm; 9–14 g. Nominative race has base of forehead and supraloral line almost pure yellow, eyering white, lores and streak below eyering dusky, ear-coverts olive-yellow; crown and upperparts yellowish-green; flight-feathers and tail feathers blackish-brown, edged yellowish-green; throat and underparts deep yellow with greenish flanks; iris brown to reddish-brown or pale yellow-brown; bill black or brownish-black above, bluish-grey below; legs slaty greyish-blue. Sexes similar. Immature is somewhat more greenish below and somewhat more greyish-green above. Race *intermedius* is smaller than

nominate, has finer bill, paler underparts, less dark greenish flanks (variable); *mentoris* is very close to previous but with smaller wing and bill, and rich yellow underparts as nominate, relatively long tail; *flavissimus* is yellowest, yellow (not blackish or dusky) lores, below which dusky-black stripe extending to under eyering, very yellow on rump, tail feathers edged yellowish; *maxi* is duller, more greenish above and paler yellow below than *intermedius*, but colour of underparts rather variable in both races. **VOICE.** Song a weak, though rich and beautiful jumbled mixture of rapid high-pitched musical seesawing and more sibilant short “si-si” notes, given in short burst of 1–3–1.5 seconds, repeated, sometimes monotonously, at intervals of 6–8 seconds; in Sulawesi sound-

On following pages: 18. Ashy-bellied White-eye (*Zosterops citrinella*); 19. Pale-bellied White-eye (*Zosterops consobrinorum*); 20. Pearl-bellied White-eye (*Zosterops grayi*); 21. Golden-bellied White-eye (*Zosterops uropygialis*); 22. Black-ringed White-eye (*Zosterops anomalus*); 23. Creamy-throated White-eye (*Zosterops atriceps*); 24. Black-crowned White-eye (*Zosterops atrifrons*); 25. Togian White-eye (*Zosterops somadikartai*); 26. Sangihe White-eye (*Zosterops nehrkorni*); 27. Seram White-eye (*Zosterops stalkeri*); 28. Black-fronted White-eye (*Zosterops minor*); 29. White-throated White-eye (*Zosterops meeki*); 30. Black-headed White-eye (*Zosterops hypoxanthus*); 31. Biak White-eye (*Zosterops mysorensis*); 32. Capped White-eye (*Zosterops fuscicapilla*); 33. Buru Yellow White-eye (*Zosterops buruensis*).

ing as “eechew-weecherechitche-chew-chicherechee-ew-cheep”; on Kalaotoa I described also as a whistle which ascends sharply and continues in very pleasant twittering. Gives real concerts at dawn and, especially, at sunset. Call a loud “ship” or “chiew” reminiscent of that of House Sparrow (*Passer domesticus*).

Habitat. Secondary forest and open woodland, scrub, mangroves, strand forest and coastal thickets, casuarinas (*Casuarina*), *Ficus* thickets in open coastal woodlands, thickets under coconut plantations, cultivation; readily found in village centres and suburban gardens; often on small islands, even those overcrowded with humans. Mainly near sea-level, but locally to 1200 m (Flores), 1660 m (Lombok), 1000 m (NC Sulawesi) and 1800 m (S Sulawesi), where it meets edge of closed forest.

Food and Feeding. Varied. Fruits from banyan tree *Ficus benjamina*, and *Eugenia* trees, also from shrub *Lantana camara* and herb *Tacca leontopetaloides*; insects taken include plant lice (Phytophthires), small white cicadas (Cicadoidea). Usually in small flocks, flying from tree to tree; often in company of flowerpeckers (Dicaeidae) and sunbirds (Nectariniidae). In non-breeding season may form larger flocks of up to 25 or more individuals. Restless. Forages at all levels of vegetation. Visits fruiting trees.

Breeding. On Sulawesi Jan–Feb in C. Sept–Apr (possibly throughout year) in S. Sept–Oct on Muna and Butung; in Java and Apr–May/Jun on Flores; possibly within Nov–Apr wet season (and dependent on climatic conditions) on islets off Bali; small fledglings in Apr in Banda Is. Nest small, c. 6–7 cm across and 2.5–2.8 cm high, with rather strong walls but thin bottom, made from tender fibres, shallow cup entirely lined with black fibres of *Arenga sacchifera* palm, attached to surrounding branches with spider web; in S Sulawesi generally suspended between two twigs 1.5–4 m above ground, but sometimes high in canopy of tree (e.g. *Anona*, *Cassia*, *Erythrina*, *Mangifera* and *Arcocarpus*) or shrub (*Vitex*, *Lagenaria* and *Lantana*) or in *Lanea* hedge, preferably in shady dense vegetation. Clutch in S Sulawesi 2–3 (occasionally 4) eggs, pale blue or snow-white, 15–15.9 × 11.9–12.4 mm, on Flores 1–4 (usually 3) eggs, pale blue to white, 16.3 × 12.6 mm, on islets in Java Sea 2 bluish-green eggs; no information on incubation and nestling periods. Breeding success of 21 nests on islets in Java Sea 33 %.

Movements. Resident; some local movement. On Menjangan (off NW Bali) some post-breeding movement in dry season (Jun–Sept) to mainland, less than 500 m away. On Bawean I (off C Java) the species was entirely absent, but in May it was found on small satellite island of Gili, where it was absent again in Nov.

Status and Conservation. Not globally threatened. Generally common. Locally abundant, e.g. Tanahjampea I, Madu I, Besar I, outliers of Aru Is. Taam; most common bird species on Butung and Kalaotoa. Apparently rare at periphery of distribution on Sulawesi (Morowali, in N Sulawesi). Density of 4–6 nest territories in 75 m² reported in S Sulawesi. Has its core distribution on mainland Sulawesi and Lesser Sunda; in E (islets off Kai Is, Aru and Seram, Banda Is) and W parts (islets off Bali, and in Java Sea) the species is distributed sporadically and occurs only on small islands, normally shunning even moderately sized ones.

18. Ashy-bellied White-eye

Zosterops citrinella

French: Zostérops pâle **German:** Zitronenbrillenvogel **Spanish:** Antojitos Pálido
Other common names: (Australian) Silvereye(1); (Australian) Pale White-eye (sometimes includes *Z. chloris*); Alor White-eye (*harterti*); White-bellied White-eye (*albiventris*)

Taxonomy. [*Zosterops*] *citrinella* Bonaparte, 1850, Timor.

Forms a superspecies with *Z. chloris*, and sometimes *Z. grayi* and *Z. uropygialis* included in same superspecies; possibly closely related to *Z. consobrinorum*. Has sometimes been treated as conspecific with *Z. flavus*, *Z. chloris* and *Z. luteus*, and sometimes with *Z. palpebrosus*. Birds of this species recorded on Lomblen (EC Lesser Sunda) of uncertain racial identity, provisionally included in *harterti*; those from Lucipara Is (in Banda Sea) provisionally included in *albiventris*. Proposed race *intercalaris* (from Sumba) merged with nominate; *griseiventris* (Tanimbar Is), *bassetti* (Damar I) and *letitiensis* (Leti I) subsumed in *albiventris*. Three subspecies currently recognized.

Subspecies and Distribution

Z. citrinella Bonaparte, 1850 – Sumba, Savu, Timor and Roti (including islets of Ndana and Ndao).
Z. harterti Stresemann, 1912 – Lomblen and Alor, in EC Lesser Sunda.
Z. albiventris Reichenbach, 1852 – Lucipara Is and Gunungapi (in Banda Sea), Wetar, Romang, Damar, Teun, Kisar, Leti, Moa, Luang, Sermata, Babar, Tanimbar Is (Molu, Lutu, Yamdena, Larat, Selaru); islands in Torres Straits (Warrior, Deliverance, Cairncross), and islets off extreme NE Australia off (Eborac S to Rocky Islets, off NE Cape York Peninsula).

Descriptive notes. 10–11 cm. Nominative race has forehead and supraloral region distinctly yellow, blackish loreal line extending under white eyering, eyering of average width and broken at front by blackish spot of loreal line; crown and upperparts pale olive-yellow, slightly more yellow on rump; flight-feathers and tail feathers blackish-brown with broad greenish margins; chin, throat, upper breast and undertail-coverts pale yellow, rest of underparts pale greyish, darkest on flanks, almost pure satin-white towards centre of belly, sometimes a mesial yellow longitudinal streak; iris pale brown or dark sandy brown; bill blackish-grey; legs dark blue-grey. Sexes alike. Immature is paler than adult. Race *harterti* has yellower rump than nominate; *albiventris* is hardly distinguishable from nominate, but has slightly heavier and larger bill. Voice. Song on Timor a series of rather weak, sweet, moderately high-pitched twittering notes, 0.8–1.2 seconds in duration, interspersed with rapidly repeated warbles, trills and slurs; on Sumba similar to that of *Z. wallacei*, but shorter and at constant pitch; in Tanimbar Is a moderately rapid rising and falling series of 10–16 relatively loud, clear notes with fairly sweet warbling quality, 2 seconds long, repeated at intervals of 2–3 seconds; on the smaller islands song heard in large choruses. Contact calls similar to those of *Z. lateralis* but louder and less plaintive.

Habitat. Scrub, forest edge, secondary growth, primary and secondary forest, heavily degraded forest, open woodland, monsoon thickets, lightly wooded cultivation, scrubby farmland, mangroves,

coastal casuarinas (*Casuarina*); often on small islands. Sea-level to 1000 m on Alor, to 1200 m on Timor; nominate race reported as reaching to 2000 m in Lesser Sunda.

Food and Feeding. Insects, berries. Gregarious, forms roaming flocks of 3–10 individuals, sometimes up to 20; also singly and in pairs. Also in mixed-species flocks. Forages actively in outer foliage of canopy; also in lower canopy, middle storey and low scrub.

Breeding. Probably Dec–Jun on Timor and islets off NE Australia; Jan in Tanimbar Is and Apr on Roti; laying female in May on Sumba. Nest a small neat cup of fine grass or long threads from *Palmira* leaves and fine stalks, bound with spider web and cocoons, lined with fine grass, suspended by rim 1.5 m above ground in slender fork of shrub or foliage of tree. Clutch 2–4 eggs, pale bluish-green/grey or white, recorded measurements 16.5 × 13 mm, 18.1 × 12.5 mm (race *albiventris*), 15.2–18.5 × 11.1–12.5 mm. No other information.

Movements. Resident; record from Booby I (in Torres Strait), lacking suitable habitat, suggests some local movement. Reported sightings on Australian mainland (at Byfield and Yeppoon) never confirmed.

Status and Conservation. Not globally threatened. Generally common. Common and widespread on Roti I; common in Tanimbar Is; status on Alor not known.

Bishop (1992), Bishop & Brickell (1999), Blakers *et al.* (1984), Coates & Bishop (1997), David & Gosselin (2002a, 2002b), Finsch (1898), Higgins *et al.* (2006b), Inskipp *et al.* (1996), Johnstone & Jepson (1996), Macgillivray (1914), Mason (1991), Mathews (1923), Mees (1961, 1969), Noske (2003), Pitzey & Knight (1997), Rand & Gilliard (1967), Rensch (1929), Schodde & Mason (1999), Strange (2001), Trainor (2005b, 2007b), Verheijen (1976), Verhoeve & Holmes (1999), White & Bruce (1986).

19. Pale-bellied White-eye

Zosterops consobrinorum

French: Zostérops à ventre pâle **German:** Celebesbrillenvogel **Spanish:** Antojitos Ventripálido
Other common names: Peninsular/Sulawesi/Celebes/Laoumera White-eye

Taxonomy. *Zosterops consobrinorum* A. B. Meyer, 1904, eastern mountain chain of south-east peninsula, Sulawesi.

Possibly closely related to *Z. citrinella*, or perhaps even conspecific. Birds from Butung differ vocally and morphologically from those in rest of species' range, and very likely represent an undescribed race. Monotypic.

Distribution. SE Sulawesi (L. Matano S to E coast and Mekong Mts), Kabaena I and Butung I, and possibly also Muna I.

Descriptive notes. 11.5–12 cm; 9.8–10.4 g. Plumage is olive-green above, forehead and supraloral region as mantle or slightly more yellowish; rather narrow eyering white, broken at front by blackish spot, lores and streak under eye blackish; remiges blackish fringed olive-green, rectrices blackish; golden-yellow chin, throat, upper breast and undertail-coverts, remainder of under parts white, more greyish on flanks and breast; iris light brown; bill black, grey base of lower mandible; legs dark grey. Differs from *Z. montanus* in smaller size, much brighter yellow throat and undertail-coverts. Sexes alike. Juvenile undescribed. Voice.

Loud, very pleasing song strophe, lacking trilling notes of *Z. atrifrons* and *Z. anomalus*.

Habitat. Scrub, cultivation, remnant patches of lowland forest, forest edge, scrubby vegetation close to forest patches, forestry plantations, gardens, and small woodland plots in deforested lowlands; locally in wooded savanna and around villages. Sea-level to 300 m and above. Apparently the ecological and altitudinal counterpart of *Z. chloris* (of race *intermedius*), which is absent from most of SE Sulawesi, but co-exists with present species on islands of Butung and Kabaena.

Food and Feeding. No information on diet. Found in pairs or small family parties, sometimes joining mixed-species flocks. Forages in canopy of tall forest trees, but more commonly in understorey and thickets along forest edge.

Breeding. Nest found in early Aug, an untidy cup of grasses placed in low bush a few metres from main road; adult feeding juvenile in Oct. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Sulawesi EBA. Locally common, e.g. on Butung, but generally uncommon. Poorly known species. Discovered relatively recently on Butung and Kabaena; possibly occurs also on underexplored island of Muna, lying between those two. Report from Kendari region of mainland Sulawesi considered dubious. Appears able to utilize secondary habitat, and unlikely to be threatened in near future so long as some forest, even degraded, remains.

Bibliography. Catterall (1997), Coates & Bishop (1997), Holmes & Holmes (1985), Holmes & Wood (1980), Inskipp *et al.* (1996), Mees (1961), Stattersfield *et al.* (1998), Stresemann & Heinrich (1940b), Wardill (2003), Wardill *et al.* (1999), White & Bruce (1986).

20. Pearl-bellied White-eye

Zosterops grayi

French: Zostérops de la Grande Kai **Spanish:** Antojitos de la Gran Kai
German: Graybrillenvogel
Other common names: Great Kai/Great Kei White-eye; Kai/Kei White-eye (with *Z. uropygialis*)

Taxonomy. *Zosterops grayi* Wallace, 1864, Kai Islands.

Forms a superspecies with *Z. uropygialis*, and these two sometimes treated as conspecific; both sometimes considered to belong to the superspecies comprised of *Z. chloris* and *Z. citrinella*. Monotypic.

Distribution. Kai Besar I, in E Banda Sea.

Descriptive notes. 13 cm. Has yellow frontal band, broad white eyering interrupted at front by blackish spot; anterior crown dark brownish, rest of crown and upperparts bright yellowish-citrine; primaries and tail feathers blackish-brown with broad yellow-citrine edges; throat, upper breast and undertail-coverts lemon-chrome, upper breast somewhat greener; satin-white belly with yellow median stripe connecting yellow of throat with that of vent; iris chocolate-brown; bill black, grey base of lower mandible; legs yellowish-plumbeous or grey. Sexes alike. Juvenile undescribed. Voice. Song a series of strident, squeaky chattering notes punctuated by 3 short, sharp, high-pitched notes repeated in quick succession, the whole lasting c. 7 seconds. Call notes a series of rapid,

Breeding. No information.
Movements. Presumably resident.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Banda Sea Islands EBA. Moderately common in all wooded habitats.
Bibliography. Anon. (2007n), Butchart & Stattersfield (2004), Coates & Bishop (1997), Collar *et al.* (2001), Hartert (1903b), Inskipp *et al.* (1996), Johnstone & van Balen (2008), Mees (1961, 1969), von Rosenberg (1867), Salvadori (1879), Sibley & Monroe (1990), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), White & Bruce (1986).

21. Golden-bellied White-eye

Zosterops uropygialis

French: Zostérops de la Petite Kai **German:** Tualbrillenvogel **Spanish:** Antojitos de la Pequeña Kai
Other common names: Little Kai/Little Kei White-eye; Kai/Kei White-eye (with *Z. grayi*)

Taxonomy. *Zosterops uropygialis* Salvadori, 1874, Kai Kecil.
Forms a superspecies, and sometimes considered conspecific, with *Z. grayi*; both sometimes thought to belong to the superspecies comprised by *Z. chloris* and *Z. citrinella*. Monotypic.
Distribution. Kai Kecil I, in E Banda Sea.

Descriptive notes. 12.5 cm. Has fuscous cap extending anteriorly over entire forehead and loreal region; eyering reduced to a number of very small scaly feathers, and therefore skin around eye partly bare; upperparts bright yellowish-citrine, primaries and tail feathers blackish-brown with broad yellow-citrine edges; throat and underparts entirely bright yellow, flanks tinged olive; iris light brown; bill brownish; legs leaden grey. Distinguished from similar *Z. grayi* by having whole forehead dusky (no yellow), eyering barely indicated, and entire underside bright yellow with more olive on the flanks, also slightly smaller in wing and tail. Sexes alike.

Juvenile undescribed. **VOICE.** Variety of calls, including squeaky nasal chatters, harsh rasping squeaks, and brief bubbling notes, by individuals and partners; loud and mellow, nasal "chow".

Habitat. Forest, and cleared land with scattered trees.

Food and Feeding. No details on diet. Usually seen in pairs and in groups of up to six individuals. Forages deliberately in canopy; moves along branches and from perch to perch in hops of c. 20 cm; posture rather upright, almost like that of an Old World flycatcher (Muscicapidae). Most food items obtained by hover-gleaning.

Breeding. No information.

Movements. Presumably sedentary.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Banda Sea Islands EBA. Recent surveys indicated that this species is scarce to rare, is found in only a few places, and may be vulnerable to forest loss within its small range. Formerly was generally considered moderately common in most wooded habitats.

Bibliography. Anon. (2007n), Butchart & Stattersfield (2004), Coates & Bishop (1997), Collar *et al.* (2001), Hartert (1903b), Inskipp *et al.* (1996), Johnstone & van Balen (2008), Mees (1953a, 1961, 1969), Sibley & Monroe (1990), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), White & Bruce (1986).

22. Black-ringed White-eye

Zosterops anomalus

French: Zostérops à gorge citron **German:** Sulawesibrillenvogel **Spanish:** Antojitos Anómalo
Other common names: Celebes/Makassar/Lemon-throated White-eye

Taxonomy. *Zosterops anomala* A. B. Meyer and Wieglesworth, 1896, Ujung Pandang (Makassar), south Sulawesi.

Closest relatives uncertain; *Z. consobrinorum*, *Z. atrifrons* and present species apparently replace one another geographically, but they differ too greatly in plumage coloration for close relationships to be likely. Monotypic.

Distribution. S peninsula of Sulawesi (S from Bolong and Rantepao, in Quarles Mts).

Descriptive notes. 12 cm. Has forehead and supraloral region yellow, broad dull black loreal line continuing backwards to encompass whole eye, thus black eyering (white feathers that would make eyering are greatly reduced); crown and upperparts generally olive-green, more yellowish on uppertail-coverts; remiges and rectrices brownish-black with greenish outer edges; chin, throat and upper breast yellow, undertail-coverts somewhat paler yellow, remainder of underparts pale grey, whitish on belly; iris light brown; bill black, pale base of lower mandible; legs pale grey to bluish-grey. Sexes alike. Juvenile undescribed. **VOICE.** Song

a muted series of slightly musical, teetering, chattering notes, 1–2 seconds in duration, repeated two or three times, or several trilling notes preceded by a prelude, e.g. "chewchicheruit-chewticherui-uu rrr", not unlike a soft version of Common Chaffinch (*Fringilla coelebs*) song. Call a peculiar quivering whistle, likened to sound made by a police whistle.

Habitat. Scrubby deforested hills, disturbed primary forest, secondary forest with open canopy, forest edge, low secondary scrub, bushes, village gardens and orchards, though seldom in immediate neighbourhood of settlements. Sea-level to 1370 m. Occurs next to *Z. chloris* but occupies different biotope (i.e. open secondary forest, low trees), especially in hills, and tends to avoid human settlements.

Food and Feeding. No details of diet. Singly, in pairs or in single-species flocks of up to 12 individuals; also in mixed-species foraging flocks. Forages in both canopy and understorey vegetation, including coffee, low scrub; visits flowering trees.

Breeding. Old nest in Apr; adults carrying nest material observed in Aug or Sept; courtship seen in Jan. Nest a relatively flat cup, exterior entirely covered with spiky *Mimosa* twigs. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Sulawesi EBA. Locally common. Rather common north to Rantepao in 1987. Appears to be adaptable and not dependent on primary habitats.

Bibliography. Andrew & Holmes (1990), Coates & Bishop (1997), Collar *et al.* (1994), Coomans de Ruiter (1950, 1951), David & Gosselin (2002b), Fraser & Henson (1996), Holmes & Phillips (1996), Inskipp *et al.* (1996), Lack (1971), Mees (1961, 1969), Sarasin & Sarasin (1905), Stattersfield *et al.* (1998), Stresemann & Heinrich (1940b), White & Bruce (1986).

23. Creamy-throated White-eye

Zosterops atriceps

French: Zostérops à gorge crème **German:** Braunscheitel-Brillenvogel **Spanish:** Antojitos Moluqueo
Other common names: (Bacan) Black-fronted(!)/Batjan Black-fronted/Green-throated/Halmahera (Black-fronted) White-eye

Taxonomy. *Zosterops (?) atriceps* G. R. Gray, 1861, Bacan, Moluccas.

Forms a superspecies with *Z. atrifrons*, *Z. somadikartai*, *Z. nehrkorni*, *Z. stalker*, *Z. minor*, *Z. meeki* and *Z. hypoxanthus*. Three subspecies recognized.

Subspecies and Distribution.

Z. a. dehaani van Bemmelen, 1939 – Morotai, in N Moluccas.

Z. a. fuscifrons Salvadori, 1878 – Halmahera.

Z. a. atriceps G. R. Gray, 1861 – Bacan and Obi.

Descriptive notes. 12 cm; 12 g. Nominat race has entirely fuscous-black forehead, becoming more fuscous olive-green on crown and fuscous grey on nape; supraloral region blackish. Lores dusky grey, rather narrow to wide grey eyering interrupted at front by dusky spot, ear-coverts light fuscous with citrine wash; upperparts olive-green, remiges and rectrices blackish-brown with greenish margins; whitish below, almost pure white on throat and centre of belly, slightly greyer on breast, and with lemon-yellow undertail-coverts; iris light brown; bill black, yellow basal half of lower mandible; legs grey. Differs from *Z. montanus*

in e.g. white (not yellow) throat. Sexes alike. Juvenile undescribed. Race *fuscifrons* is smaller than nominate, nape and crown olive-green like back, and fuscous only on forehead; *dehaani* is distinctive, larger and heavier-billed than others, has darker, blackish crown and more extensively dark ear-coverts, pale lores, wider eyering. **VOICE.** Rather thin, high-pitched series 1.5 seconds in duration, of fairly sweet whistles, each note alternating rapidly up and down, each phrase ending with 1 or 2 upslurred, whistled disyllabic "tu-wit" notes; phrases repeated at intervals of 4–5 seconds. A slightly louder, harder version of song, lacking concluding disyllabic notes, on Halmahera (race *fuscifrons*).

Habitat. Primary and secondary lowland forest and hill forest, forest edge and cultivation; also mangroves (Halmahera). Sea-level to 1050 m on Halmahera, lowlands to 700 m on Bacan, and 220–700 m on Obi.

Food and Feeding. No details of diet. Usually in small groups of up to six individuals; also singly and in pairs. Relatively inconspicuous and skulking. Forages in thickets 1–2 m above ground; also in middle storey and canopy.

Breeding. Juvenile in Nov. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Maluku EBA. Moderately common. Recently discovered on Obi I, where uncommon and may be a fairly recent arrival.

Bibliography. van Bemmelen (1939, 1948), Coates & Bishop (1997), Lambert (1994), Mees (1961, 1969), Poulsen *et al.* (1999), Stattersfield *et al.* (1998), Strange (2001), White & Bruce (1986).

24. Black-crowned White-eye

Zosterops atrifrons

French: Zostérops à front noir **German:** Wallacebrillenvogel **Spanish:** Antojitos Frentinegro
Other common names: Moluccan (Black-fronted) White-eye; Black-fronted White-eye(!) (within *Z. atrifrons-minor* species group)

Taxonomy. *Zosterops atrifrons* Wallace, 1864, Manado, north Sulawesi.

Forms a superspecies with *Z. atriceps*, *Z. somadikartai*, *Z. nehrkorni*, *Z. stalker*, *Z. minor*, *Z. meeki* and *Z. hypoxanthus*. Was formerly sometimes treated as conspecific with all except first two of those. Is ecologically and behaviourally close to *Z. anomalus*, with vocal resemblance also, and has in the past been considered its sibling species in N Sulawesi. Races may constitute two separate species, nominate race and *surdus* representing one species and *sulaensis* and *subatrifrons* the other; latter would then include birds of this species found near L Matano (N end of SE peninsula of Sulawesi, more than 100 km from nearest known population), having relatively long tail and distinctive plumage (distinct yellow rump, golden-yellow throat, yellow undertail-coverts, white

rest of underparts, legs dark grey), which presumed to represent an undescribed race. Four subspecies currently recognized.

Subspecies and Distribution.

Z. a. atrifrons Wallace, 1864 – N Sulawesi.

Z. a. surdus Riley, 1919 – NC Sulawesi.

Z. a. subatrifrons A. B. Meyer & Wigglesworth, 1896 – Banggai Archipelago (Peleng, Banggai), off E Sulawesi).

Z. a. sulaensis Neumann, 1939 – Sula Is (Taliabu, Seho, Mangole, Sanana).

alike. Juvenile has duller throat than adult, black on crown less extensive and somewhat mottled with olive, and eyering smaller. Race *surdus* is somewhat larger and with more greenish upperparts than nominate, and has yellow throat more greenish-tinged; *subatrifrons* is larger than nominate, with cheeks and throat pure yellow; *sulaensis* is close to nominate, but has broader white eyering, rich orange-yellow throat. VOICE. On Sulawesi, usual call a loud and characteristic double note followed by rapid tinkling twitter, descending and trailing off; noisy twittering chirrup, very different from normal call, from small flocks; also an excited twittering consisting of repeated brief high-pitched, rising double note by members of small flock; also a high-pitched "tittiti" trill, a wheezy "zzzzz", and "zi-zi-zi-zi" call; song a distinctive shrill warble (unusual for a white-eye). On Taliabu (race *sulaensis*), high-pitched sweet notes in rapid series lasting 1.8–2.2 seconds, also clear high-pitched, rapid, rolling series (2 seconds) of 8–9 sweetly whistled notes; relatively weak, plaintive, high-pitched single "pee", "tiuw" or "teew" given as contact by members of small group.

Habitat. Primary and secondary lowland forest and hill forest, selectively logged and heavily degraded forest, forest edge, scrub, cultivated highlands; lowlands to 1500 m. Readily penetrates forest along rivers or roads. Occurs together with *Z. consobrinorum*, the two not completely replacing each other geographically. In N Sulawesi nominate race inhabits Mt Empung, whereas *Z. montanus* found on nearby, slightly higher Mt Lokon.

Food and Feeding. Arthropods, fruits; seeds found in stomach contents. Not very gregarious, sometimes in small flocks (Sulawesi), or in flocks of up to 20 individuals (Taliabu), but also flocks of up to 100 birds reported from Minahasa (N Sulawesi). Has broad vertical foraging niche, ranging from substage to canopy levels. Actively gleans and probes under leaves and epiphytes for arthropods; also hover-gleans, and plucks small fruits.

Breeding. Apr–May; male with enlarged gonads in Jan. Nest a cup-shaped structure suspended in fork of twig by means of fibres, cobweb, etc. Clutch 2–3 eggs, uniform blue. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Generally common. Common in C Sulawesi to 1400 m. and common on Taliabu I. Occurs in Lore Lindu National Park.

Bibliography. David & Gosselin (2002b), Holmes, D.A. & Phillips (1996), Holmes, P.R. & Holmes (1985), Holmes, P.R. & Wood (1979), Inskipp *et al.* (1996), Lack (1971), Mees (1961, 1969), Meyer & Wigglesworth (1895, 1898b), Rasmussen *et al.* (2000), Rozendaal & Dekker (1989), Sarasin & Sarasin (1905), Stones *et al.* (1997), Strange (2001), Stresemann & Heinrich (1940b), Watling (1983), White & Bruce (1986).

25. Togian White-eye

Zosterops somadikartai

French: Zostérops des Togian **German:** Togianbrillenvogel **Spanish:** Antojitos de las Togian

Taxonomy. *Zosterops somadikartai* Indrawan *et al.*, 2008, Malenge, in Togian Islands.

Forms a superspecies with *Z. atriceps*, *Z. atrifrons*, *Z. nehrkorni*, *Z. stalker*, *Z. minor*, *Z. meeki* and *Z. hypoxanthus*. Monotypic.

Distribution. Togian Is (Malenge, Talatakoh and Batudaka), in N Sulawesi.

Descriptive notes. c. 11 cm. Has forehead and forecrown (to above eye) and lores black, bare fleshy eyering dark slaty grey with some tiny white feathers (visible only at extremely close range), surrounded by black feathered eyering; upperparts from rear crown to back citrine, more olive on side of head, rump yellow-tinged olive-green; upperwing-coverts olive-green, flight-feathers and tail feathers with yellowish olive-green edges and blackish tips; chin and throat sulphur-yellow, upper breast pale grey, lower breast and belly white, vent sulphur-yellow; white underwing-coverts; iris dark red; bill black, pale flesh base of lower mandible; legs metallic horn. Differs from other members of the superspecies in lacking clearly marked white eyering, and has slightly heavier bill than most others. Sexes believed similar. Juvenile undescribed.

VOICE. Song a thin sweet warble, similar to that of *Z. atrifrons* but less modulated; twittering chirrups heard from small moving flocks.

Habitat. Low bushes near mangroves, gardens, coconut groves, secondary scrub (e.g. *Lantana*) in logged-over forest, from sea-level to 100 m. Typically roosts in shrubs (*Macaranga*, larger bamboos etc.) 5–15 m tall.

Food and Feeding. Insects, including caterpillars, gleaned from branches and beneath leaves. Forages in pairs or small flocks of up to five individuals; often visits dense, low shrubs.

Breeding. No information.

Movements. No information; presumed sedentary.

Status and Conservation. Not assessed. Very poorly known; described only recently. Believed to be uncommon and localized. Although apparently tolerant of habitat disturbance, considered to merit conservation status of Endangered; restricted to three small islands on which extent and

quality of habitat likely to decrease owing to conversion and overexploitation of resources. The Togian Islands have been declared a National Park, including all the islands.

Bibliography. Indrawan (2004), Indrawan, Rasmussen, & Sunarto (2008), Indrawan, Somadikarta *et al.* (2006), Rasmussen *et al.* (2000).

26. Sangihe White-eye

Zosterops nehrkorni

French: Zostérops de Sangihe **German:** Nehrornbrillenvogel **Spanish:** Antojitos de la Sangihe
Other common names: Black-fronted White-eye(!) (within *Z. atrifrons*–*Z. minor* species group)

Taxonomy. *Zosterops nehrkorni* A. W. H. Blasius, 1888, Sangihe Island.

Forms a superspecies with *Z. atriceps*, *Z. atrifrons*, *Z. somadikartai*, *Z. stalker*, *Z. minor*, *Z. meeki* and *Z. hypoxanthus*. Formerly considered conspecific with *Z. atrifrons*, but re-examination of the single type specimen (previously thought to have been lost) and recent field observations indicate clear differentiation, particularly in coloration of bill and legs, measurements and some other characters; differs also in song and in being restricted to pristine habitats at higher altitudes. Monotypic.

Distribution. Mt Sahendaruman and adjacent Mt Sahengbalira, on Sangihe I, N of Sulawesi.

Descriptive notes. 10.5–12 cm. Has black forehead and forecrown, contrasting sharply with bright golden-olive of rear crown; upperparts rich yellowish olive-green (paler than *Z. atrifrons*), brighter on lower back, rump and uppertail-coverts; white eyering rather narrow (on skins) to wide (in the field), olive side of face clearly demarcated from throat by almost blackish moustachial streak; tail feathers brownish-black, edged greenish; chin, throat and undertail-coverts bright canary-yellow, remaining underparts pearly white, flanks grey, becoming darker ventrally; iris light brown to red-brown; bill and legs relatively

pale orange-flesh. Sexes alike. Juvenile undescribed. VOICE. Song sounds thinner, more tinkling and less warbling than that of *Z. atrifrons*, and having first notes more constant in frequency and terminal section falling strongly. Contact calls described as thinner and higher-pitched than those of *Z. atrifrons*; also three high-pitched "swit...swit...swit" calls, c. 2 seconds in duration, similar to calls of some flowerpeckers (*Dicaeum*) but higher and sharper.

Habitat. Primary ridgetop (low-stature) forest and broadleaf-trophophyllous hill rainforest, with considerable density of *Pandanus*, at c. 750–920 m; absent from secondary habitats such as mixed plantations, and seems to be confined to submontane low-stature forest in S of island. Not found near lower limit of presently existing forest, where one would expect it had it ever occurred in low-elevation forest.

Food and Feeding. Insects. Forages in groups of three, in dense canopy and subcanopy; gleans leaves.

Breeding. Singing by three birds in Feb strongly suggests breeding or pre-breeding activity. No other information.

Movements. Presumed sedentary.

Status and Conservation. CRITICALLY ENDANGERED. Restricted-range species: present in Sangihe and Talaud EBA. Rare. Had been known only from a single specimen, collected in late 1886, but rediscovered during two-week survey on Mt Sahengbalira in Aug 1996, when three individuals were observed on two consecutive days. During a subsequent survey on the mountain for two weeks in Nov 1996, three birds seen only once, at same locality; during 60 days spent in same area between Aug 1998 and Feb 1999, a sight record of a single individual and aural records on three consecutive days. Numerous other observers in recent times failed to see the species. The very few records suggest that this species is now extremely rare, and may already have been so for a long time. It may be wide-ranging in search of fruits, and the small area of suitable habitat (800 ha) remaining within its present range, which is under pressure from small-scale agricultural encroachment by local farmers, may critically restrain the population. Conservation of remaining forest is critical for the survival of this species, which is the only white-eye on Sangihe I.

Bibliography. Anon. (2007n), Blasius (1888a, 1888b), Butchart & Stattersfield (2004), Collar *et al.* (2001), Finsch (1901), Mees (1961), Meyer & Wigglesworth (1898b), Rasmussen *et al.* (2000), Riley (1997, 2002), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Wardill & Hunowu (1998).

27. Seram White-eye

Zosterops stalker

French: Zostérops de Céram **German:** Sagobrillenvogel **Spanish:** Antojitos de Seram
Other common names: Black-fronted White-eye(!) (within *Z. atrifrons*–*Z. minor* species group)

Taxonomy. *Zosterops stalker* Ogilvie-Grant, 1910, Manusela, Seram.

Forms a superspecies with *Z. atriceps*, *Z. atrifrons*, *Z. somadikartai*, *Z. nehrkorni*, *Z. minor*, *Z. meeki* and *Z. hypoxanthus*. In past, often considered conspecific with *Z. atrifrons*, but differs from that species and from other members of superspecies in bill morphology, plumage and voice. Monotypic.

Distribution. Seram, in SE Moluccas.

Descriptive notes. c. 11 cm; 9–12 g. Has rather narrow white eyering interrupted at front by blackish spot; black on head extending over whole of crown and side of head (blackish ear-coverts), merging into nape; upperparts bronzy olive, with bronzy-yellow rump; flight-feathers and tail brownish-black, marginal upperwing-coverts black; chin and throat bronzy olive to pyrite-yellow, some blackish on chin, underparts whitish, with greyish-white side of breast, orange-yellow undertail-coverts; iris dark red-brown; bill black or bluish, lower mandible light grey-brown; legs pale blue-grey. Differs from other members of the superspecies

in having extensive black on crown, dull greenish plumage, bronzy overall coloration, black mar-

ginal wing-coverts, straighter and more peg-like bill; from sympatric *Z. kuehni* mainly by black (not olive-green) crown, and from *Z. montanus* also by whitish (not yellow) belly. Sexes alike. Juvenile undescribed. **VOICE.** Songs and calls include series of rapidly repeated, sweet tinkling notes terminating with a few ringing notes; also a fairly rapid series of slightly rolling short “swi” notes, quite different from anything found in other members of the superspecies.

Habitat. Secondary forest; occurs at 100–850 m, where most abundant in mid-mountain regions; overlaps with *Z. montanus* in narrow belt between 650 m and 850 m.

Food and Feeding. Small seeds found as stomach contents. Not very gregarious, sometimes in small flocks; often in mixed-species foraging flocks, frequently associating with *Tephrozosterops stalkerii*, Ashy Flowerpecker (*Dicaeum vulneratum*) and Streaky-breasted Fantail (*Rhipidura dedemi*), also other small birds. Forages in undergrowth.

Breeding. No information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Seram EBA. Little-known species; appears to be fairly common. Hitherto recorded only in W & C parts of Seram, but SE part of the island still ornithologically unexplored.

Bibliography. van Bemmelen (1948), Bowler & Taylor (1989a, 1993b), Mayr (1967), Mees (1961, 1969), Ogilvie-Grant (1910), Rasmussen *et al.* (2000), Stattersfield *et al.* (1998), Stresemann (1914a), White & Bruce (1986).

28. Black-fronted White-eye

Zosterops minor

French: Zostérops mineur **German:** Neuguineabrillenvogel **Spanish:** Antojitos Menor
Other common names: (Papuan/New Guinea) Black-fronted/(Papuan) Mountain(!) White-eye (*minor* and *gregarius*); Arfak/Arfak Black-fronted/Arfak Yellow-throated White-eye (*chrysolaemus*); Small (Black-fronted) White-eye (*delicatulus*)

Taxonomy. *Zosterops albiventer minor* A. B. Meyer, 1874, Yapen Island, New Guinea. Forms a superspecies with *Z. atriceps*, *Z. atrifrons*, *Z. somadikartai*, *Z. nehrkorni*, *Z. stalkerii*, *Z. meeki* and *Z. hypoxanthus*. Sometimes considered conspecific with *Z. atrifrons*, *Z. meeki* and *Z. hypoxanthus*. Distinctive nominate race possibly represents a separate species from other three races; review desirable. Proposed race *rothschildi* (described from Gebroeders Mts, in Weyland Range), attributed to birds from Weyland Mts in W part of species' range and Adelbert Mts in NE, better treated as hybrid or intergrade between nominate race and *chrysolaemus*; *tenuifrons* (from Wau, in Morobe District of E New Guinea) is synonymized with *chrysolaemus*; and *pallidogularis* (from Fergusson I, in D'Entrecasteaux Is) is considered indistinguishable from *delicatulus*. Four subspecies currently recognized.

Subspecies and Distribution.

Z. m. minor A. B. Meyer, 1874 – Yapen I, and N watershed of mainland New Guinea (Cyclops Mts, Weyland Mts and Nassau Mts) E to Sepik Mts and Adelbert Mts.

Z. m. chrysolaemus Salvadori, 1876 – mountains of Vogelkop (Tamrau Mts, Arfak Mts, Farfak Mts), S watershed of New Guinea, and Herzog Mts E to Hydrographer Range.

Z. m. gregarius Mayr, 1933 – NE New Guinea (Huon Peninsula).

Z. m. delicatulus Sharpe, 1882 – S slopes of mountains of SE New Guinea (E to Milne Bay), and D'Entrecasteaux Is (Goodenough I, Fergusson I).

Descriptive notes. 11 cm; 10.3–11.6 g. Nominant race has forehead, crown and ear-coverts to upperparts bright yellowish-green, upper-tail-coverts slightly more yellow; very narrow white eyering (almost lacking); chin and throat to upper breast orange-yellow, remainder of underparts greyish-white, undertail-coverts yellow; iris chestnut-brown to grey-brown; bill blackish; legs bluish-grey. Differs from *Z. novaeguinae* in generally brighter coloration, much narrower white eyering. Sexes alike. Juvenile apparently undescribed. Races differ mainly in coloration of head and prominence of eyering, nominate being brightest and almost lacking eyering, other three having black forehead and broad eyering; *chrysolaemus* has greener upperparts than nominate, and very conspicuous greenish edges on tail feathers; *gregarius* is more yellow and duller on back, with narrower eyering than previous and slightly more orangeish-yellow on throat, thus approaching nominate; *delicatulus* has whole forehead, loreal line and area under eye black, very broad white eyering, greener back than *chrysolaemus*, distinctly less orange throat (closely resembles race *sulaensis* of *Z. atrifrons*). **VOICE.** Song diagnostic, frequently heard, sweet-sounding, consists of a series (2.5–4 seconds long) of 7–12 liquid notes almost immediately reaching its highest pitch in seesawing fashion and then descends scale, notes like the sounds produced by a squeaking wheel, although details of pattern may vary geographically; some regional variation in length and speed, but quality and overall patterns remain much same, e.g. “dyudyu dyodyo dee dyo dyu”. Calls include repeated inquiring, high upslurred “tswee”, “sweei” or “zweeit”; and often repeated high-pitched, wheezy, somewhat trilled downslurred “tseew”, “chee” or “weedit”.

Habitat. Hill forest and edges and second growth, locally town gardens (Wau); between 150 m and 1460 m, but mainly above 400 m. In mainland New Guinea occurs almost exclusively on the mountains; on Yapen I, where no forested hills above 1500 m, found in mid-montane area. In parts of E New Guinea overlaps broadly in altitudinal range with ecologically very similar though more montane *Z. novaeguinae*.

Food and Feeding. Insects and fruits; latter include berries and arillate fruits, of various figs (*Ficus*), *Schefflera*, *Polyscias ledermanni*, *Elmerrillia tsiampaca*, *Xylopiu papuana*; nectar taken from *Rhus taiensis*, and sometimes from flowering *Evodia* trees. In single-species flocks, also in mixed flocks with e.g. Old World warblers (Sylviidae); sometimes found in same flock as *Z. novaeguinae*. Frequents canopy, where it forages amid foliage and visits flowering and fruiting trees. Obtains food by gleanng.

Breeding. “Breeding individuals” in Oct and Nov, and laying females in E Huon Peninsula in late Dec and early Jan. No other information.

Movements. Little known. Possibly nomadic.

Status and Conservation. Not globally threatened. Fairly common to abundant throughout most of range. Occurs in several protected areas, e.g. Varirata National Park.

Bibliography. Beehler (1980b), Beehler & Finch (1985), Beehler *et al.* (1986), Brown & Hopkins (1995, 2002), Coates (1990), Coates & Peckover (2001), David & Gosse (2002b), Diamond (1972a), Finch (1981b), Gilliard & LeCroy (1967a, 1970), Mayr (1933a), Mayr & Meyer de Schauensee (1939b), Mayr & Rand (1937), Mees (1961, 1969), Rand (1942b), Rand & Gilliard (1967), Rothschild (1931), Strange (2001).

29. White-throated White-eye

Zosterops meeki

French: Zostérops à gorge blanche **German:** Tagulabrillenvogel **Spanish:** Antojitos Goliblanco
Other common names: Tagula (Black-fronted)/Louisiade Black-fronted White-eye

Taxonomy. *Zosterops meeki* E. J. O. Hartert, 1898, Tagula Island (Sudest Island), in Louisiade Archipelago.

Forms a superspecies with *Z. atriceps*, *Z. atrifrons*, *Z. somadikartai*, *Z. nehrkorni*, *Z. stalkerii*, *Z. minor* and *Z. hypoxanthus*. Sometimes treated as conspecific with *Z. minor*, of which it may be merely a race which has lost its yellow throat. Monotypic.

Distribution. Tagula I (in Louisiade Is), off SE New Guinea.

Descriptive notes. 10.5 cm. Has forehead to middle of crown, lores, region below eyering and ear-coverts blackish, shading into olive-green on rear crown and upperparts, which shade into olive-yellow on rump; broad white eyering interrupted at front by black spot; ill-defined yellow malar stripe; chin to abdomen white, faintly tinged buffy, vent and undertail-coverts yellow; iris dark brown; bill black, slaty blue at base; legs slate-blue or slate-brown. Sexes alike. Juvenile undescribed. **VOICE.** Not recorded.

Habitat. Lowland forest and forest edge at 300 m; probably most numerous in hills.

Food and Feeding. No information.

Breeding. No information.

Movements. Not known.

Status and Conservation. Data-deficient. Restricted-range species: present in Louisiade Archipelago EBA. Virtually unknown. No modern records from Tagula (700 km²); none seen during a ten-day trek from N coast S to Mt Riu in 1992. Large-scale logging could have a devastating effect on this and other species on Tagula, but no immediate plans for logging are known.

Bibliography. Anon. (2007n), Butchart & Stattersfield (2004), Collar *et al.* (1994), Finsch (1901), Hartert (1898a), Mayr (1933a, 1967), Mees (1961, 1969), Rand & Gilliard (1967), Sibley & Monroe (1990), Stattersfield & Capper (2000), Stresemann (1931a).

30. Black-headed White-eye

Zosterops hypoxanthus

French: Zostérops des Bismarck **Spanish:** Antojitos de las Bismarck
German: Schwarzkopf-Brillenvogel

Other common names: Bismarck Black-fronted/Bismarck (Yellow-bellied) White-eye

Taxonomy. *Zosterops hypoxanthus* Salvadori, 1881, New Britain. Forms a superspecies with *Z. atriceps*, *Z. atrifrons*, *Z. somadikartai*, *Z. nehrkorni*, *Z. stalkerii*, *Z. minor* and *Z. meeki*. Sometimes considered conspecific with *Z. minor*, and has been thought to be conspecific with *Z. fuscicapilla*. Three subspecies recognized.

Subspecies and Distribution.

Z. h. admiralitatis Rothschild & E. J. O. Hartert, 1914 – Manus I (Admiralty Is), in Bismarck Archipelago.

Z. h. ultimus Mayr, 1955 – islands of New Hanover and New Ireland (Bismarcks).

Z. h. hypoxanthus Salvadori, 1881 – Umboi I, New Britain, Watom I and Mioko I (Duke of York).

Descriptive notes. 10.5–11.5 cm; 7.6–13 g. Nominant race has top and side of head, including cheek, black, white eyering of moderate width; upperparts yellowish olive-green or yellowish-olive, except for blackish-brown wingtips and tail; chin, throat and underparts bright yellow, washed olive on flanks; iris light brown to reddish-brown, occasionally grey; bill blackish, light grey lower mandible; legs light grey to slaty blue. Sexes similar. Juvenile probably less black on head. Race *ultimus* is brighter above and below than nominate, has broader eyering, and black of crown not extending so far back on to nape; *admiralitatis*

has top and side of head brown, becoming blackish on face, and duller underparts, with chin to upper breast strongly (but variably) washed dusky brown, also narrower eyering. **VOICE.** Tinkling song reminiscent of that of a bushlark (*Mirafra*), given from top of bush. Calls “zching” and piercing sibilant “sip sip”, very different from usual white-eye calls.

Habitat. Forest, forest edge, secondary forest and partly cleared and regrowth areas, gardens, plantations. Mainly in hills and mountains, above 670 m on Umboi, and generally between c. 800 m and 1450 m, locally to 1680 m, and on New Ireland to 1760 m; occasionally down to sea-level locally, in particular New Britain and Watom, and probably elsewhere.

Food and Feeding. Small food items: various seeds, tiny fruits, and insects (e.g. caterpillars). Singly, in pairs or, especially in dry season, in small parties of 4–8 individuals. Visits flowering trees in company of *Myzomela* honeyeaters; associates also with other birds, such as Island Thrush (*Turdus poliocephalus*), Island Leaf-warbler (*Phylloscopus poliocephalus*), Golden Whistler (*Pachycephala pectoralis*) and Blue-faced Parrot-finch (*Erythrura trichroa*), usually in multi-species foraging flocks. On Umboi it remains in crown of trees in flocks of 3–5 individuals.

Breeding. Nominant race breeds in most months, but mainly during early wet season (Oct–Dec) and again in latter part (Apr–May); juveniles of race *ultimus* seen in Jan–Feb. Nest a thin-walled but strongly built basin-shaped structure 55–60 mm wide and 35–42 mm high, composed mainly of leaf-sheath fibres, with spider web and hair or cotton externally, and so finely constructed that contents may be seen through it, suspended in forked branch low down in bush or bamboo. Clutch 2 or 3 eggs, pale blue, 15.7–19 × 12–14 mm. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Admiralty Islands EBA and in New Britain and New Ireland EBA. Nominant race on New Britain fairly common at 800–1450 m, uncommon above (to 1680 m), but scarce and of rather peripatetic occur-

rence in lowlands, this probably associated with paucity of food resources in mountains and the fruiting of certain (unidentified) shrubs and trees in foothills and lowland forest; on Umboi only above 670 m and to summits of all four mountains, where uncommon. Race *ultimus* is very scarce in lowlands but abundant in mountains (at 1500–1760 m) on New Ireland, where fairly common in forested areas and regrowth; regularly seen in secondary habitat on New Hanover. Race *admiralitatis* is fairly common to common in lowlands and hills on Manus.

Bibliography. Beehler (1978b), Bishop & Jones (2001), Coates (1990), David & Gosselin (2002b), Diamond (1976), Eastwood (1995a), Fletcher (2000a), Gregory (1995c), Hartert (1925), Leavesley & Leavesley (2000b), Mees (1961, 1969), Meyer (1930), Reichenow (1899).

31. Biak White-eye

Zosterops mysorensis

French: Zostérops de Biak **German:** Biakbrillenvogel **Spanish:** Antejitos de la Biak
Other common names: Soepiori/Black White-eye

Taxonomy. *Zosterops mysorensis* A. B. Meyer, 1874, Korido, on Supiori, north Geelvink Bay, New Guinea.

Relationships unclear, but possibly distantly related to *Z. atrifrons* and *Z. novaeguineae*. Monotypic.

Distribution. Supiori I and Biak I (N Geelvink Bay), in NW New Guinea.

Descriptive notes. 11.5 cm; male 15 g. Has top of head and entire upperparts olive, paler on rump; lores fuscous, white eyering greatly reduced, greyish-black loreal line continued as streak under eye; cheek and side of neck grey; flight-feathers and tail feathers brownish-black, edged olive; throat and underparts white, heavily washed grey on upper breast and flanks, undertail-coverts pale yellow; iris dull brownish; bill dark; legs pale. Sexes alike. Juvenile undescribed. **Voice.** Song is typical of the genus, based on a repeated five-note pattern. Call a medium-high, slightly downslurred “pii”, also “prtt”.

Habitat. Forest, forest edge, regrowth with tall trees, low secondary growth, also shrubs in open old wasteland along roads. From sea-level to 675 m.

Food and Feeding. Apparently mainly insectivorous, and not frugivorous. Forages in flocks of 3–12 individuals, often in small mixed-species flocks with gerygones (*Gerygone*), drongos (*Dicrurus*), fantails (*Rhipidura*) and flowerpeckers (*Dicaeum*). Observed while gleaning in dense foliage or hover-gleaning at base of palm fronds.

Breeding. No information.

Movements. Not known.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Geelvink Islands EBA. Only small numbers recorded during recent visits, and in some cases observers failed to find this species at all. On Biak forest is under heavy threat from logging and subsistence farming, but in interior of Supiori there are still large forest areas remaining. This white-eye appears to avoid heavily disturbed habitats and is more common in forested areas, but its occurrence in degraded forest and its presence within a relatively large (11,000 ha) protected area suggest that it is not yet at immediate risk.

Bibliography. Anon. (2007n), Beaufort (1909), Beehler *et al.* (1986), Bishop (1982), Butchart & Stattersfield (2004), Eastwood (1996a), Mayr & Meyer de Schauensee (1939a), Mees (1961, 1969), Rand & Gilliard (1967), Rothschild *et al.* (1932a), Stattersfield & Capper (2000), Stattersfield *et al.* (1998).

32. Capped White-eye

Zosterops fuscicapilla

French: Zostérops mitré **German:** Arfakbrillenvogel **Spanish:** Antejitos de las Arfak
Other common names: Yellow-bellied (Mountain)/Western Mountain White-eye; Crookshank's White-eye (*crookshanki*)

Taxonomy. *Zosterops fuscicapilla* Salvadori, 1876, Arfak Mountains, New Guinea.

Sometimes treated as conspecific with *Z. hypoxanthus*; indeed, nominate race is strikingly similar to latter species, and may perhaps be an older offshoot of the “*Z. atrifrons* group”. Races sometimes treated as two separate species. Two subspecies recognized.

Subspecies and Distribution.

Z. f. fuscicapilla Salvadori, 1876 – mountains of W & C New Guinea (Tamrau, Arfak, Fakfak, Wandammen Mts, Foja Mts, W Central Ranges, Cyclops Mts and N Coastal Range).

Z. f. crookshanki Mayr & Rand, 1935 – Goodenough I (d'Entrecasteaux Is).

Descriptive notes. 9.5–11 cm; 10.8 g. Male nominate race has forehead, lores and a streak under eyering black, black extending over anterior part of crown and merging with green nape; eyering white, rather narrow, broken at front by black spot; upperparts dark yellowish olive-green, rump yellowish; wingtips and tail dusky brownish; throat and underparts yellowish olive green, becoming almost pure lemon-yellow on centre of belly and undertail-coverts; iris reddish-brown to dark brown; bill dark grey to blackish, basal half of lower mandible light grey; legs grey. Female is like

male, but on average duller, less yellowish. Juvenile has orange bill, lacks dark on face, has paler yellow flanks. Race *crookshanki* differs strikingly from nominate in having olive head like back, with black confined to a spot on lores, wider eyering, less yellow-toned underparts, and very greenish undertail-coverts. **Voice.** Flock call a wheezy, whistled “tyew” note, repeated, drier than calls of other mainland New Guinea white-eyes; also a rolling series of “chip” notes, suggestive of call of House Sparrow (*Passer domesticus*).

Habitat. Montane forest, second growth, isolated shrubs in mid-mountain grasslands (e.g.

in highly cultivated Baliem Valley), abandoned cultivation and bushes in native gardens. Mainly between 1200 m and 1850 m, but to at least 2500 m in W and 2600 m in E, and as low as 750 m in C parts of N Coastal Range. Marginal altitudinal overlap with ecological counterpart *Z. atrifrons*, which replaces present species at lower altitudes.

Food and Feeding. Fruit and insects. Gregarious. Moves about among twigs and branches in canopy and middle storey in relatively compact, quickly moving noisy flocks of up to several dozen individuals, or in mixed-species flocks with e.g. Mountain Gerygone (*Gerygone cinerea*) and Tit Berrypecker (*Oreocharis arfaki*). Sometimes in treetop flocks of considerable size. Occasionally in pairs.

Breeding. Dec. Nest a basin-shaped, slightly oval structure composed mainly of dried stems of plants, lightly woven, and partly covered externally with green moss together with pieces of soft greenish-gold down-like substance (arthropod silk), internal dimensions 30 × 40 × 50 mm; one nest was suspended from thin horizontal stems of bamboo leaves in clump of garden bamboo. Nest containing single nestling found. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Common to scarce. Locally one of the most common bird species, together with Mountain Leaf-warbler (*Phylloscopus trivirgatus*), at c. 1500 m in Weyland Mts.

Bibliography. van Balen & Rombang (1998), Coates (1990), Coates & Peckover (2001), Coles (1995), David & Gosselin (2002a, 2002b), Diamond (1985), Hadden (1975), Mayr & Meyer de Schauensee (1939b), Mayr & Rand (1935), Mees (1961, 1969), Rand (1942b), Rand & Gilliard (1967), Stein (1936), Strange (2001), Weston (1976c).

33. Buru Yellow White-eye

Zosterops buruensis

French: Zostérops de Buru **German:** Burubrillenvogel **Spanish:** Antejitos de Buru
Other common names: Buru (Island) White-eye

Taxonomy. *Zosterops buruensis* Salvadori, 1878, Buru Island.

Relationships uncertain. Monotypic.

Distribution. Buru I, in S Moluccas.

Descriptive notes. 11.5–12 cm; 11–13 g. Has white eyering interrupted at front by black loreal line, latter continuing under eye-ring as narrow dusky line; top of head and upperparts generally dusky olive, slightly more yellowish on rump, and limited area of yellowish on forehead and over lores; remiges and rectrices blackish-brown, more or less narrowly edged greenish; throat and underparts entirely yellow, darker on sides; iris black or brown; bill black, sometimes light grey base; legs black or grey. Distinguished from sympatric *Z. montanus* by yellow belly, different mantle colour, and dark eyes. Sexes alike. Juvenile

undescribed. **Voice.** Quiet, quickly repeated “tsu-tsu-tsu-tsu” during foraging, and “chewit, chewit, chewit”; no other information.

Habitat. Primary forest, second growth, scrub, selectively logged forest, and farmland, from sea-level to 1750 m; well distributed in lower and middle montane zone to 1500 m. Replaced at higher elevations by *Z. montanus*.

Food and Feeding. No details of diet. Moves around in dense canopy and subcanopy in mixed flocks with Old World flycatchers (Muscicapidae).

Breeding. No information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Buru EBA. Moderately common to very common in primary and secondary forest, but less so in logged forest; probably at much lower density in non-forest area. Population estimated at 598,000–1,459,000 individuals in 1989.

Bibliography. van Bemmel (1948), Coates & Bishop (1997), Hartert (1900b), Inskipp *et al.* (1996), Jepson (1993a), Marsden *et al.* (1997), Mees (1961, 1969), Poulsen & Lambert (2000), Salvadori (1878), Stattersfield *et al.* (1998), Stresemann (1914b), White & Bruce (1986).

34. Ambon Yellow White-eye

Zosterops kuehni

French: Zostérops d'Amboine **German:** Ambonbrillenvogel **Spanish:** Antojitos de Ambon
Other common names: Ambon/Amboina/Kühn's White-eye

Taxonomy. *Zosterops kuehni* E. J. O. Hartert, 1906, Ambon.

Relationships uncertain; has been thought to be closest to *Z. novaeguineae*, and dusky feather centres on forecrown and white-greyish abdomen may indicate relationship to *Z. atrifrons*. Has been suggested to be related to *Z. stalkerii*, although both species may occur on Seram. Monotypic.

Distribution. Ambon, and also recorded once on N Seram (Wahai), in S Moluccas.

Descriptive notes. 12 cm. Has top of head and upperparts olive-green, forecrown more dusky, lores and distinct streak under eye dull black; white eyering broken at front by blackish lore line; flight-feathers and tail feathers blackish-brown, broadly margined with olive-green; chin, throat and undertail-coverts yellow, remainder of underparts greyish-white; iris brown; bill black above, greyish below; legs grey. Sexes alike. Juvenile undescribed. Voice. Song a musical warble; calls include sibilant single "teeu" note.

Habitat. Lowland forest, remnant patches of secondary forest and woodland, and lightly

wooded cultivation, scrub, and gardens; sea-level to 500 m.

Food and Feeding. No details of diet. Usually in pairs and in small groups of three or four individuals. Fairly active, and movement rather deliberate. Forages mainly at inconspicuous flowers in crown of *Albizia* and acacia (*Acacia*) trees.

Breeding. No information.

Movements. Not known.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Seram EBA. Moderately common on Ambon. On Seram known only from a single specimen from Wahai, on N coast, in 1862; was not located on the island during searches in 1987 and 1990. Wooded habitats are diminishing on the densely populated and relatively small island of Ambon; this species could soon be at risk there.

Bibliography. Anon. (2007n), van Bemmel (1948), Bowler & Taylor (1993b), Butchart & Stattersfield (2004), Coates & Bishop (1997), Collar *et al.* (2001), Inskipp *et al.* (1996), Mees (1961, 1969), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), Stresemann (1931a), White & Bruce (1986).

35. New Guinea White-eye

Zosterops novaeguineae

French: Zostérops de Nouvelle-Guinée **German:** Papuabrillenvogel **Spanish:** Antojitos Papú
Other common names: (New Guinea) Mountain White-eye

Taxonomy. *Zosterops novaeguineae* Salvadori, 1878, Arfak Mountains, New Guinea.

Possibly related to *Z. kuehni*; formerly suggested affinity to either *Z. montanus* or *Z. lateralis* not supported by morphological or ecological characters. Lowland races (*aruensis*, *wuroi* and *magnirostris*) smaller than montane ones (nominate, *wahgiensis*, *oreophilus*, *crissalis*), but the two groups have no phylogenetic significance. Birds of this species in Kumawa Mts are of uncertain racial identity, provisionally placed in nominate. Seven subspecies recognized.

Subspecies and Distribution.

Z. n. novaeguineae Salvadori, 1878 – Arfak Mts and (race dubious) Kumawa Mts, in NW New Guinea.

Z. n. aruensis Mees, 1953 – Aru Is.

Z. n. wuroi Mayr & Rand, 1935 – Trans-Fly region from R Bensbach E to Fly R mouth, in lowland S New Guinea.

Z. n. magnirostris Mees, 1955 – Awar, opposite Manam I, perhaps also lower parts of Adelbert Range, in NE New Guinea.

Z. n. oreophilus Mayr, 1931 – Saruwaged Mts (Huon Peninsula), in NE New Guinea.

Z. n. wahgiensis Mayr & Gilliard, 1951 – Wahgi valley E to Okapa area, and surrounding mountains, Mt Wilhelm and Mt Orata (Eastern Highlands Province), in E New Guinea.

Z. n. crissalis Sharpe, 1884 – mountains of SE New Guinea.

Descriptive notes. 11 cm; 11–13.5 g. Nominate race has rather narrow white eyering, dark grey lores; top of head and upperparts dark yellowish olive-green; remiges and rectrices blackish-brown, broadly bordered with olive-green; chin, throat, upper breast and undertail-coverts not very bright sulphur-yellow, rest of underparts satin-white, more greyish on flanks and breast; iris blackish to grey-brown; bill black; legs grey, brown or blackish. Distinguished from *Z. minor* locally either by lack of black on forecrown, or by less bright throat. Sexes similar. Juvenile is similar to adult, but eyering smaller. Races differ mainly in size,

plumage tones and width of eyering: *aruensis* is small, with rather wide eyering, deeper dark yellow throat; *wuroi* is small, greener above than other races, lore line blackish-grey, wide eyering, rather pale yellow throat; *wahgiensis* is similar to nominate but larger, slightly greener above, throat rather bright yellow, sometimes has slight yellow longitudinal streak below; *oreophilus* is similar to previous, but some yellow on forehead and above lores, and has lower half of eyering white and upper half grey; *crissalis* is more yellowish, less dark green, on upperparts, with forehead and

supraloral region distinctly yellow; *magnirostris* is small, with large bill, rather pale yellow, more greenish throat, has yellowish median streak down to belly. Voice. Song in Arfak Mts (nominate race) of several notes varying in pitch, followed by high-pitched note and sweet trill on lower pitch; in Kumawa Mts (presumed also nominate race) loud, bright, fast and medium-high in pitch, consisting of up to c. 12 notes, the first 2–6 at several varying pitches, last 6 notes all on same lower pitch; in E of range a protracted series of sweet-sounding whistles and upslurs, not unlike that of Pied Bushchat (*Saxicola caprata*). Calls include sweet descending "tsyew", often by many members of a flock; also a short, dry upslurred trilled note and sharp hard "zeez".

Habitat. Rainforest, monsoon forest (Trans-Fly only) and edge, bushes of secondary growth, patches of secondary growth on grassland areas, disturbed areas, gardens, and groves of casuarinas (*Casuarina*). Mostly in hills and lower mountains, between 650 m and 2600 m (mainly 1250–2400 m); in S (*wuroi*) and N (*magnirostris*) locally at sea-level, and occurs at low elevations also on Aru Is (*aruensis*). At lower elevations locally replaced by *Z. atrifrons*, at higher elevations locally (W New Guinea) by *Z. fuscicapilla*.

Food and Feeding. Stomach contents included spiders (Araneae), insects, fruits and seeds. Occurs in small to large parties of up to 50 or more individuals; occasionally associates with flocks of *Z. atrifrons*. Forages in crown to middle levels, occasionally descends to understorey of forest, where seen to feed on fruits of small trees; gleans through foliage in search of small insects. Visits fig trees (*Ficus*) and flowering trees of *Rhus taitensis*.

Breeding. Recorded in Aug, Sept, Dec–Jan and Apr. Nest a basin-shaped cup, externally c. 7 cm wide and 3.7–4.5 cm high, internally c. 5 cm wide and 3–3.8 cm deep, composed of fine light brown fibres, thinly woven, with complete thin outer layer of green moss among which are a few small feathers and some spider webs, slung by rim from forked twig. Clutch 2 eggs, very pale blue, 16.3–17.3 × 11.4–13 mm. No other information.

Movements. Probably nomadic, and absent from some breeding areas during parts of year. Commonly in flocks in Dec–Feb.

Status and Conservation. Not globally threatened. Locally common to very common.

Bibliography. Beechler *et al.* (1986), Coates (1990), Coates & Peckover (2001), David & Gosse (2002b), Diamond (1972a, 1985), Finch (1981b), Gyldestolpe (1955a), Harrison & Frith (1970), Mack & Wright (1996), Mayr (1931c), Mayr & Gilliard (1954), Mayr & Rand (1935, 1937), Mees (1955, 1961, 1969), Pratt (1982), Strange (2001).

36. Yellow-throated White-eye

Zosterops metcalfei

French: Zostérops à gorge jaune **Spanish:** Antojitos Goliamarillo

German: Goldkehl-Brillenvogel

Other common names: Solomon Yellow-throated/Bukida/Metcalfe's White-eye

Taxonomy. *Zosterops metcalfei* Tristram, 1894, Santa Isabel, Solomon Islands.

Affinities unclear. Geographic variation is not very pronounced and mainly exists in presence or absence of eye-ringing. Three subspecies recognized.

Subspecies and Distribution.

Z. m. exiguus Murphy, 1929 – Buka, Bougainville, Shortland Is and Choiseul, in N Solomon Is.

Z. m. metcalfei Tristram, 1894 – Santa Isabel and San Jorge, in NC Solomons.

Z. m. floridanus Rothschild & E. J. O. Hartert, 1901 – Florida Is, in EC Solomons.

Descriptive notes. 11–11.5 cm; male 13.6 g, female 13.8 g. Nominate race has dusky lores, narrow white eyering broken before and behind eye (not easily seen in field, and may be absent altogether); top and side of head and upperparts, including upperwing-coverts, bright yellowish olive-green, remiges and rectrices blackish-brown, edged olive-green; throat and upper breast bright yellow, undertail-coverts paler yellow, lower breast and abdomen greyish-white; iris pale brown to medium red-brown; bill greyish-black or dark brown, paler horn-coloured base of mandible; legs grey. Sexes alike. Juvenile resembles adult.

Races differ minimally: *exiguus* is close to nominate, but has paler lower mandible, paler yellow throat and upper breast; *floridanus* has no white eyering but bare eyelid, and is slightly lighter and more yellowish above, especially on head. Voice. Song fairly strong and loud, a pleasant but nondescript mix of 6–9 variably pitched notes. Call fairly loud sibilant, high-pitched "tew tew" or "peep peep", uttered frequently by flock-members; also harsh trill of 4 or 5 notes and a "chirrup".

Habitat. Primary forest, forest edge, secondary growth, gardens and open areas with trees; often present in trees in Panguna town (Bougainville). From sea coast to hills, mainly to c. 900 m, occasionally to 1200 m. Replaced at higher elevations by *Z. rendovae*, but often mixes with that species where their ranges overlap.

Food and Feeding. Fruits (e.g. *Trema* spp.), grubs and insects. Usually in pairs and in parties of 3–5 birds, occasionally in flocks numbering 20–30 individuals; sometimes in company of flowerpeckers (*Dicaeum*). In river-edge vegetation and forest interior, is dominant member in most mixed-species foraging flocks, but not restricted to them. Moves quickly through canopy to middle levels of forest, but descends to c. 3 m above ground in secondary growth and at forest edge.

Breeding. Recorded Apr–Jun, also nestlings Nov–Jan and Apr and birds with enlarged gonads in Sept in N of range (race *exiguus*); eggs in Sept and Oct in C (nominate). Nest a neatly woven but thin bowl of grasses (looking almost white when made from very pale fibres), slung by rim from small twigs up to 10 m above ground in thin leafy tree or similar. Clutch 2 eggs, pale blue (*exiguus*). No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Common to abundant through most of small range.

37. Christmas White-eye

Zosterops natalis

French: Zostérops de Christmas

German: Weißstirn-Brillenvogel

Spanish: Antejitos de la Christmas

Other common names: Christmas Island White-eye

Taxonomy. *Zosterops natalis* Lister, 1889, Christmas Island.Distinct species with no known close relatives; in appearance most resembles *Z. griseovirescens* of Gulf of Guinea (W Africa), Monotypic.**Distribution.** Christmas I (Indian Ocean); introduced on Horsburgh I, in S Cocos Is.**Descriptive notes.** 11.7–13.5 cm; male 10.8 g, female 11.5 g. Has forehead and supraloral stripe whitish to yellowish, wide black on lores continuing to half-way under white eyering, latter of average width. ear-coverts pure grey; crown and upperparts dull greenish; flight-feathers and tail feathers dull brownish with dull greenish outer edges; greyish-white below, rarely a trace of pale yellow on throat and belly, flanks with pale buff tinge, undertail-coverts pale yellow; iris deep chestnut-brown; bill black or dark brown, base of lower mandible pale blue; legs greenish-grey to blue-grey. Sexes alike. Juvenile apparently very like adult, but has grey eyes.**VOICE.** Series of loud notes believed to be song, described as “yerr yerr weet yerr yerr weet...”. Variety of calls, include twittering and chirping reminiscent of sparrow (*Passer*); high thin, but not drawn-out “ts-ee- seet...tsee-eet...” (function not known), “tsirr...tsirr...” as alarm and agitation call, and high “cheeuw...cheeuw...cheeuw...” for scolding at Australasian Goshawk (*Accipiter fasciatus*).**Habitat.** Found in all tree and shrub habitat types on the island; perhaps most often in open country and near forest edge.**Food and Feeding.** Fruits, seeds and nectar, some insects. Fruits include ripe bananas (*Musa*), mangoes (*Mangifera*), sour-sops (*Annona muricata*), custard-apples (*Annona squamosa*) and particularly papayas (*Carica papaya*), also wild *Passiflora* species and berries of *Callicarpa albidia*; nectar from *Stachytarpheta* taken. Boiled rice also accepted. Gregarious, in small flocks. Forages from canopy down to lower levels, on branches and among foliage; sometimes descends to ground. Clings to tree trunks. Gleans items from substrate; sallies after aerial insects.**Breeding.** Breeds in almost all months, peak from beginning Sept to end Jan or slightly later. Nest a neat and compact cup 5–5 cm wide and 2–2.5 cm deep, outer portion woven from dried grass and other fibres, rarely *Arenga*, sometimes few feathers or even dried leaves, carefully lined with fine fibres of sago palm (*Arenga listeri*), usually firmly attached in fork of very thin branch 1.5–4.5 m up in medium-sized bush, occasionally higher in tree. Clutch 2 eggs, less frequently 3 and once 4, pale watery blue, 17.8 × 12.4 mm; incubation period 15–16 days; fledging period 17 days at least; young fed by parents for at least a week after leaving nest.**Movements.** Sedentary.**Status and Conservation.** VULNERABLE. Restricted-range species; present in Christmas Island EBA. Formerly considered Near-threatened, or even not threatened, but conservation category recently upgraded because of loss of a third of forested habitat through mining activities (these ended in 1987, but could be resumed), threat of further forest clearance for satellite launch pads and for refugee transit stations, and species' tiny global range of just 135 km². Ecology of Christmas I also under modification by activities of introduced yellow crazy ant (*Anoplolepis gracilipes*), which formed massive “supercolonies” during 1990s and spread rapidly to cover c. 25% of island (since 2000 spread of ants under permanent human control); ants had direct impact on mortality of nestlings, as well as indirect impact through their farming of scale insects (Coccoidea), a practice which damages the native trees. This white-eye is nevertheless still abundant, and the commonest bird species on Christmas I; seems to tolerate some habitat modification, although only few are found around settlements. In 1961 population estimated at several thousands to tens of thousands of individuals; most recent (2005) estimate for Christmas I is 20,000 individuals. Christmas Island National Park was established in 1980; the setting-up of a captive population has been proposed. Introduced between 1885 and 1900 on Horsburgh I, in Cocos (Keeling) Is, where it still survives. Very common on Horsburgh in 1941, when 400 individuals present, but has not spread to any of the other islands in the Cocos group; it remained abundant on Horsburgh only in remnants of the original forest vegetation along shoreline of lagoon.**Bibliography.** Andrews (1900), Anon. (2007n), Butchart & Stattersfield (2004), Carter (1994), Chasen (1933), Collar *et al.* (1994), Garnett & Crowley (2000), Gibson-Hill (1947, 1950b), Higgins *et al.* (2006b), Lansley (1997), Lever (1987), Mees (1957, 1969), Schodde & Mason (1999), Stattersfield & Capper (2000), Stokes *et al.* (1984).

38. Australian Yellow White-eye

Zosterops luteus

French: Zostérops à ventre jaune

German: Mangrovebrillenvogel

Spanish: Antejitos Australiano

Other common names: Mangrove/Yellow/Golden White-eye, (Yellow) Silvereye(1)

Taxonomy. *Zosterops luteus* Gould, 1843, Greenhill Island, Van Diemen Gulf, Northern Territory, Australia.Formerly considered conspecific with *Z. flavus*, *Z. chloris* and *Z. citrinella*. Geographical variation in plumage and size clinal across entire range, this further complicated by local variation in colour; races intergrade considerably and their validity perhaps doubtful, but genetic data suggest a split between W & E populations. Two subspecies recognized.**Subspecies and Distribution.***Z. l. balstoni* Ogilvie-Grant, 1909 – coastal NW Australia from Shark Bay (including Dirk Hartog I) E to Wotjulum (King Sound) and N Kimberley District.*Z. l. luteus* Gould, 1843 – coastal N Australia from N Kimberley District E, including coastal islands of Melville, Bickerton, Groote Eylandt and Sir Edward Pellew Group, to W Cape York Peninsula (Edward R); isolated population in E Queensland (region of Ayr–mouth of Burdekin R).**Descriptive notes.** 9.5–11 cm; 8.4–11.3 g. Nominate race has forehead and supraloral region yellow, white eyering interrupted at front by blackish lore stripe, latter continuing to half-way under eyering; crown and upperparts yellow-olive; remiges and rectrices blackish-brown, edged yellowish-olive; all bright yellow below, brightest on throat, paler elsewhere, and with greenish-grey wash on flanks; iris brown to chestnut-brown; bill grey or black to dark brown, blue-grey base of lower mandible; legs(Eucalyptus), paperbark (*Melaleuca*) woodland, monsoon thickets, vegetation on coastal rivers; also trees and gardens in coastal towns. On mangroveless islands off NE Arnhem Land (Northern Territory) common in heaths and open woodland. Extends some distance inland along rivers.**Food and Feeding.** Insects including larvae, most importantly Diptera (mosquitoes and midges), small beetles (Coleoptera), bugs (Hemiptera), Lepidoptera, also wasps (Hymenoptera), ants (Formicidae), Orthoptera; also molluscs, spiders (Araneae) and once a pseudoscorpion (Pseudoscorpiones); prey items mostly 2–12 mm long. Also seen to eat seeds and pulp from *Passiflora foetida* growing in mangrove edge; presumed to take nectar as seen to probe flowers of most mangrove species, as well as *Melaleuca cajuputi*. Probably mainly insectivorous, as fruits rare in mangroves and nectar seasonal. Moves about in parties of 7–8 individuals, sometimes up to 40 birds, in mangroves and thickets; occasionally in mixed flocks with *Z. lateralis*, but otherwise separated by habitat. Searches for insects in foliage of mangrove trees; gleans arthropods from leaves and twigs, and probes flowers.**Breeding.** Mainly Oct–Mar; no obvious seasonality and throughout year (except Nov) in Darwin region, with possible peak in late dry season (Sept–Oct). Nest a deep cup of soft grass, lined with fine rootlets, with cobweb and pieces of bark on outside, suspended from horizontal fork usually in top third of mangrove tree overhanging water, mostly below 3–8 m, rarely up to 6 m in acacia. Clutch 2–3 eggs, sometimes 4, pale bluish-green or white, 14.7 × 10.3 mm; incubation period 9–12 days; nestling period 10–11 days.**Movements.** Seemingly nomadic locally outside breeding season, when wanders inland (never farther than several km from coast) and mobile flocks of considerable size spread over scrubby coast and sandhill areas. Daily routine movements between roosts (in mangroves) and daytime foraging sites (in acacia scrub) described.**Status and Conservation.** Not globally threatened. Common locally; dependent on mangroves. One of the four most abundant species in mangroves of Darwin area (Northern Territory), with densities of 5 birds/ha.**Bibliography.** Barrett *et al.* (2003), Blakers *et al.* (1984), Carter (1910), Crawford (1972), David & Gosselin (2002b), Franklin & Noske (2000a), Garnett *et al.* (2004), Harrison (1968a), Higgins *et al.* (2006b), Hill (1911), Johnstone (1990), Lane (1986), Lavery & Grimes (1974), Le Souëf (1903), Macgillivray (1914), Mathews (1914), McCarthy (2006), Mees (1961, 1969), Noske (1996, 1999), Pizzey & Knight (1997), Schodde & Mason (1999), Serventy & Whittell (1962), Thomson (1935).

39. Louisiade White-eye

Zosterops griseotinctus

French: Zostérops des Louisiade

Spanish: Antejitos de las Luisiade

German: Louisiadenbrillenvogel

Other common names: Louisiade/Dull-colored White-eye; Nissan White-eye (*eichhorni*); Islet/Island White-eye (with *rennellianus*)**Taxonomy.** *Zosterops griseotincta* G. R. Gray, 1858, Duchateau Island, Louisiade Archipelago. Forms a superspecies with *Z. rennellianus*, *Z. vellaivelva*, *Z. splendidus*, *Z. luteostrictis* and *Z. kulambangrae*, possibly with *Z. murphyi* a member of same group. Sometimes considered conspecific with *Z. rennellianus*. Proposed race *ottomeyeri* (described from Nauna I, in Admiralty Is) is merged with *eichhorni*, and *aignani* (Misima, in Louisiade Archipelago) is synonymized with nominate. Four subspecies recognized.**Subspecies and Distribution.***Z. g. eichhorni* E. J. O. Hartert, 1926 – Nauna (E Admiralty Is); Nissan (Green Is), E of Bismarcks; and islands of Vitiaz Strait (Crown, Long, Tolokiwa), between New Britain and New Guinea.*Z. g. longirostris* E. P. Ramsay, 1879 – Rogaia I (Heath I), in Milne Bay (off extreme SE tip of New Guinea); Bonvouloir Group (East I and Hastings I), in W Louisiade Archipelago; and Alcester I (between Woodlark I and Louisiades).*Z. g. griseotinctus* G. R. Gray, 1858 – WC & C Louisiade Archipelago in Conflict Group (Panasesa Is), Kimuta, Deboyne Group (Panepompong Is), Renard Is and Misima.*Z. g. pallidipes* De Vis, 1890 – Rossel, in E Louisiade Archipelago.**Descriptive notes.** 11–12.5 cm; 14 g. Nominant race has well-developed white eyering interrupted at front by darker spot, dusky lore line continuing as streak to half-way under eye; top of head and upperparts yellowish olive-green; remiges and rectrices blackish-brown, margined olive-green; greenish-yellow below, throat and middle of abdomen purer yellow, more olive on flanks; iris light grey; bill proportionately large and heavy, light brown; legs greenish-slate. Sexes similar. Juvenile undescribed. Race *longirostris* is similar to nominate race, with slightly longer bill; *pallidipes* is fairly distinctive, with dirty yellow to yellowish-horn or greyish legs, and has somewhat longer bill, darker lores and more greyish underparts than nominate; *eichhorni* is slightly brighter above, plumage harder and stronger and slightly more yellow below, with bill dull straw-yellow, feet yellowish-brown or yellowish-slate. **VOICE.** Following details refer to race *eichhorni*. Song a somewhat monotonous, fairly rapid series of quite high-pitched loud notes, variable and reminiscent of Pied Bushchat (*Saxicola caprata*), with typical flourish at end of each phrase, continuing with few pauses especially during dawn chorus. Call “chew”, typical of genus; loud musical “chip-chip-chip...” in flight.**Habitat.** Forest edge, secondary growth and probably forest.**Food and Feeding.** Mainly fruits, especially figs (*Ficus*), ripe papaya (*Carica*) and berries; also insects, nectar and some seeds. Gleans insects from foliage.

Breeding. Recorded in Aug in N of range (race *eichhorni*). Cup-shaped nest loosely made from rootlets, fibres, fine grasses, sometimes moss or wool (plant down), lined with even finer grasses, sparsely covered on outside with small pieces of wood, bark or insect cocoons, suspended by rim usually in fork of twig, c. 3 m above ground. Clutch 2 eggs, very pale blue, unmarked, size 17.3–19.6 × 13–14 mm (nominat race), 18–20 × 14–14.6 mm (*eichhorni*). No other information.

Movements. Resident; at least some races, such as *eichhorni*, are highly vagile.

Status and Conservation. Not globally threatened. Restricted-range species: present in New Britain and New Ireland EBA and in Louisiade Archipelago EBA. Very abundant on Nissan I, where probably most common bird species; abundant in all habitats in 1999 on Long I. Apparently common on Rossel I at end of nineteenth century, and possibly still common.

Bibliography. Beehler *et al.* (1986), Coates (1990), David & Gosselin (2002b), Diamond (1975b, 1998), Doughty *et al.* (1999), Hadden (2004), Harding (1982), Hartert (1899a, 1899b), LeCroy & Peckover (1998), Mayr (1945b), Mayr & Diamond (2001), Mees (1961, 1969), Rand & Gilliard (1967), Schipper *et al.* (2001).

40. Rennell White-eye

Zosterops rennellianus

French: Zostérops de Rennell **German:** Rennellbrillenvogel **Spanish:** Antojitos de la Renell

Taxonomy. *Zosterops rennelliana* Murphy, 1929, Rennell, Solomon Islands.

Forms a superspecies with *Z. griseotinctus*, *Z. vellaavella*, *Z. splendidus*, *Z. luteirostris* and *Z. kulambangrae*, possibly with *Z. murphyi* also a member of same group. Sometimes considered conspecific with *Z. griseotinctus*. Monotypic.

Distribution. Rennell, in SE Solomon Is.

Descriptive notes. c. 12 cm; 12–17 g. Plumage is olive-green above, with little or no yellow on forehead and above lores; lores greenish dusky, eyering no more than a narrow area of bluish or grey bare skin; yellowish-green below, brightest on throat; iris reddish-brown or brown; bill bright orange; legs pale orange. Sexes alike. Juvenile undescribed. **VOICE.** Song and call different from those of congeners, approaching voice of *Woodfordia superciliosa*. Song unusually fast for this genus, a quiet, rather strong high-pitched tinkling warble of 7–11 seconds, within pitch span of a few notes, reminiscent of that of Blackcap (*Sylvia atricapilla*), repeated at intervals of 4–30 seconds, interspersed with occasional characteristic “tjnk-tjnk-tjnk”. Chattering series of weak contact notes “chu, chu, chu...”; springy “zhe-hee-hee”.

Habitat. Forest, especially forest edge; less common in regrowth and scrub.

Food and Feeding. Insects, e.g. locusts (Orthoptera), also spiders (Araneae), small seeds, and variety of fruits smaller than 0.8 cm (including *Pipturus argenteus* and *Macaranga tanarius*). Arthropods may form larger part of the diet than does fruit. Usually forages quietly in pairs and small flocks, often on edge of mixed-species flocks. Forages mainly in lower and middle storeys. Often creeps along trunks and branches, and hops up vines. Techniques include hover-gleaning, hanging upside-down and gleaning at dead leaves and twigs; much feeding from bark, climbing trunks in manner of nuthatch (*Sitta*).

Breeding. Few data. Cup-shaped nest 2.5–5 cm in diameter, built from dead leaves and moss woven together, much live green moss on outside, lined with fine grass or dry fibres (similar to that of *Woodfordia* but only two-third the size), suspended 1 m above ground from horizontal fork. Clutch 2 eggs. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Rennell and Bellona EBA. Common and widespread within range. The only white-eye on Rennell, where it is one of the less common passerines; absent from islets in L Tegano.

Bibliography. Bradley & Wolff (1958), David & Gosselin (2002b), Diamond (1991), Doughty *et al.* (1999), Gibbs (1996a), Mayr (1967), Mayr & Diamond (2001), Mees (1961, 1969), Murphy (1929), Sibley & Monroe (1990), Wolff (1976).

41. Banded White-eye

Zosterops vellaavella

French: Zostérops de Vella Lavella **Spanish:** Antojitos de la Vella Lavella
German: Bänderbrillenvogel

Other common names: Vellaavella White-eye

Taxonomy. *Zosterops vellaavella* E. J. O. Hartert, 1908, Vella Lavella, Solomon Islands.

Forms a superspecies with *Z. griseotinctus*, *Z. rennellianus*, *Z. splendidus*, *Z. luteirostris* and *Z. kulambangrae*, possibly with *Z. murphyi* also a member of same group. Monotypic.

Distribution. New Georgia Is (Vella Lavella and Mbava), in C Solomon Is.

Descriptive notes. 11.5 cm. Plumage is yellowish-olive above, white eyering broken at front by dusky spot, dusky loreal line continuing under eye; remiges and rectrices blackish-brown, broadly edged yellowish-olive; almost light orange-yellow chin and throat separated from greyish-white lower breast and belly by olive breastband; undertail-coverts yellow; iris reddish-brown; bill bright yellow; legs yellow. Sexes alike. Juvenile has horn-brownish bill and grey legs. **VOICE.** Song, given strongly in early morning, slow series of c. 10 downslurred notes with irregular silent breaks. Strong “tse” contact call; also a springy “tse-tse-se-se” call.

Habitat. Primary forest, secondary growth, scrub, and forest edge, including coconut plantations with some undergrowth and scattered old trees.

Food and Feeding. No information.

Breeding. Nestling in Nov, and laying presumably in Oct. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Solomon Group EBA. The only white-eye on the two islands

of its range, where presently common. Likely to be at risk because of the extensive logging on Vella Lavella; majority of this island has already been or is scheduled to be logged, and this may lead to a major decline in numbers of this species. No information from Mbava.

Bibliography. Anon. (2007n), Butchart & Stattersfield (2004), David & Gosselin (2002b), Doughty *et al.* (1999), Dutson (2007b), Gibbs (1996b), Hartert (1908), Mayr (1945b, 1967), Mayr & Diamond (2001), Mees (1961, 1969), Murphy (1929), Sibley & Monroe (1990), Stattersfield & Capper (2000), Stresemann (1931a).

42. Ranongga White-eye

Zosterops splendidus

French: Zostérops de Ganongga **Spanish:** Antojitos Espléndido
German: Ranonggabrillevogel

Other common names: Ganongga White-eye

Taxonomy. *Zosterops splendida* E. J. O. Hartert, 1929, Ranonga, Solomon Islands.

Forms a superspecies with *Z. griseotinctus*, *Z. rennellianus*, *Z. vellaavella*, *Z. luteirostris* and *Z. kulambangrae*, possibly with *Z. murphyi* also a member of same group. Most closely related to *Z. luteirostris*; sometimes treated as conspecific, but differs in plumage and morphology. Monotypic.

Distribution. Ranongga, in WC Solomon Is.

Descriptive notes. 11.5–12 cm. Has fairly wide white eyering interrupted at front by big blackish spot; forehead, forecrown, lores and area under eyering black, merging posteriorly into yellowish-olive of rear crown and upperparts; flight-feathers and tail feathers blackish-brown, margined yellowish-olive; golden-yellow below; merging on side of breast into olive of upperparts; iris reddish-brown; bill black; legs yellow. Differs from *Z. luteirostris* in having relatively longer tail, black (instead of yellow) bill, more black on crown and brighter coloration. Sexes alike. Juvenile undescribed. **VOICE.** Sings often, especially at dawn, a short simple but unpredictable series of c. 9 staccato down- and/or upslurred notes. Contact call “cheu”, slightly louder and more disyllabic than that of other white-eyes.

Habitat. Primary forest, scrub, gardens, secondary forest.

Food and Feeding. No information.

Breeding. No information.

Movements. Not known.

Status and Conservation. **VULNERABLE.** Restricted-range species: present in Solomon Group EBA. Small and declining population confined to a single island, where it is the only white-eye present. True population size perhaps underestimated; this species considered common by some ornithologists, and may be better reclassified as Near-threatened. On the other hand, if it is found to have a severely fragmented range, and if current local demand for timber persists, its conservation status may have to be upgraded in future to that of Endangered.

Bibliography. Anon. (2007n), Butchart & Stattersfield (2004), David & Gosselin (2002b), Diamond (1998), Doughty *et al.* (1999), Dutson (2007b), Gibbs (1996a, 1996b), Mayr (1945b, 1967), Mayr & Diamond (2001), Mees (1961, 1969), Murphy (1929), Stattersfield & Capper (2000), Stresemann (1931a).

43. Splendid White-eye

Zosterops luteirostris

French: Zostérops de Gizo **German:** Gizobrillenvogel **Spanish:** Antojitos de la Gizo

Other common names: Gizo/Hartert's White-eye

Taxonomy. *Zosterops luteirostris* E. J. O. Hartert, 1904, Gizo, Solomon Islands.

Forms a superspecies with *Z. griseotinctus*, *Z. rennellianus*, *Z. vellaavella*, *Z. splendidus* and *Z. kulambangrae*, possibly with *Z. murphyi* also a member of same group. Close to *Z. splendidus* and sometimes considered conspecific, but differs in plumage and morphology; approaches *Z. vellaavella* in some characters (colours of mantle and bill). Monotypic.

Distribution. Gizo (Ghizo), in WC Solomon Is.

Descriptive notes. 11.5–12 cm. Has white eyering interrupted at front by black spot; forehead, supraloral region, lores and a streak half-way under eye black, merging into yellowish-olive of upperparts on forecrown (about one-third along head from base of bill); remiges and rectrices blackish-brown, edged yellowish-olive; entirely yellow below, flanks and side of breast washed greenish; iris reddish-brown; bill bright yellow; legs yellow. Sexes alike. Juvenile undescribed. **VOICE.** Series of loud upslurred notes, slow, unusual in its unvaryingly sweet and piercing notes (without hoarse or sharp ones), with some inserted sections reminiscent

of an *Acrocephalus* warbler, in so-called “telegraph” song; calls upslurs and downslurs, the first similar to those of Collared Kingfisher (*Todiramphus chloris*). Contact call a soft “pee-u”.

Habitat. Forest in gulleys, and other secondary growth.

Food and Feeding. No information.

Breeding. No information.

Movements. Not known.

Status and Conservation. **ENDANGERED.** Restricted-range species: present in Solomon Group EBA. Confined to the densely populated, virtually deforested, small (37 km²) island of Gizo, where fairly common. Its habitat is limited by demand for agricultural land. Remaining tall or old-growth forest on the island is very fragmented and now covers less than 1 km² in total extent. This species appears to have adapted well to scrub and secondary growth, and is found in reasonable numbers near Gizo town, but these surviving forest patches are also threatened by local cutting for timber use and by clearance for gardens.

Bibliography. Anon. (2007n), Buckingham *et al.* (1995), Butchart & Stattersfield (2004), Collar *et al.* (1994), Diamond (1998), Doughty *et al.* (1999), Dutson (2007b), Gibbs (1996b), Mayr (1945b, 1967), Mayr & Diamond (2001), Mees (1961, 1969), Stattersfield & Capper (2000).

44. Solomon White-eye

Zosterops kulambangrae

French: Zostérops des Salomon

German: Kulambangrabrillenvogel

Spanish: Antejitos de las Salomón

Other common names: Central Solomons/Rendova White-eye

Taxonomy. *Zosterops kulambangrae* Rothschild and E. J. O. Hartert, 1901, Kolombangra, Solomon Islands. Forms a superspecies with *Z. griseotinctus*, *Z. rennellianus*, *Z. vellalavella*, *Z. splendidus* and *Z. luteirostris*, and possibly *Z. murphyi*. Species has been listed as *Z. rendovae*, but original description now seen clearly to be based on specimens from San Cristobal, not Rendova, and thus applicable to a different species. Geographical variation rather well marked, including vocal differentiation; races possibly better treated as separate species. Three subspecies currently recognized.

Subspecies and Distribution.

Z. k. kulambangrae Rothschild & E. J. O. Hartert, 1901 – New Georgia Group (Kolombangra, Vonavona, Kolinggo, New Georgia, Vangunu and Ngatokae), in WC Solomon Is.

Z. k. paradoxus Mees, 1955 – Rendova, in S New Georgia Group.

Z. k. tetiparius Murphy, 1929 – Tetepare, in S New Georgia Group.

Descriptive notes. 11–12 cm. Nominate race has fairly narrow white eyering interrupted at front by black spot; feathers behind nostrils, broad loreal area and stripe under and continuing behind eye blackish; forehead slightly tinged fuscous, crown and upperparts yellowish-tinged greenish-olive; remiges and rectrices brownish-black, edged yellowish-olive; olive-yellow below, centre of belly and undertail-coverts yellow, flanks greenish; iris reddish-brown; bill black; legs straw-yellow. Sexes alike. Juvenile is paler on throat and belly and greener on breast and flanks than adult. Races differ mainly in extent of yellow and presence or absence of eyering, nominate being slightly greener, less yellow, above than others; *paradoxus* lacks white eyering but has bare skin instead, also narrower blackish loreal patch, yellowish-olive forehead, throat and breast, bright canary-yellow abdomen and undertail-coverts; *tetiparius* is very close to preceding race, but has whitish flanks and belly sharply contrasting against greenish breast, and sometimes traces of eyering present. Voice. Typical “telegraph” song of genus, various loud notes in slow fairly more or less uniform series; *tetiparius* has hoarse “chewy” notes, fast with narrow pitch span, thus almost identical to flight song of a distant Singing Parrot (*Geoffroyus heteroclitus*); song pitch of *paradoxus* higher, with various piercing and hoarse notes, whereas nominate has various sweet, piercing, chirping notes, both these songs reminiscent of Common Blackbird (*Turdus merula*). Calls include series of light “tsit” notes during foraging, loud “chirp” like that of a sparrow (*Passer*), and short musical “cheep-cheep”.

Habitat. Found in all habitats, and equally abundant in virgin jungle and (taller) secondary growth, from sea-level to 1350 m. Overlaps commonly with *Z. murphyi* at 950–1350 m.

Food and Feeding. No details of diet. Occurs in flocks, often associated in loosely organized parties of Solomon Flycatchers (*Myiagra ferrocyanæa*), monarchs (*Monarcha*), Cockerell’s Fantail (*Rhipidura cockerelli*) and Rufous Fantail (*Rhipidura rufifrons*). Forages at all heights.

Breeding. No information.

Movements. Sedentary.

Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Locally common to abundant. Very common in area of Munda, on New Georgia I. **Bibliography.** David & Gosselin (2002b), Diamond (1998, 2002), Doughty *et al.* (1999), Dutson (2007b), Hadden (1981), Mayr (1945b, 1967), Mayr & Diamond (2001), Mees (1957, 1961, 1969), Sibley (1951), Sibley & Monroe (1990).

45. Kolombangra Mountain White-eye

Zosterops murphyi

French: Zostérops de Murphy

German: Murphybrillenvogel

Spanish: Antejitos de Murphy

Other common names: Hermit/Murphy’s/Kulambangra White-eye

Taxonomy. *Zosterops murphyi* E. J. O. Hartert, 1929, Kolombangra, Solomon Islands.

Very large white-eye, morphologically extremely similar to and possibly very closely related to *Z. griseotinctus*; may belong to the superspecies formed by latter and *Z. rennellianus*, *Z. vellalavella*, *Z. splendidus*, *Z. luteirostris* and *Z. kulambangrae*. Monotypic.

Distribution. Kolombangra (New Georgia Group), in WC Solomon Is.

Descriptive notes. 13–14 cm. Has very broad white eyering interrupted at front by darker loreal line, lores pale greyish-yellow, faint dusky streak under eyering; rest of head and upperparts olive-green; remiges and rectrices brownish-black, edged olive-green; underside as upperparts but paler, more yellowish on middle of throat, middle of breast, abdomen and undertail-coverts; iris brown; bill black, yellowish base of lower mandible; legs grey. Sexes alike. Juvenile undescribed. Voice. Song a very long (up to 5 seconds) high-pitched warble, not broken into distinct syllables, of very sweet quality, sometimes penetrating; many notes sharp, reminiscent of sound made by dropping coin on to hard surface. Call a repeated sharp peeping note, or a descending whinny; single plaintive note from flock-members during foraging.

Habitat. Mossy cloudforest from 950 m (sometimes down to 660 m, even 350 m) to at least 1620 m; overlaps commonly with *Z. kulambangrae* at 950–1350 m.

Food and Feeding. Insects, small fruits. In large flocks of 100 and more individuals, often in company of lorikeets (Psittacidae) and myzomelas (*Myzomela*). Forages in canopy in tall forest, mainly above 5 m, but descending to 1 m in lower vegetation at summit of Kolombangra. Picks in fruits of 3 mm diameter; probes at flowers (*Eugenia*).

Breeding. One nest with two naked chicks in Oct, and birds with enlarged gonads in Oct–Nov. Nest a cup 5 cm deep and 5 cm across, woven from tiny dry twigs, placed 1.5 m up in bush 1.8 m tall, site at elevation of 1620 m.

Movements. Resident. Daily movements downslope in morning and back uphill in mid-afternoon.

Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Common. The most abundant bird species in mountains of Kolombangra.

Bibliography. Diamond (2002), Gibbs (1996a), Mayr (1945b, 1967), Mayr & Diamond (2001), Mees (1961, 1969), Murphy (1929), Snouckaert van Schauburg (1931), Stresemann (1931a).

46. Grey-throated White-eye

Zosterops rendovae

French: Zostérops à gorge grise

German: Graukehl-Brillenvogel

Spanish: Antejitos Gorgjigris

Other common names: Variable White-eye, Solomon Grey-throated White-eye

Taxonomy. *Zosterops rendovae* Tristram, 1882, Rendova; error = San Cristobal, Solomon Islands. Affinities unclear; probably an old endemic species of Solomon Is. Previously listed as *Z. ugiensis*, as present name was erroneously applied to *Z. kulambangrae*. Three subspecies recognized.

Subspecies and Distribution.

Z. r. hamlini Murphy, 1929 – Bougainville I, in NW Solomon Sea.

Z. r. oblitus E. J. O. Hartert, 1929 – Guadalcanal, in EC Solomon Is.

Z. r. rendovae Tristram, 1882 – San Cristobal, in SE Solomon Is.

Descriptive notes. 12.5 cm; male 15 g and female 15.8 g (*oblitus*), unsexed 19.1 g (nominate). Nominate race is dark olive or brownish-olive above, face and forehead washed with dark brown, primaries and rectrices blackish-brown with dark olive outer margins; throat and breast dirty white, more greyish at sides; abdomen and undertail-coverts almost pure satin-white, sometimes a trace of yellow on undertail-coverts; iris pale to dark orange-brown; bill blackish, whitish base of lower mandible; legs pale leaden grey. Sexes alike. Juvenile undescribed. Races differ mainly in presence or absence of eyering and in colour of

forehead, throat and undertail-coverts: *oblitus* has face and forehead olive-green as back, throat and breast more greyish than nominate, pale yellow undertail-coverts; *hamlini* has narrow white eyering (broken before and behind eye), forehead and face sooty brown, upper throat greenish-olive, lower throat, breast and flanks dark grey, middle of belly white, yellow undertail-coverts. Voice. Song a loud rambling musical warble of mellow whistles (these almost run together), varying in pitch. Call a loud downslurred mellow “peeu” (mellowness of which unique among Pacific members of genus); monotonous “peep...peep...peep...” heard from foraging parties, and once a whispered, almost growling “churewuwurwui” heard from a foraging group; sharp “tk tk tk tk...” when chasing one another.

Habitat. Forest, especially forest edge and secondary forest, but rarely in low bushes; in hills and mountains, less commonly in stunted upper montane forest, and rare or nomadic in lowlands. On Bougainville occurs in mountains at 900–1950 m, largely replacing *Z. metcalfei* at these elevations; rarely, as low as 500 m on Guadalcanal and San Cristobal. Locally associated with kandaka, a small second-growth tree.

Food and Feeding. Soft seedy fruit, mostly small seeds, and probably occasionally insects. Reported as being fond of the seeds of kandaka trees. Usually in flocks of 6–12 individuals; readily associates with *Z. metcalfei* where ranges overlap at lower elevations. Frequents middle level to canopy. Sometimes hover-gleans.

Breeding. Juvenile not long out of nest in Apr; birds with small to large gonads in Nov (nominate race), and all birds with enlarged gonads in Jul and Aug (*oblitus*). No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Common to abundant, especially in mistforest. The most abundant bird species of the Bougainville mountains at 1200–1950 m.

Bibliography. Bishop (1987), Cain & Galbraith (1956), Coates (1990), David & Gosselin (2002b), Diamond (1975a), Doughty *et al.* (1999), Dutson (2007b), Galbraith (1957), Hadden (1981, 2004), Mayr (1945b), Mayr & Diamond (2001), Mees (1961, 1969), Murphy (1929), Schodde (1977).

47. Malaita White-eye

Zosterops stresemanni

French: Zostérops de Malaita

German: Malaitabrillenvogel

Spanish: Antejitos de la Malaita

Taxonomy. *Zosterops stresemanni* Mayr, 1931, Malaita, Solomon Islands.

Affinities unclear. Monotypic.

Distribution. Malaita I, in E Solomon Is.

Descriptive notes. 13.5 cm; male 22.2 g, female 21.7 g. Has top and side of head and upperparts olive-green, very slight fuscous wash on crown; lores ash-grey, area around eye bare (but no eyering); flight-feathers and tail feathers blackish-brown, broadly margined pyrite-yellow; pale olive-green faintly barred yellow on throat, breast and flanks, becoming yellow on belly and undertail-coverts; iris light brown; upper mandible greyish, lower mandible dull orange with grey tip; legs greenish-grey. Sexes alike. Juvenile undescribed. Voice. Song very melodious, like that of a Thrush (*Turdidae*); single-note call, typical of genus.

Habitat. Gardens, scrub, primary forest, secondary growth; sea-level to 1100 m.

Food and Feeding. No information.

Breeding. No information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Rare on coastal plain and uncommon to fairly common inland around Auki in 1990s–2004. In mid-1940s was apparently common to abundant from sea-coast to mountains. The only white-eye on Malaita.

Bibliography. Cain (1954), Doughty *et al.* (1999), Mayr (1945b), Mayr & Diamond (2001), Mees (1961, 1969), Sibley & Monroe (1990), Snouckaert van Schauburg (1931).

48. Santa Cruz White-eye

Zosterops sanctaecrucis

French: Zostérops de Santa Cruz

German: Einfarb-Brillenvogel

Spanish: Antejitos de las Santa Cruz

Other common names: Nendo White-eye

Taxonomy. *Zosterops sanctaecrucis* Tristram, 1894, Santa Cruz Island.

Affinities unclear; suggested relationship to *Z. samoensis* seems unlikely due to morphological and ecological differences. A taxon resembling this species, but with slightly more slender bill and entirely yellowish-orange legs, was found in 1994 on nearby Vanikoro I; shortly to be described. Monotypic.

Distribution. Ndeni, in Santa Cruz Is (N of Vanuatu).

Descriptive notes. 12.5 cm. Plumage is generally dull olive above, with broad dusky area on lores and narrowly around eye; flight-feathers and tail feathers blackish-brown, broadly edged with rather bright olive; greenish-yellow below, yellowish towards centre of belly and vent; iris brown; bill black, yellow base; legs blue-grey. Differs from *Z. samoensis* in having e.g. dark iris, longer tarsus, much larger size, no white eyering. Sexes alike. Juvenile undescribed. **VOICE.** Song a rich melodic warble; subsong a stuttering series of short notes, e.g. "zhay-zhay-zhe..."; call a low-pitched nasal trill.

Habitat. Scrub, gardens, primary forest, forest edge, secondary growth.

Food and Feeding. No information.

Breeding. No relevant information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Vanuatu and Temotu EBA. Fairly common to common in 1994–2005.

Bibliography. Doughty *et al.* (1999), Dutton (2007b), Finsch (1901), Gibbs (1996a, 1996b), Mayr (1945b, 1967), Mees (1961, 1969), Murphy & Mathews (1929), Stresemann (1931a), Tristram (1894).

49. Samoan White-eye

Zosterops samoensis

French: Zostérops des Samoa

German: Samoabrillenvogel

Spanish: Antejitos de Samoa

Other common names: Savaii/Savau White-eye

Taxonomy. *Zosterops samoensis* Murphy and Mathews, 1929, Savai'i, Samoa.

Suggested relationship to *Z. sanctaecrucis* seems unlikely on grounds of morphological and ecological differences. Monotypic.

Distribution. Island of Savai'i, in W Samoa.

Descriptive notes. 10–11 cm. Has narrow white eyering more or less broken at front, lores yellowish-green; including forehead, crown and upperparts dull citrine; flight-feathers and tail brownish-black, former broadly edged greenish; rectrices rather narrowly edged greenish; throat and undertail-coverts light yellow, breast and flanks pale yellowish-green, trace of buffish on flanks, centre of belly very pale yellowish (rather weak demarcation between upperside and underside); iris yellowish-white; bill brown above, yellow below; legs greyish or greenish. Differs from *Z. sanctaecrucis* in e.g. white eyering, pale iris, shorter

tarsus, much smaller size. Sexes alike. Juvenile undescribed. **VOICE.** No information.

Habitat. Upland forest above 900 m, occasionally down to 780 m; was recorded also in open scrub-like habitat after a cyclone in 1991.

Food and Feeding. No details of diet. Feeds in canopy of forest; sometimes in low bushes in more open scrub. Highly gregarious; travels in flocks of 10–20 individuals, occasionally more (up to 40).

Breeding. No information.

Movements. Not known.

Status and Conservation. **VULNERABLE.** Restricted-range species: present in Samoan Islands EBA. Uncommon. Total population fewer than 2500 individuals within global range of 520 km². Flocks of 15–20 birds seen in highlands in 1987, and again in 1991. Remaining areas of upland forest on Savai'i threatened by slash-and-burn cultivation, as forestry roads from heavily logged lowland forests provide access to formerly inaccessible land. Early introduction of predators may have had adverse effects on the species. The possible introduction of or colonization by *Z. japonicus* and *Z. lateralis* considered by some a potential threat, as these species have become established in rainforest on Hawaii and other Pacific islands. Occurs in Mount Silisili Park, an area of montane cloudforest in C part of the island.

Bibliography. Anon. (2007n), Baker (1951), Beichle & Baumann (2003), Bellingham & Davis (1988), Butchart & Stattersfield (2004), Collar *et al.* (1994), Evans *et al.* (1992), Mayr (1945b, 1967), Mees (1969), Murphy & Mathews (1929), duPont (1976), Pratt *et al.* (1987), Snouckaert van Schauburg (1931), Stattersfield & Capper (2000).

50. Fiji White-eye

Zosterops explorator

French: Zostérops des Fidji

German: Layardbrillenvogel

Spanish: Antejitos de Fiji

Other common names: Layard's White-eye

Taxonomy. *Zosterops explorator* E. L. Layard, 1875, Kandavu Island, Fiji. Affinities unclear; may form a superspecies with *Z. flavifrons*, *Z. minutus* and *Z. xanthochroa*. Monotypic.

Distribution. Fiji Is: Vanua Levu, Taveuni, Viti Levu, Ovalau and Kadavu.

Descriptive notes. 10–11 cm; 10.5 g. Has well-developed entire white eyering, blackish stripe from under lores continuing back under eyering; top of head and entire upperparts yellowish-olive, more

yellow on forehead and lores; remiges and rectrices brownish-black, edged yellowish-olive; chin, throat and breast lemon-yellow, undertail-coverts paler yellow, sides tawny-buff, remainder of underparts greyish-white, yellowish wash along middle; iris brown; bill black or brown above, horn-coloured below; legs grey. Sexes alike. Juvenile undescribed, but plumage of nestling only slightly paler than that of adult.

VOICE. Song a rambling series of unvarying notes. Call a high-pitched reedy "seeu-seeu" or "pleu", and squeaky "see"; also short "zick".

Habitat. Occurs in many habitats, especially forest (including hill forest) and plantations; has preference for inland habitats. Overlaps broadly with *Z. lateralis*, but there is little intermingling of the two species; latter is typical of open habitats and forest edge, whereas present species tends to be more common in heavily forested areas.

Food and Feeding. Insects recorded. Moves about in small parties of ten or more individuals; sometimes found in mixed flocks with *Z. lateralis*. Gleans foliage of small trees and shrubs. Visits cotton (*Gossypium*) fields to devour the minute insects that infest the cotton buds.

Breeding. Nestling in Nov. Nest reported typical of genus. Clutch 2 eggs, bluish-white. No other data.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Fiji EBA. Common to fairly common.

Bibliography. Dunning (1993), Langham (1987), Layard (1876a, 1876b, 1876c), Mayr (1945b), Mees (1969), Mercer (1966), Murphy & Mathews (1929), Nehrkorn (1879), duPont (1976), Pratt *et al.* (1987), Watling (2001).

51. Yellow-fronted White-eye

Zosterops flavifrons

French: Zostérops à front jaune

German: Gelbstirn-Brillenvogel

Spanish: Antejitos Frentigualdo

Other common names: Vanuatu/Yellow White-eye

Taxonomy. *Muscicapa flavifrons* J. F. Gmelin, 1789, Tanna Island, Vanuatu.

Affinities obscure; may form a superspecies with *Z. explorator*, *Z. minutus* and *Z. xanthochroa*. Race *perplexus* sometimes synonymized with *macgillivrayi*, and *efatensis* with *gauensis*; further study needed. Seven subspecies currently recognized.

Subspecies and Distribution.

Z. f. perplexus Murphy & Mathews, 1929 – extreme N & NE Vanuatu from Banks Is (Vanua Lava, Mere Lava) S to Maéwo, Aoba, Pentecost, Ambrym, Paama, Lopévi, Épi, Tongoa and Émaé.

Z. f. gauensis Murphy & Mathews, 1929 – Santa Maria I (Gaua), in N Vanuatu.

Z. f. brevicauda Murphy & Mathews, 1929 – Espiritu Santo and Malo, in NW Vanuatu.

Z. f. macgillivrayi Sharpe, 1900 – Malakula, in NC Vanuatu.

Z. f. efatensis Mayr, 1937 – Nguna, Éfaté and Erromango, in SC Vanuatu.

Z. f. flavifrons (J. F. Gmelin, 1789) – Tanna, Aniwa and Futuna (Erronan), in S Vanuatu.

Z. f. majusculus Murphy & Mathews, 1929 – Anatom (Aneityum), in extreme S Vanuatu.

Descriptive notes. 11.5–12.5 cm; 10.9–11.9 g.

Nominate has yellowish forehead and supraloral region, broad white eyering interrupted at front by small dusky to blackish spot, blackish continuing onto lores and under eyering; crown and upperparts yellowish-olive, flight-feathers and tail blackish-brown, edged yellow-olive; chin, throat and underparts rich yellow, tinged olive on flanks; iris brown; upper mandible brown, lower mandible pinkish-brown; legs greyish. Sexes alike. Juvenile undescribed. Races vary little, mainly in brightness of plumage, amount of yellow on forehead, size, and relative tail length, nominate slightly larger and stronger-

billeted than others: *perplexus* has more greenish-tinged yellow underparts and darker upperparts than nominate, with virtually no yellow on forehead; *brevicauda* is like previous but with some yellow on forehead, and tail shorter than all others; *macgillivrayi* is distinctive, with no yellow on forehead, has yellow-olive throat and breast, much larger eyering, and on average slightly smaller than *perplexus*; *gauensis* is like nominate but smaller, with distinctly shorter and more brownish bill; *efatensis* doubtfully distinct from last, but perhaps with blackish bill; *majusculus* has little yellow on forehead, is a little duller green than others, otherwise mainly like *perplexus* but with slightly longer bill. **VOICE.** Pleasant, often repeated warbling song. Contact call a short, high-pitched "chip-chip" or "tzeep-tzeep".

Habitat. Primary forest, secondary forest, plantations, scrub, scattered bushes, trees, second growth and native gardens; apparently breeds in cotton fields locally (race *efatensis*). From sea-level upwards; may be more common in hill country than in lowlands. Co-occurs with *Z. lateralis* throughout its range; possibly favours less open country than that preferred by latter.

Food and Feeding. Arthropods, fruits, nectar, fruit seeds, probably also small buds. Insects include beetles (Coleoptera), also eggs and larvae, e.g. caterpillars; spiders (Araneae). Fruits especially of introduced *Lantana*, chilli (*Capsicum*) and soft, sweet wild figs (*Ficus*); ripe but uncollected papayas (*Carica*) are hollowed out. Moves about in sizeable groups; outside breeding season, gathers and wanders in often fairly large noisy flocks, sometimes with whistlers (*Pachycephala*), fantails (*Rhipidura*) and honeyeaters (Meliphagidae). Seen to feed on the ground in tall forest with scant undergrowth.

Breeding. Season Sept–Jan, sometimes to Mar; young just out of nest in Dec in NW (race *brevicauda*), and birds with enlarged gonads in Nov on Santa Maria I (*gauensis*) and in Mar and Jun in SC part of range (*efatensis*). Nest a neat cup 6 × 5.5 cm externally, made from fine grass, thin bark, shreds and spider webs, occasionally lined with few feathers and fine vegetable fibres, attached at rim to thin horizontal fork or two leaf stems 2.5 m or more above ground. Clutch 3 eggs, pale blue, 17.8 × 13.8 mm (race *perplexus*); incubation period 12–13 days; no information on nestling period.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Vanuatu and Temotu EBA. Common and widespread; perhaps the most numerous bird species in Vanuatu. Occurs on almost all major islands, but not yet recorded on Uréparapara and Mota Lava (both in N Banks Is).

PLATE 34

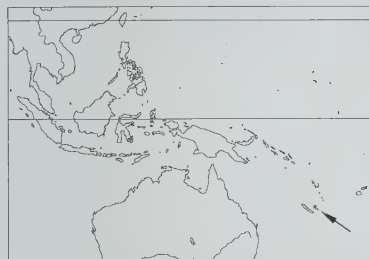

52. Small Lifou White-eye

*Zosterops minutus***French:** Zostérops minute **German:** Ameisenbrillenvogel **Spanish:** Antejitos Menudo

Taxonomy. *Zosterops minuta* E. L. Layard, 1878, Lifou, Loyalty Islands. Affinities unclear; may form a superspecies with *Z. explorator*, *Z. flavifrons* and *Z. xanthochroa*. Looks exactly like an intermediate between last two species. Monotypic.

Distribution. Lifou I, in C Loyalty Is.

Descriptive notes. 10–11 cm; male 8.9 g, female 7.6 g. Has forehead and supraloral region yellowish, lores and narrow streak below eye blackish-grey, broad white eyering narrowly interrupted at front by loreal streak; crown and upperparts bright olive-green, remiges and rectrices blackish, broadly margined with olive-green; throat, breast, middle of abdomen and undertail-coverts yellow, flanks pale buffish (in the field white side patches very conspicuous, giving impression of a white, instead of black, wing edge); iris drab; bill pale brown; legs grey-brown. Sexes alike. Juvenile undescribed. Voice. Call a mournful “tee-oo”, typical of genus.

Habitat. Forest edge, low shrubs, native villages and gardens.

Food and Feeding. Insects, in particular ants (Formicidae), also caterpillars, grubs, beetles (Coleoptera) etc.; also seeds, fruits. Fruits eaten said to be restricted to papaya (*Carica papaya*) and banyan (*Ficus*). Generally in small to larger flocks, numbering 4–25 and more individuals, occasionally mixed with others of genus. Forages at all levels, but mainly above 3 m.

Breeding. Breeds throughout greater part of year, but rarely from Feb to late May; probably several broods. Nest said to be typical of genus, but no details available; clutch 2–4 eggs. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in New Caledonia EBA. Very common on Lifou, where the most abundant of the three white-eye species present. Rather shy, as it suffers persecution by native people to some extent. Reportedly very destructive to fruits of all kinds, especially when moving in large flocks, although damage may be limited (as fruit-eating said also to be restricted to very few plant species).

Bibliography. Bruce (1975), David & Gosselin (2002b), Doughty *et al.* (1999), Layard & Layard (1880), Mayr (1945b, 1967), Mees (1969), Sarasin (1913), Sibley & Monroe (1990), Stresemann (1931a), Tristram (1879), Warner (1947).

53. Green-backed White-eye

*Zosterops xanthochroa***French:** Zostérops à dos vert **German:** Waldbrillenvogel **Spanish:** Antejitos Dorsiverde
Other common names: New Caledonian White-eye

Taxonomy. *Zosterops xanthochroa* G. R. Gray, 1859, Nu, New Caledonia. Affinities unclear; may form a superspecies with *Z. explorator*, *Z. flavifrons* and *Z. minutus*. Monotypic.

Distribution. New Caledonia, including I of Pines (off SE coast), and S Loyalty Is (Maré).

Descriptive notes. 11.5–12.5 cm; 8.5–12 g. Has lores and streak under eye blackish-grey, fairly broad white eyering broken at front by loreal line; top and side of head and upperparts dark olive-green, remiges and rectrices blackish-brown, margined olive-green; throat and breast yellow, undertail-coverts and faint streak down centre of abdomen paler yellow, rest of underparts dirty white; iris light brown; bill dark slate, white base of lower mandible; legs pale greyish-slate. Sexes alike. Juvenile undescribed. Voice. Song a rapid jumbled warble of short warbles and whistles. Call a thin repeated “see”.

Habitat. Mainly primary forest, also native gardens and open glades; from lowlands into mountains, but less common above 1000 m. More or less replaced by *Z. lateralis* in brush and semi-open woodland.

Food and Feeding. Insects; fruits e.g. papaya (*Carica papaya*), and berries, especially those of introduced *Lantana*. Towards end of breeding season (Jan) begins to form flocks, these increasing in size in succeeding months. When fruits and berries ripen, flocks venture outside forest and associate with *Z. lateralis*, Fan-tailed Gerygone (*Gerygone flavolateralis*) and Red-throated Parrot-finches (*Erythrura psittacea*).

Breeding. Aug–Oct, perhaps to Jan or later; possibly double-brooded. Nest a beautiful structure of soft rootlets, hair, feathers, cobweb and similar, placed in branch fork in tree or shrub. Clutch 2–4 eggs, pure turquoise-blue, 16.5 × 13 mm. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in New Caledonia EBA. Common and widespread in New Caledonia, perhaps especially S part; common also on Maré I. Although consuming fruit, this species is believed not to cause much damage in native gardens.

Bibliography. David & Gosselin (2002a), Doughty *et al.* (1999), Layard & Layard (1882), Mayr (1945b, 1967), Mees (1969), Nehrkorn (1910), Ogilvie-Grant (1912), Sarasin (1913), Sibley & Monroe (1990), Warner (1947).

54. Silvereye

*Zosterops lateralis***French:** Zostérops à dos gris **German:** Graumantel-Brillenvogel **Spanish:** Antejitos Dorsigris

Other common names: Grey-backed/Grey-breasted/Western White-eye; Western Silvereye (*chloronotus*); Grey-backed Silvereye (“*halmaturinus*”); Grey-breasted Silvereye (*lateralis*); Capricorn Silvereye (*chlorocephalus*); Lord Howe (Island) White-eye (*tephroleptus*)

Taxonomy. *Sylvia lateralis* Latham, 1801, Port Jackson, New South Wales, Australia.

Member of a species group which includes also *Z. tenuirostris*, *Z. albogularis* and *Z. inornatus*. Australian races sometimes grouped into three separate species, differing in plumage characters, size and vocalizations; all mainland forms, however, intergrade through broad zones, and DNA–DNA analysis indicates that neighbouring races are each other’s closest relatives. Lord Howe race *tephroleptus* sometimes treated as a further separate species. In Australia, birds in W of range previously known as race *gouldi*, but *chloronotus* has priority and not preoccupied by “*chloronotus*”. Recent taxonomic review has led to several changes to the previously accepted arrangement: in E Australia, population in N Queensland (S to Mackay region) formerly known by name *ramsayi* (but type description based on intergrade specimens) and those from Mackay region S to E Victoria as *familiaris* (which appears to consist of two intergrading races), hence N populations of *ramsayi* now known as race *vegetus* and S populations along with most of *familiaris* replaced by name *cornwalli*; S populations of former *familiaris* now known as *westernensis*; S populations (CS South Australia E to SW New South Wales and W Victoria) formerly treated as race *halmaturinus*, but that name invalid (type material seems to represent intergrades between *chloronotus* and dull birds from SE South Australia), hence birds in E of that range described as new race *pinarochrous*; in addition, birds on King I (in Bass Strait), formerly included in nominate, considered to differ sufficiently to warrant racial separation, and thus described as new race *ochrochrous*; further research, including genetic analyses, required as a priority to enable better understanding of racial limits. Otherwise, proposed race *macmillani* (from Tanna, in S Vanuatu) is considered synonymous with *vatensis*. Sixteen subspecies currently recognized.

Subspecies and Distribution.

Z. l. chloronotus Gould, 1841 – SW & S Western Australia (S from Point Cloates and Shark Bay, and from Wongan Hills) E (S of Nullarbor Plain) to S South Australia.

Z. l. vegetus E. J. O. Hartert, 1899 – NE Queensland (E Cape York Peninsula) in NE Australia.

Z. l. cornwalli Mathews, 1912 – EC & SE Queensland and NE New South Wales.

Z. l. chlorocephalus A. J. Campbell & S. A. White, 1910 – Capricorn Group (notably Heron I) and Bunker Group, in S Great Barrier Reef, off SE Queensland.

Z. l. westernensis (Quoy & Gaimard, 1830) – SE New South Wales (from upper Lachlan R) S to E Victoria.

Z. l. pinarochrous Schodde & Mason, 1999 – SE South Australia, SW New South Wales and W Victoria.

Z. l. tephroleptus Gould, 1855 – Lord Howe I, off E Australia.

Z. l. ochrochrous Schodde & Mason, 1999 – King I (W Bass Strait).

Z. l. lateralis (Latham, 1801) – Flinders I (Furneaux Group, in E Bass Strait), Tasmania, Norfolk I, New Zealand (both main islands, all smaller adjacent islands) and Chatham Is; non-breeding also SE Australia.

Z. l. valuensis Murphy & Mathews, 1929 – Mota Lava, in E Banks Is (in extreme NE Vanuatu).

Z. l. tropicus Mees, 1969 – Torres Is, Banks Is (except Mota Lava) and NW Vanuatu (Malé, Espiritu Santo).

Z. l. vatensis Tristram, 1879 – C & S Vanuatu (Malakula, Ambrym, Paama, Lopévi, Épi, Émaé, Tongariki, Tongoa, Makura, Éfaté, Erromanga, Tanna, Aniwa).

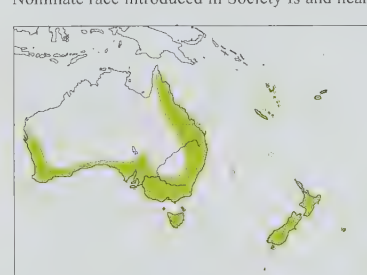

Z. l. griseonota G. R. Gray, 1859 – New Caledonia.

Z. l. nigrescens F. Sarasin, 1913 – Beaufort Bay, Ouvéa and Maré, in Loyalty Is.

Z. l. melanops G. R. Gray, 1860 – Lifou, in C Loyalty Is.

Z. l. flaviceps Peale, 1848 – Fiji Is (main islands and all adjacent smaller islands from Vanua Levu and Taveuni S to Viti Levu and Kadavu; also Koro, Gau and Moala).

Nominate race introduced in Society Is and nearby Tubuai Is, and on Lord Howe I.

Descriptive notes. 12 cm; 9.2–16.9 g. Male nominate race has broad white eyering broken at front by black loreal line, this continuing below eyering; top and side of head bright yellowish-green; upper back and scapulars grey, tinged yellowish-green, upperwing-coverts, lower back, rump and upperpart-coverts yellowish-green; remiges and rectrices brown, with yellowish-green on outer webs; pale greyish-white below, throat and undertail-coverts often tinged yellow, entire underside sometimes darkened (to distinct grey), sides and flanks chestnut-brown; underwing-coverts white; iris brown; bill yellowish-horn, blackish tip; legs

pale brown. Female is like male, but with colour of sides and flanks less intense, more pale cinnamon-brown. Immature resembles adult, but lacks white eyering. Races differ mainly in colour of back, throat and flanks, in wing formula (with migratory races having longest primary P2) and in size (larger on smaller islands): *chloronotus* is smallest, distinctive, has upperparts uniformly olive-green, throat olive-yellow, breast grey, flanks washed buff; *vegetus* is smaller than nominate, with throat and undertail-coverts citrine-yellow, tail relatively shorter than in other races; *cornwalli* has general appearance close to nominate, but with throat yellow, undertail-coverts lemon, flanks grey or buffish; *chlorocephalus* is similar to previous but very much larger, with throat duller, flanks greyer; *westernensis* is intermediate between *cornwalli* and *pinarochrous*; *pinarochrous* differs from last in somewhat duller head, paler and browner upperparts, greyish throat and undertail-coverts, grey breast, pale rufous flanks; *tephroleptus* closely resembles *cornwalli*, but differs in having more robust build, slightly heavier and longer bill, larger feet and claws, slightly paler yellow chin and throat, slightly richer yellow undertail-coverts; *ochrochrous* is shorter-billed than nominate, also on average paler below; *tropicus* is extremely similar to *tephroleptus*, but paler yellow on undertail-coverts, more slender bill; *valuensis* is similar to *tropicus*, but has whole upper back green (sometimes some admixed grey); *vatensis* is large, with much grey on back, much black below eye, and a tendency towards blackening of forehead and crown in S population; *griseonota* has rather greyish breast, inconspicuous brownish wash on flanks; *nigrescens* is intermediate between previous race and following one; *melanops* has rather grey back, most of breast distinctly grey, rather dark olive colours, differs from all others in having blackish on forehead and whole of forecrown; *flaviceps* is very similar to *griseonota* and *tropicus*. Voice. Song, surprisingly loud and

On following pages: 55. Slender-billed White-eye (*Zosterops tenuirostris*); 56. White-chested White-eye (*Zosterops albogularis*); 57. Large Lifou White-eye (*Zosterops inornatus*); 58. Dusky White-eye (*Zosterops finschii*); 59. Grey-brown White-eye (*Zosterops cinereus*); 60. Abyssinian White-eye (*Zosterops abyssinicus*); 61. Cape White-eye (*Zosterops pallidus*); 62. African Yellow White-eye (*Zosterops senegalensis*); 63. Pemba White-eye (*Zosterops vaughani*).

melodious, a rapid, loosely organized succession of high-pitched notes, trills, warbles and slurs; autumn subsong includes mimicry. Flocking call in flight a chirping “cli-cli-cli...”; other calls include rather plaintive “cree” or thin peevish “psee”, dry “rick”, and various alarm and other calls; in W Australia (race *chloronotus*) calls harsher, and flight note a staccato “chip chip”.

Habitat. Found in coastal/subcoastal Australia in most vegetation types so long as at least moderate vegetation cover present, thus from shrubland and heathland to rainforest and mangroves; although penetrates several hundred kilometres inland, not found in arid interior of Australia. In all types of settled habitat with tree cover; also in coastal shrubland and in native forest and subalpine scrub in New Zealand; in urban New Zealand becomes more abundant in areas with higher percentage of native plants. Native gardens and other open country and only rarely in true forest on New Caledonia and Loyalty Is. From sea-level to uplands. Commonly found from sea coast to mountains in Society Is (where introduced).

Food and Feeding. Insects, earthworms (Oligochaeta), spiders (Araneae); fruits and softer berries; nectar, and sepals of *Feijoa*. Also takes household foods provided at feeders. In forest, fruits of a number of trees and shrubs taken (e.g. *Rhagodia parabolica*, *Hymenanthera dentata*), mostly red and black in colour, but also ripe green fruits of *Persoonia*, *Brachyloma ericoides* and *Oxal benthamiana* in Australia (preferred any red fruit during experiments in captivity, but green fruits preferred if sugar concentration was increased); in New Zealand fruits of introduced strawberry tree (*Arbutus unedo*) and of strawberry dogwood (*Dendrobenthamia capitata*) and, in subalpine scrub, fruits of *Cupressoma*, *Hymenanthera* and others; favourite fruits in Vanuatu are the introduced *Lantana camara*, also chilli (*Capsicum*), soft sweet figs (*Ficus*) and papaya fruits (*Carica*). Many introduced plants provide nectar (e.g. *Rondeletia*) and other food items (e.g. the weed *Asparagus asparagoides*). Arthropods taken by race *chlorocephalus* on Heron I (S Great Barrier Reef) were mainly ants (Formicidae) and other small hymenopterans, small flies (Diptera), bugs (Hemiptera, including homopterans), larval lepidopterans, and spiders; almost all smaller than 5 mm. Young are fed with grubs, caterpillars, fruits (ripe figs), occasionally with adult insects and spiders. Forages in small groups of 2–8 individuals. Also in mixed flocks with whistlers (*Pachycephala*), thornbills (Acanthizidae), fantails (*Rhipidura*) and others, and seen in five of 105 mixed-species flocks studied in SE Australia, where 40% of the white-eyes seen were in these flocks; in a New Zealand study, present species was not found in 66% of 76 mixed flocks, but sometimes was the nuclear species leading flock direction; at times in small flocks with whistlers, monarch-flycatchers (Monarchidae) and other white-eye species in Vanuatu. In winter months, on Heron I, forages in flocks among low vegetation of *Messerschmidia*, *Scaevola*, *Wedelia*, in tall casuarinas (*Casuarina*), and in canopy of *Pisonia grandis*, the locally dominant tree; also visits fruiting trees, e.g. *Ficus* and *Pipturus*. When food scarce, eats fruit in orchards and vineyards. Also frequents birdtables, and takes items such as fat, fruit, sugar, honey, syrup, jam, bread. In New Zealand prevented from attending feeding stations by New Zealand Bellbirds (*Anthornis melanura*), and in many localities nectar-feeding from flowers may be limited by various honeyeaters (Meliphagidae). Prey taken mostly by gleaning and probing.

Breeding. Sept–Jan in Australia and Aug–Feb in New Zealand and Vanuatu; two or three broods, locally even up to five broods in a season. Pair-bond long term, mated partners remain together in winter flock; flock disintegration brought about as pairs leave to establish individual territories; first-year individuals form pairs while in flock. Nest a small cup 6.5 × 6 cm, strongly woven from fine grasses, fibres, fragments of moss, etc. and spider webs, attached at rim to twigs or foliage in hammock-like fashion, generally in outermost foliage at height of 1–9 m (occasionally to 14 m), usually in shrub, but other sites recorded include bracken-fern (*Pteridium*) and a clump of bamboo (nest 2 m above ground between two slender stems). Clutch 2–4 eggs, usually 3, delicate pale blue, average 17 × 13 mm; incubation by both parents, beginning with second egg, period 10–11 days; nestlings fed by both sexes, fledging period 9–13 days; first flocks, probably resulting from fusion of family parties and young of early broods, noted in mid-Feb in New Zealand (Auckland). Nests parasitized by Shining Bronze-cuckoo (*Chrysococcyx lucidus*).

Movements. Races on tropical islands more or less sedentary. Otherwise, some races nomadic and/or migratory, but details poorly understood; movements involve only parts of populations, also individuals migrate in some years and not in others. Some populations of nominate race leave Tasmania after breeding, dispersing N through coastal SE Australia N to SE Queensland; return to Tasmania in Aug–Oct. Ringing studies showed distances covered more than 300 km along E coast and between Tasmania and Australia, and as far N as near Murwillumbah (extreme NE New South Wales), 1600 km from Tasmania; breeders at Wollomombi (NE New South Wales) disappear in winter, and are replaced by Tasmanian birds. In SW Australia (e.g. Perth), movements of up to 100–300 km recorded, and small numbers have been observed while moving S along coast in summer; migratory individuals move through area N of Perth in Jun–Jul when nectar production high. On migration flocks gather in trees, and dash into air on next stage of journey. In Jun 1856, large flocks that appeared on Wellington coast in New Zealand may have represented beginning of the spread of this species throughout New Zealand (scattered records before that time, earliest in 1832); movements of thousands of individuals are now recorded in autumn–winter in New Zealand, mostly on South I and moving N, possibly into North I.

Status and Conservation. Not globally threatened. Common to abundant throughout most of range. Common and often very abundant in Australia; the only dominant native bird species (5.9–10.3 %) in Canberra suburbs, where 3.4–8.7 territories/10 ha recorded. Densities in Australian eucalypt (*Eucalyptus*) woodland 0.03–1.8 birds/ha, in heath 3–5 birds/ha; densities up to four times greater after breeding season. Common in Vanuatu, New Caledonia and Loyalty Is. Common generally throughout New Zealand, and locally one of the most abundant bird species, but curiously scarce as a breeder on many offshore islands. Great Barrier Reef race *chlorocephalus* has its largest population on Heron I (of only 16.8 ha in extent), where between 1967 and 1993 numbers fluctuated between 225 and 445 individuals; breeding densities of 6.4–11 pairs/ha recorded on the island. Race *rephroleptus* inhabits the small (17 km²) island of Lord Howe, where it is widespread; was earlier thought to be extinct, as there had been no reliable reports since 1914, but found again in 1963. Although this race has adapted to presence of introduced rats (*Rattus*), genetic swamping by nominate race would be a potential threat should the latter colonize the island (as it has Norfolk I); nevertheless, individuals of nominate race from Norfolk I and of race *westernensis* from New South Wales were released on Lord Howe in 1924–1936, but no traces of either are left. In 1930s, nominate race introduced from New Zealand to Society Is, including Tahiti (where it is now firmly established), and more recently to nearby Tubuai Is. In SW Australia, this species is beneficial to man as it is the most important avian predator of potato moth (*Phthorimaea operculella*) larvae; on the other hand, it is unfortunately also the most important disperser of the introduced *Asparagus asparagoides*, as it consumes the berries of this environmentally unwelcome plant and voids the seeds.

55. Slender-billed White-eye

Zosterops tenuirostris

French: Zostérops à bec fin **German:** Dünnschnabel-Brillenvogel **Spanish:** Antojitos Picofino
Other common names: Norfolk (Island) White-eye

Taxonomy. *Zosterops tenuirostris* Gould, 1837, Murrumbidgee River; error = Norfolk Island. Member of a species group which includes also *Z. lateralis*, *Z. albogularis* and *Z. inornatus*. Closely related to first of those; extinct *Z. strenuus* (formerly occurring on Lord Howe I) sometimes treated as conspecific with present species. Monotypic.

Distribution. Norfolk I, E of Australia.

Descriptive notes. 13–15 cm; 16–18 g. Has black lores continuing under and behind medium-sized white eyering, latter interrupted at front by the black of lores; forehead, crown, neck and side of head olive-green; upperparts greyish-olive to buffy olive (not sharply demarcated against greenish neck and head), uppertail-coverts more greenish; flight-feathers and tail feathers brownish-black with greenish outer margins; throat and upper breast yellow, paler yellow lower breast and citron-yellow undertail-coverts, greyish-buff belly and flanks; iris bright to yellowish-brown; bill grey; legs light grey-blue or dirty flesh-

coloured. Sexes alike. Juvenile undescribed. **VOICE.** Song said to be similar to that of *Z. lateralis* but lower in pitch and more musical in quality. Contact call a short whistle, searching call a slowly repeated “kyeeeh” and alarm “ti-hi-hi-hi”; all calls similar to those of *Z. lateralis*, but generally lower, louder and somewhat less melodious.

Habitat. Forest, forest remnants and tall secondary growth.

Food and Feeding. Invertebrates; also vegetable matter, such as fruits of lemons (*Citrus limon*), loquat (*Eriobotrya japonica*) and guavas (*Psidium*), and nectar. Wanders in small groups of 3–20 individuals through lower stages of forest. Items obtained mostly by probing, less often by gleaning.

Breeding. Sept–Dec. Nest a cup-shaped structure composed of mosses, fibrous roots and grasses, lined with hair, suspended by rim from thin twigs up to 8 m (usually lower) above ground in low tree or scrub. Clutch 2–4 eggs, occasionally up to 6, reportedly pale blue, 19.5–21.5 × 13.5–16.3 mm. No other information.

Movements. Sedentary.

Status and Conservation. **ENDANGERED.** Restricted-range species: present in Norfolk Island EBA. Confined to small island of Norfolk, less than 35 km² in extent, where moderately abundant in its habitat, which is centred today on Norfolk Island National Park. Although certainly a forest-dwelling species, is able to survive in secondary growth, and can be found throughout the island except in denuded C & S parts. Interbreeding with *Z. lateralis* ceased ten years after latter’s arrival on the island at beginning of 20th century, and the two now maintain their own discrete populations. Current threats include forest clearance, and introduced black rats (*Rattus rattus*) and probably cats. **Bibliography.** Anon. (2007n), Burchart & Stattersfield (2004), Collar *et al.* (1994), Gill, F.B. (1970b), Hermes (1985), Higgins *et al.* (2006b), Hull (1910), Mathews (1928), McCarthy (2006), Mees (1969, 1970a), Ogilvie-Grant (1912), Schodde & Mason (1999), Schodde *et al.* (1983), Stattersfield & Capper (2000), Stresemann (1931a).

56. White-chested White-eye

Zosterops albogularis

French: Zostérops à poitrine blanche **German:** Norfolkbrillenvogel **Spanish:** Antojitos Pechiblanco
Other common names: Norfolk (Island)/White-throated White-eye

Taxonomy. *Zosterops albogularis* Gould, 1837, Murrumbidgee River; error = Norfolk Island. Member of a species group which includes also *Z. lateralis*, *Z. tenuirostris* and *Z. inornatus*. Closely related to first of those. Monotypic.

Distribution. Norfolk I, E of Australia.

Descriptive notes. 13–14 cm. Has lores and area below and behind white eyering blackish, eyering interrupted at front by the black of lores; cheek greenish or greyish, forehead, crown, side of head and uppertail-coverts olive-green, merging into greenish-tinged brownish-bronze remainder of upperparts; flight-feathers and tail feathers blackish-brown, edged olive-green; throat, upper breast and middle of belly white, flanks brown, undertail-coverts citron-yellow; iris brown; bill black above, grey below; legs greyish. Sexes alike. Juvenile undescribed. **VOICE.** Little known. Song said to be more musical than

those of congeners on island (*Z. lateralis*, *Z. tenuirostris*); one individual once heard to give (in apparent subsong) perfect imitations of two introduced and locally common *Turdus* thrushes.

Habitat. Forest; found in remnants of tall rainforest, usually undisturbed, occasionally in disturbed areas.

Food and Feeding. Small caterpillars or grubs; also fruit. Fruits include e.g. wild olive (*Olea africana*), these roundish and 6 mm in diameter, and swallowed whole. Forages by moving quietly in middle and upper levels of forest; down to 4–5 m above ground in smaller trees and shrubs. Gleans insect larvae from leaves and branches; probes in foliage and branches. Occurs together with *Z. lateralis* and *Z. tenuirostris*, and sometimes forages with them in same tree.

Breeding. Oct–Dec. Cup-shaped nest made from moss, grass and fibrous roots, lined with hair, suspended in fork of twig. Clutch 2 eggs, pale blue, 21–23.5 × 15–16.6 mm. No other information.

Movements. Sedentary.

Status and Conservation. CRITICALLY ENDANGERED. Restricted-range species: present in Norfolk Island EBA. CITES I. Confined to remoter forest of Norfolk Island National Park, in NW of the island, where last confirmed sighting dates from 1980. Is believed never to have been common. Current total population “officially” fewer than 50 individuals, and almost certainly fewer than 20, within global range of just 5 km². Although formal searches have failed to find any individuals of this species for almost three decades, there have been reported sightings scattered throughout this period, including four in 1978, one in 1979, one in 1981, one in 1987, two in 1991, four in 1994 and one in March 2000; last an unconfirmed report in 2005. Causes of decline are predation by introduced rats (*Rattus*) and cats, and possibly clearing of natural vegetation, invasion of exotic weeds and competition from *Z. lateralis*, which colonized the island at beginning of 20th century. Control of predators essential for this species to have any chance of survival, if it is not already extinct.

Bibliography. Anon. (1978d, 2007n), Butchart & Stattersfield (2004), Collar *et al.* (1994), Higgins *et al.* (2006b), Hinkelmann (1988), Mathews (1928), Mees (1969, 1970a), Rooke (1985), Schodde & Mason (1999), Sibley & Monroe (1990), Stattersfield & Capper (2000), Stresemann (1931a).

57. Large Lifou White-eye

Zosterops inornatus

French: Zostérops de Lifou **German:** Lifubrillenvogel **Spanish:** Antejitos Sencillo

Taxonomy. *Zosterops inornata* E. L. Layard, 1878, Lifou, Loyalty Islands.

Member of a species group which includes also *Z. lateralis*, *Z. tenuirostris* and *Z. albogularis*. Related to and a derivative of first of those, possibly closest to its New Caledonian population (*griseonota*). Monotypic.

Distribution. Lifou I, in C Loyalty Is.

Descriptive notes. 15 cm; male 22.9–25.8 g, female 20–23.8 g. A large, plump, rather shy white-eye with slow, deliberate movements. Has eyering consisting of extremely small white feathers (invisible in field), pale grey lores and region below eye; olive-green above, mixed with grey on lower rump and uppertail-coverts, and dark olive-grey on back; remiges and rectrices brownish-black, edged olive-green; throat and breast lime-green, lower breast pale greyish, flanks buffish, centre of belly whitish or very pale yellow, undertail-coverts light yellow; iris dull or dark crimson; upper mandible black, lower mandible reddish-horn colour; legs yellowish-flesh. Differs from *Z. lateralis* mainly in reduced eyering, extent of greenish-yellow on breast, and bill and leg colours. Sexes alike. Juvenile undescribed. Voice. A low chatter, a chirp like that of a lost chick, and a less frequent low chuckling sound like that of a parrot (Psittacidae) are described as call notes; another call, or possibly song, described as a loud whistle resembling that of a whistler (*Pachycephala*).

Habitat. Primary forest and forest edge, where it prefers tall trees. May be found in low scrub at considerable distance from forest, and thus in almost any habitat on the island.

Food and Feeding. Stomachs contained a variety of fruits and berries, including figs (*Ficus*), pineapple (*Ananas comosus*), papaya (*Carica*), the blue berries of a vine, the hard seeds of a cane species, palm seeds; occasionally insects, molluscs. Forages in high trees, generally in pairs or flocks, sometimes associating with *Z. lateralis* and Striated Starling (*Aplonis striata*).

Breeding. Nov–Jan. Nest said to be like that of *Z. lateralis* but larger and thicker; clutch 2 eggs. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in New Caledonia EBA. Fairly numerous within its very small range.

Bibliography. Barré *et al.* (2006), Bruce (1975), David & Gosse (2002b), Doughty *et al.* (1999), Gadow (1884), Layard & Layard (1880), Mayr (1945b, 1967), Mees (1969), Sibley & Monroe (1990), Stresemann (1931a).

58. Dusky White-eye

Zosterops finschii

French: Zostérops de Finsch **German:** Palaubrillenvogel **Spanish:** Antejitos de Finsch
Other common names: Finsch's White-eye; Caroline/Grey White-eye (when treated as conspecific with *Z. cinereus*)

Taxonomy. *Tephros finschii* Hartlaub, 1868, Palau Islands.

Forms a superspecies with *Z. cinereus*; previously treated as conspecific, but differs in voice and behaviour. Monotypic.

Distribution. Palau Is on Babeldaob, Koror, Ngabad, Ngergoi (Garakayo) and Peleliu.

Descriptive notes. 10 cm. Plumage is almost pure sepia above, with head blacker, wing and tail browner, rump and uppertail-coverts somewhat paler and browner; lores dark, side of head and neck brownish (no white eyering); mostly brownish-grey below, chin and throat smoky grey, breast and abdomen more brown and less grey, side and flanks and undertail-coverts tawny-brown; iris reddish-brown; bill blackish-horn; legs grey. Sexes alike. Juvenile undescribed. Voice. Very noisy when in flocks; call notes “chee”, like that of *Z. semperi*, which co-occurs in Palau Is but louder and lower, and not so sweet; in flight and perched gives rollicking “chéé-che-che-ché”, resembling call of American Goldfinch (*Carduelis tristis*).

Habitat. Secondary bush, grassland, low bush of small islands; all kinds of vegetation, in addition to woodland. More in deep woodland compared with *Z. conspiciatus* of nearby Northern Mariana Is. Forages out along margins of woodlands, along roadsides, and in low trees near summits of hills.

species on all main islands (except Angaur). Very common in deep woodland, and outnumbering *Z. semperi*; less common on the smaller islands.

Bibliography. Baker (1948, 1951), Hartlaub & Finsch (1868, 1872), Marshall (1949), Mayr (1945b, 1967), Mees (1969), Owen (1977), Pratt, Bruner & Berrett (1987), Pratt, Engbring *et al.* (1980), Sibley & Monroe (1990).

59. Grey-brown White-eye

Zosterops cinereus

French: Zostérops cendré **German:** Kittlitzbrillenvogel **Spanish:** Antejitos Cenizo
Other common names: Kosrae White-eye (*cinereus*); Pohnpei White-eye (*ponapensis*); Caroline/Grey White-eye (when treated as conspecific with *Z. finschii*)

Taxonomy. *Drepanis cinerea* Kittlitz, 1832, Kosrae, Caroline Islands.

Forms a superspecies with *Z. finschii*; previously treated as conspecific, but differs in voice and behaviour. The two races are distinctive, and may well merit treatment as separate species. Two subspecies recognized.

Subspecies and Distribution.

Z. c. ponapensis Finsch, 1876 – Pohnpei, in EC Caroline Is.

Z. c. cinereus (Kittlitz, 1832) – Kosrae, in E Caroline Is.

Descriptive notes. 10–11 cm; one male 11.2 g (*ponapensis*). Nominat race is deep greyish-olive above, approaching mouse-grey on crown and upperwing-coverts; very narrow white eyering (often lacking); dirty pale or sepia below, flanks and side of breast somewhat darker than remainder, approaching colour of upperparts; iris reddish-brown; bill leaden, tip blackish; legs light brown to lead-coloured. Sexes alike. Juvenile has conspicuously yellow bill with dark tip of upper mandible, and darker plumage. Race *ponapensis* has upperparts more sepia, less grey, and forehead and underparts pale ash-grey, flanks brownish-buff. Voice.

Calls like those of a sparrow (*Passer*) and calls reminiscent of those of tits (*Paridae*) reported.

Habitat. Most vegetated habitats. On Pohnpei occurs at low altitudes in and around native gardens.

Food and Feeding. Small, large-seeded berries, seeds, also insects. Takes food items from twigs and leaves in bushes and small trees. Moves about often in noisy and quarrelsome flocks, sometimes in tops of tall trees; often solitary too, and small family groups sometimes accompany flocks of *Z. semperi*.

Breeding. Fledglings being fed by parents in Feb on Kosrae (nominat); eggs in Aug, fledgling just out of nest in Mar, on Pohnpei. Two nests found on Pohnpei, with outer layer of fine roots, fibres, leaves and petals, interwoven with cotton wool, inner layer of fibres of fine roots only, built on branch, not suspended. Clutch 1 egg, pale greenish-blue, 18.5 × 13.5 mm (Pohnpei).

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in East Caroline Islands EBA. Common on both Pohnpei and Kosrae. May have declined on Pohnpei: encounter rates (individuals per hour) in Pohnpei forest above 200 m was 37.6 in 1983 and 7.2 in 1994 (81% decrease), while below 200 m was 60.9 in 1983 and 10.4 in 1994 (83% decrease).

Bibliography. Baker (1951), Buden (2000), David & Gosse (2002b), Finsch (1880), Kittlitz (1832), Kuroda (1933b), Marshall (1949), Mayr (1945b, 1967), Mees (1969), Owen (1977), Yamashina (1932).

60. Abyssinian White-eye

Zosterops abyssinicus

French: Zostérops à flancs jaunes **German:** Somalibrillenvogel **Spanish:** Antejitos Abisinio
Other common names: White-breasted/Yellow White-eye, Abyssinian (Yellow) White-eye; Kenya (Yellow) White-eye (*flavilaterialis*, *omoensis*)

Taxonomy. *Zosterops abyssinicus* Guérin-Méneville, 1843, Ethiopia.

Sometimes included in a superspecies with *Z. pallidus*, *Z. senegalensis* and *Z. poliogastrus*. Races believed by some authors to represent two separate species, nominate, *arabs*, *socotranus* and *jubaensis* forming one species and *omoensis* and *flavilaterialis* another. Six subspecies recognized.

Subspecies and Distribution.

Z. a. abyssinicus Guérin-Méneville, 1843 – NE Sudan (region of Erkowit), Eritrea and N & C Ethiopia.

Z. a. arabs Lorenz von Lübnau & Hellmayr 1901 – SW Saudi Arabia, Yemen and S Oman.

Z. a. socotranus Neumann, 1908 – N Somalia and Socotra I.

Z. a. omoensis Neumann, 1904 – W Ethiopia.

Z. a. jubaensis Erlanger, 1901 – S Ethiopia, N Kenya (S to Kulal) and S Somalia.

Z. a. flavilaterialis Reichenow, 1892 – E, C & S Kenya S to NE & E Tanzania.

Descriptive notes. 10.2 cm; 7.2–12 g. Nominat race has yellow supraloral stripe extending to yellow area above bill, narrow blackish-brown line from lores to below narrow white eyering; cheek flecked yellow; forehead to upperparts pale greyish-green, yellower on uppertail-coverts; flight-feathers and primary coverts dark brown, edged green to yellowish-green; tail dark brown, feathers narrowly edged yellowish-green; chin to throat and centre of upper breast pale yellow, lower breast and sides pale grey, belly and thighs greyish-white, undertail-coverts pale yellow; underwing and inner borders of flight-feathers whitish; iris light red-brown to brown; bill horn-

brown above, pinkish-brown below; legs brown or flesh-coloured. Sexes alike. Juvenile resembles adult; young fledgling has lax plumage, duller upperparts and underparts, darker (black) eyes and flight-feathers, pinkish bill, thick pale yellow gape. Race *arabs* is like nominate, but with fairly dark greyish-green upperparts; *socotranus* resembles nominate, but blackish bill, brighter yellow throat, darker grey sides and underparts; *omoensis* also is like nominate, but with pale yellowish-green upperparts, brighter yellow throat, and grey underparts tinged buff; *flavilateralis* has upperparts yellowish-green, is wholly pale

powdery canary-yellow below, washed greenish on sides and flanks, bill black, eyes grey-brown, legs blue-grey to blackish; *jubaensis* is like previous, but has greyish tinge on upperparts, duller underparts. **VOICE.** Sweet and lilting song of burry quality, like that of Afrotropical congeners. Buzzing and twittering call notes by foraging groups, also plaintive calls described as "teeyu", "tew" and "tyew-tip", and sharper sibilant "pseeyp"; race *arabs* occasionally gives fine purring call reminiscent of that of Snow Bunting (*Plectrophenax nivalis*), and short, deep low "waouw".

Habitat. Broadleaf woodland and thorn-woodland (e.g. *Adenium*, *Ziziphus* on Socotra), wooded mountain slopes and wadis, bushland, savanna, forest edge, copses and thickets; common in parks and gardens; in Somalia associated with olive trees (*Olea*), acacias (*Acacia*), euphorbias (*Euphorbia*), fruiting figs (*Ficus*) and junipers (*Juniperus*). Mainly from sea-level to 1800 m; between 300 m and 3100 m, usually at middle to higher altitudes, in Arabian Peninsula.

Food and Feeding. Aphids (Aphidoidea) and other small insects, including caterpillars 10–38 mm long; fruits. Nestling diet exclusively insects, mainly small moth larvae (Lepidoptera), on first and second day, but exclusively fruits after day 6. Forages at flowers, e.g. *Acanthus arboreus*, whereby forehead often dusted with pollen. Forages in flocks of 12–20 individuals, working through canopy of tall bushes.

Breeding. Mainly Feb–Jul, but towards end of year on Socotra I. Nest built by both sexes, a small open cup or hammock of fine bark strips, cemented with spider web and often decorated externally with spider cocoons, slung in twig fork or between parallel petioles 1–3 m up in bush or tree. Clutch 2–4 eggs, pale blue, 14 × 10 mm; incubation of eggs and feeding of chicks by both parents; incubation period 11 days, nestling period 14 days; fledglings dependent on parents for several days. Nests parasitized by Eastern Green-backed Honeyguide (*Prodotiscus zambeziac*). Breeding success low; many eggs and young taken by predators.

Movements. Mainly sedentary; in most of N Tanzania (race *flavilateralis*) moves out of forest-edge habitats in Oct–Nov, but present all year in and around Arusha.

Status and Conservation. Not globally threatened. Common throughout most of its range. Occurs in several protected areas, including Serengeti National Park, in Tanzania.

Bibliography. Archer & Godman (1961), Britton (1980), David & Gosselin (2002b), Erlanger (1901), Fry *et al.* (2000), Harvey (1993), Hailom *et al.* (1988), Jennings (1981), Kirwan (2007), Lewis & Pomeroy (1989), Meinertzhagen (1954), Neumann (1904), Pearson (1983), Reichenow (1892), Short *et al.* (1990), van Someren (1956).

61. Cape White-eye

Zosterops pallidus

French: Zostérops du Cap **German:** Kapbrillenvogel **Spanish:** Antojitos de El Cabo

Other common names: (African) Pale/Pallid/Cape-and-Green White-eye; Green White-eye (*virens*, *capensis*, *atmorii*); Orange River White-eye (*pallidus*, *sundevalli*); Pale White-eye (*pallidus*, *sundevalli*, *caniviridis*)

Taxonomy. *Zosterops pallida* Swainson, 1838, east of Prieska, Northern Cape, South Africa. Sometimes included in a superspecies with *Z. abyssinicus*, *Z. senegalensis*, *Z. vaughani* and *Z. polioastrus*. Races *capensis*, *virens* and *atmorii* formerly treated as representing a separate species, nominate and *sundevalli* (often united with *caniviridis*) together constituting another species. Races *atmorii* and *virens* interbreed in Eastern Cape Province. Six subspecies recognized.

Subspecies and Distribution.

Z. p. pallidus Swainson, 1838 – Namibia and W South Africa (W Northern Cape).

Z. p. capensis Sundevall, 1850 – SW South Africa (E to W Eastern Cape).

Z. p. caniviridis Clancey, 1962 – E & SE Botswana and adjacent N South Africa.

Z. p. sundevalli Hartlaub, 1865 – C South Africa (North West Province, E Northern Cape Province, Free State).

Z. p. virens Sundevall, 1850 – extreme SW Mozambique, E South Africa (S to Eastern Cape) and Swaziland.

Z. p. atmorii Sharpe, 1877 – Lesotho and adjacent South Africa (mainly W KwaZulu-Natal).

Descriptive notes. 10–13 cm; 8–20 g. Nominant race has yellow supraloral stripe extending over base of upper mandible (narrow yellow forehead band), narrow (1 mm) white eyering, blackish loreal line broadening around lower front margin of eyering; top of head and upperparts pale dull olive-green, upperwing-coverts edged pale yellow-green; flight-feathers, primary coverts and tail blackish-brown with narrow green edges; chin, throat and undertail-coverts pale yellow, narrow olive-grey band across upper breast, tawny-buff side of breast and flanks, white or buffish-white centre of breast to belly; underwing-coverts whitish; iris

dark brown or grey-brown; bill blackish-brown, greyer base of lower mandible; legs brownish-grey or blue-grey. Sexes similar. Immature is duller than adult, eyering develops at c. 5 weeks of age. Race *virens* is larger than nominate, with darker, brighter upperparts, darker, less yellow edges of wing feathers than nominate, yellow supraloral stripe continuous with yellow forehead, brighter yellow below, with olive-green breast, flanks and belly; *caniviridis* is like previous, but with lighter upperparts, yellower underparts, olive-green more restricted to breast side and flanks; *atmorii* also resembles *virens*, but yellow below restricted to chin, throat and undertail-coverts, with buffish-grey upper breast, sides and flanks, and whitish lower breast and belly; *capensis* is like preceding race, but darker and more olive above and darker grey on underparts, usually lacks yellow on forehead and supraloral line; *sundevalli* is slightly larger than nominate, with rather greener

upperparts. **VOICE.** Daytime song composed of short subdued twittering followed by louder subsong, including mimicry, which breaks into typical song (often given alone) of slightly burry warbles and whistles; dawn song shorter, lacks first part; song described also as longish jerky phrases of sweet reedy notes, varying in pitch, volume and tempo, usually starting with "tee tee" or "pirrup pirrup" notes before becoming jumble of "tee tippee twee yip yip twee...", often incorporating brief imitations of other birds' calls. Calls include sweet piping notes or slightly trilled "pee, prree" or "pirree" for contact in flocks, and "chip-chirrrr" and "chrrree" as alarm. Some geographical variation reported: nominate race and *sundevalli* have more muted, subdued songs, a little deeper in tone, less ringing and variable, more staccato, and lower-pitched contact calls.

Habitat. Wide variety of habitats in open hilly and coastal country with scattered stands of trees, acacia (*Acacia*) thickets, savanna, dune scrub, also riverine scrub and bush, parks, wooded gardens, tree-lined streets, exotic plantations e.g. eucalypts (*Eucalyptus*), pines (*Pinus*), oaks (*Quercus*), poplars (*Populus*), wattles (*Acacia*); also tall coastal to montane evergreen forest; favours native and alien willows (*Salix*), flower gardens with hedges, ornamental and fruit trees. Sea-level to 2770 m.

Food and Feeding. Nectar, fruits and other plant parts; arthropods (mainly insects). Nectar taken from aloes (*Aloe*), *Reyena*, *Scutia*, *Watsonia*, *Tecomaria*, *Poinsettia*, *Erythrina*, *Callistemon*, grevilleas; fruit pulp of e.g. oranges taken; small soft and hard fruits eaten entire, include figs (*Ficus*), *Kiggelaria*, olives (*Olea*), *Cotoneaster*, *Pyraecantha*, *Lantana*, *Schinus*, *Rhus*, apricots, peaches, mulberries, grapes, plums, pears, blackberries; fleshy flower petals consumed. Insects include aphids (Aphidoidea), scale insects (Coccoidea), flying termites (Isoptera), moths and caterpillars (Lepidoptera), katydids (Tettigoniidae), mantises (Mantodea), stick-insects (Phasmida) up to 5 cm long, beetles (Coleoptera); also honeydew; spiders (Araneae) and their eggs taken. Visits garden birdtables, taking sugar and jam. Aphids consumed in large quantities by systematic gleaning of infested bushes, trees etc.; flying insects taken in short hawking flights, other insects seized opportunistically. In pairs and small parties throughout year; also in large flocks of up to 100 individuals outside breeding season. Although mainly arboreal, sometimes comes to within 2 m of ground in low bushwood; sometimes even down to ground to pick up insects, and dropped items, to take juice or flesh from fallen fruits, or to ingest gastroliths (e.g. sand).

Breeding. Season generally Aug–Apr in SW of range, gradually shifting to Jun–Feb in NE. Often sings from same place throughout breeding season, starting at dawn; no fixed songposts recorded during dawn song, but singers typically perched 100–300 m apart in tall trees. Nest built in 5–10 days, a small, delicate but durable cup 3.7–4.5 cm in diameter and 4.1–5.1 cm deep, made from fine plant materials, lined with some feathers and plant down, and bound together and to twigs with spider cocoons, sometimes artificial materials (e.g. string, threads and doormat coir) used as materials; usually 1–6 m above ground and concealed in dense foliage in small shrub (*Erica*, *Metastasia*, *Salvia*, *Randia*) or tree, typical site at end of horizontal branch of leafy thin-branched sapling in shade of larger trees. Clutch usually 2–3 eggs, sometimes up to 4, white (*capensis* and *virens*) or pale blue to greenish-blue (other races), 16.8 × 12.3 mm; incubation by both sexes, period c. 10.5–12 days; chicks brooded and fed by both parents, nestling period 12–13 days; young often leave nest prematurely, able to fly at 10–12 days. Success moderate to fairly good, 50–57% of nestlings survive to fledging; main nest predators are Common Fiscal (*Lanius collaris*), Southern Boubou (*Laniarius ferrugineus*) and snakes of genus *Dispholidus*. Recorded longevity in ringing studies 7 years 11 months; estimated average annual mortality of adults 35%.

Movements. Usually sedentary. There may be some movement into arid interiors of Karoo and Namaqualand (W South Africa) during austral winter and some emigration in spring; ringing records show movements of up to 164 km.

Status and Conservation. Not globally threatened. Locally very common to scarce. Locally common in S Namibia, but scarce and irregular in much of N part of range. Very common in much of South Africa. In Botswana, very common locally (Gaborone) and common in Lobatse and Kanye. Locally common in S Mozambique.

Bibliography. Bannerman (1948), Broekhuysen & Winterbottom (1968), Brown, C.R. *et al.* (2001), Brown, K.J. & Downs (2003), Bunting (1985), Clancey (1966, 1967b, 1980b), Clancey & Winterbottom (1961), Cohen & Winter (1992), Colahan (1981), Craig & Hullely (1996), David & Gosselin (2002b), Dowsett (1985), Franke *et al.* (1998), Fry *et al.* (2000), Harrison *et al.* (1997), Hullely *et al.* (2004), Kopij (2004b), Lawson (1966), Lunt *et al.* (2004), Maclean (1993), McCarthy (2006), Moreau (1957b), Noll (1992), Porter (1975), Prys-Jones (1985), Rajimakers (1999), Schmidt (1955), Sinclair *et al.* (1993), Skead (1967), Skead & Ranger (1958), Symes, Downs & Brown (2001), Symes, Nicolson & McKechnie (2008), Tree (2002), Vincent (1949), Whitelaw (1985), Winterbottom (1955).

62. African Yellow White-eye

Zosterops senegalensis

French: Zostérops jaune **German:** Senegalbrillenvogel **Spanish:** Antojitos Senegalés

Other common names: Yellow White-eye; Jackson's White-eye (*jacksoni*)

Taxonomy. *Zosterops senegalensis* Bonaparte, 1850, Senegal.

Forms a superspecies and sometimes regarded as conspecific with *Z. vaughani*; both sometimes suggested as being part of a larger superspecies that includes also *Z. abyssinicus*, *Z. pallidus* and *Z. polioastrus*, or, more unlikely, a close relationship to race *kirkii* of *Z. maderaspatanus* proposed. Races *gerhardi* and *jacksoni* have in the past been included in *Z. polioastrus*; *jacksoni* sometimes considered a separate species. Race *stenocricotus* differs vocally from others and may merit full species status. Races intergrade widely, e.g. nominate intergrades with *demeryi*, *stenocricotus* and *stuhlmanni*, and *quanzue* with *kasaicus*, *heinrichi* and *andersoni*, etc. Described races *phylliscus* from W Cameroon (Tatum, in Bamenda Highlands) and *poensis* from Bioko I (in Gulf of Guinea) synonymized with *stenocricotus*. Fourteen subspecies recognized.

Subspecies and Distribution.

Z. s. senegalensis Bonaparte, 1850 – S Mauritania, Senegal and Guinea E to S Chad, Central African Republic (except SW), S Sudan, NW Ethiopia and N Eritrea.

Z. s. demeryi Büttikofer, 1890 – Sierra Leone, Liberia and Ivory Coast.

Z. s. stenocricotus Reichenow, 1892 – SE Nigeria, highlands of Cameroon and SW Central African Republic S to N Gabon; Bioko I (Fernando Póo).

Z. s. gerhardi van den Elzen & König, 1983 – S Sudan and NE Uganda.

Z. s. toroensis Reichenow, 1904 – NE DR Congo and W Uganda.

Z. s. reichenowi A. J. C. Dubois, 1911 – E DR Congo (highland forests W of L Kivu and NW of L Tanganyika).

Z. s. stuhlmanni Reichenow, 1892 – SC Uganda S to NW Tanzania.

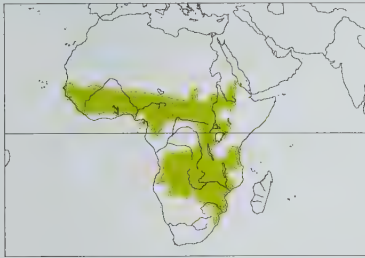

Z. s. jacksoni Neumann, 1899 – highlands of Kenya and N Tanzania (Loliondo).

Z. s. stierlingi Reichenow, 1899 – highlands of E Zambia, S & E Tanzania, Malawi and N & NW Mozambique.

Z. s. kasaicus Chapin, 1932 – C DR Congo S to NE Angola.

Z. s. heinrichi Meise, 1958 – NW Angola.

Z. s. quanzae Meyer de Schauensee, 1932 – C Angola.
Z. s. anderssoni Shelley, 1892 – savannas of SE Zaire, SW Tanzania, W Malawi and W Mozambique S to S & E Angola, N Namibia, N & NE Botswana, Zimbabwe plateau and N South Africa (E Limpopo lowveld).
Z. s. tongensis Roberts, 1931 – lowlands of SE Zimbabwe, S Mozambique and NE South Africa (NE KwaZulu-Natal).

Descriptive notes. 11·5 cm; 6·8–14·1 g. Nominate race has broad area of yellow on forehead and above eye, rather narrow white eyering, black on loreal area extending back under eyering; crown and upperparts greenish-yellow, yellow on rump and uppertail-coverts; flight-feathers and primary coverts dark brown, edged greenish to yellow-green; tail brown, narrowly fringed yellowish; check, throat and underparts bright yellow, more greenish on sides, flanks and often in diffuse band across breast (at times contrasting noticeably with yellow throat and belly); underwing-coverts creamy white; iris brown; bill dark horn to

blackish above, paler below; legs grey or blue-grey. Sexes alike. Immature is like adult, but paler below. Races differ mainly in plumage tone and pattern: *demeryi* is greener above than nominate, with narrower yellow forehead band and supraloral stripe, slightly paler below, breast side and flanks greenish; *stenocricotus* is more richly coloured than previous, has broader yellow forehead and supraloral stripe, darker green above and on body side below, contrasting with otherwise yellow underparts; *stuhmanni* is like *demeryi* but slightly larger, with slight brownish or cinnamon tinge on upperparts, has forehead and supraloral area yellower, breast side and flanks olive-green (contrasting less with yellow ventral parts than in preceding race); *gerhardi* is similar to last but lacks brownish tinge on upperparts; *toroensis* is smaller and paler than previous; *reichenowi* is large, dark green above with little yellow on forehead, mainly greenish below, with yellow confined to chin, throat and centre of belly; *jacksoni* is like *stenocricotus*, but eyering larger and better defined; *stierlingi* is similar to previous but smaller, with paler upperparts, less yellow on forehead, narrower supraloral stripe, and yellower below, with slightly less green on side; *kasaicus* is small, dull green above, with no yellow on forehead, olive-green flanks, narrow eyering; *heinrichi* is larger and slightly brighter than last, with yellow forehead; *quanzae* is rather large, with entirely green upperparts and side of head, olive-green breast and flanks, yellowish chin, throat and belly also tinged green; *anderssoni* is similar to nominate but larger, and with yellowish-green upperparts and side of head, and breast side tinged green; *tongensis* is like last, but slightly duller and greener above and duller yellow below, tinged more olive on side. **VOICE.** Song from top of tall forest tree, at and shortly after dawn (seldom continues for long after sunrise), a rising-and-falling series of 12–30 burred notes, often introduced by 4 or 5 clear slurred notes, “tree-turri weecu-teu, dzree-dzri-dzee chiri-tseeu-tseu zhee-zhee chew-chew-chew dzi-chew dzi-chew tze-zizi-chew”; described also as a melodious whistled warble like that of Willow Warbler (*Phylloscopus trochilus*), “tsee-tseer-tsi-tsi-tseer-tsee”, followed by pause before next phrase; other songs described are faster, almost a trill or chatter. Song in Cameroon highlands (race *stenocricotus*) very different, lacks burry quality of songs of other races. Song repeated frequently, sometimes in turn by two or more birds 100–150 m apart. Contact calls a soft piping and twittering, rather tinny; other calls include repeated rolling rasp, “sreep”, and a faster “sreep-sreep-sreep”.

Habitat. Wide variety of habitats, from woodland (*Isoberlinia*, *Brachystegia*, *Baikiaea*, *Uapaca*), open primary forest (not in interior), forest clearings, riverine bushes and wooded swamps, to thorn bushes, forest-grassland mosaic, acacia (*Acacia*) and savanna woodland, cultivated land, smallholdings, rural and urban gardens, parks, boulevards in towns, and plantations e.g. of flowering eucalypts (*Eucalyptus*). Generally avoids high forest and secondary forest. Mainly in highlands, above 1100 m; it extends to 3400 m in giant-heath (*Erica*) and moorland zones (except where *Z. polioastrus* present); in Ethiopia and in S of range found in lowlands.

Food and Feeding. Mainly small arthropods, e.g. aphids (Aphidoidea), small moths and many caterpillars (Lepidoptera), flies (Diptera) and termites (Isoptera); also nectar (of *Eucalyptus*, *Grevillea robusta*), juices, wild and cultivated fruits (e.g. *Ficus burtdavyi*, *Cussonia*, *Tetrorchidium*, grapes); occasionally small seeds. Forages in small loose parties of 4–10 individuals in forest, sometimes up to 50 individuals in farmland and towns; also a nuclear species in mixed flocks, e.g. where 17–20 % of flocks of race *anderssoni* in Zambia mixed with sunbirds (Nectariniidae), Brubrus (*Nilaus afer*) and sylviid warblers e.g. Green-capped Eremomela (*Eremomela scotops*). Keeps in dense foliage in upper half of trees.

Breeding. Probably mainly Sept–Oct in W, C & S parts of range, and Sept–Mar (occasionally to Jul) in E, but in many places breeding recorded throughout year and apparently dependent on local climatic patterns. Nest built by both sexes, taking c. 7 days, a small, compact but thinly constructed

cup made from fine plant material (grass strips, bark, chaffed grass, twiglets, etc.) bound with some spider web, and attached to supporting twiglets and live leaves with spider cocoons, or placed in vertical or horizontal fork of twig, well concealed 1–3·5 m from ground at tip of branch, near top and centre of dense shrub. Clutch 1–4 eggs, usually 2–3, immaculate white to bluish or bluish-green, average dimensions 15·3 × 11·7 mm; incubation by both sexes, period 11 days; chicks fed by both parents, nestling period 14 days. Nests parasitized by Klaas’s Cuckoo (*Chrysococcyx klaas*) and Eastern Green-backed Honeyguide (*Prodotiscus zambeziae*). Recorded longevity 5–7 years; average annual survival rate 34%.

Movements. Resident; may move locally during non-breeding period, e.g. reportedly more common in winter (especially Jul) in Zimbabwe.

Status and Conservation. Not globally threatened. Frequent to locally common, and generally widespread throughout range. Rather unevenly distributed in W Africa, where uncommon in some areas.

Bibliography. Bannerman (1948), Borrow & Demey (2001), Britton (1980), Chapin (1954), David & Gosselin (2002b), Dowsett (1985), Dowsett *et al.* (2008), Eisentraut (1973), Elgood (1982), Fry *et al.* (2000), Gatter (1997), Gore (1990), Grimes (1987), Harrison *et al.* (1997), Irwin (1981b), Kalinganire *et al.* (2001), Kunkel (1975), Louette (1981), Mackworth-Præd & Grant (1945a), Maclean (1993), McGregor *et al.* (2007), Neumann (1902), Reichenow (1892), Serle *et al.* (1977), Vernon (1985), Vincent (1949), White (1963), Williams & Arlott (1980), Winterbottom (1943), Wolff-Metternich & Stresemann (1956), Zimmerman *et al.* (1996).

63. Pemba White-eye

Zosterops vaughani

French: Zostérops de Pemba **German:** Pembabrillenvogel **Spanish:** Anteojitos de Pemba

Taxonomy. *Zosterops vaughani* Bannerman, 1924, Pemba Island.

Forms a superspecies with *Z. senegalensis* and sometimes regarded as conspecific, but differs in appearance and voice; both sometimes suggested as being part of a larger superspecies that includes also *Z. abyssinicus*, *Z. pallidus* and *Z. polioastrus*. Monotypic.

Distribution. Pemba I and adjacent coral islets, off NE Tanzania.

Descriptive notes. 10–10·5 cm. Has prominent black loreal spot and very narrow (c. 1 mm) and inconspicuous white eyering; broad yellow on forehead, extending to above lores and eye, merging into greenish on crown; upperparts yellowish-green; flight-feathers blackish-brown, narrowly edged yellowish, tertials brown with greenish-yellow edges; alula blackish-brown, inner webs tinged green, primary coverts brown, tinged green; tail blackish-brown, outer webs narrowly edged greenish towards base, central pair of feathers yellowish-green; yellow below, washed greenish-olive on sides and flanks, pale yellow axillaries,

yellow-tinged whitish underwing-coverts; iris dark brown to blackish; bill black, blue-grey base of lower mandible; legs blackish or slate-grey. Sexes alike. Immature is like adult. **VOICE.** Song high-pitched and sweet, “seweet-sureteet-trwerila-eeta-eet” or “weet, su-weet-see-sur-seeiwee-see”, first note distinct, others often run together, the whole lasting 5–8 seconds; shorter but fuller than that of *Z. senegalensis*. Low liquid twittering trill 0·5 seconds long also given.

Habitat. Woody vegetation: mangrove forest, bushland, thickets on coral rag (rubbly limestone of ancient coral reef material), copses and hedges in grassland, clove (*Syzygium aromaticum*) plantations, gardens. Highest frequencies in coral-rag scrub.

Food and Feeding. Mainly fruits and berries of *Margaritaria discoidea*, *Antidesma venosum*; particularly fond of fruits of wild mulberry (*Morus nigra*), flowerbuds of chillies (*Capsicum*), seeds of *Tacca leontopetaloides*, and soft seeds. Also insects. Forages in pairs and in groups of up to 20 or more individuals. Searches in foliage.

Breeding. Aug–Mar, mainly Oct–Dec. Nest a small open cup of fine grass or palm fibres, placed 1–3 m above ground in branches of shrub or small tree, often in young clove tree. Clutch 2 eggs, pale blue. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Pemba EBA. Abundant; one of the commonest bird species throughout its tiny range, including on coral islets.

64. African Montane White-eye
Zosterops poliogastrus

French: Zostérops alticole **German:** Heuglinbrillenvogel **Spanish:** Antejitos Serrano
Other common names: Broad-ringed White-eye, Heuglin's/Highland/(African) Mountain White-eye; Kikuyu White-eye (*kikuyuensis*); Kula White-eye (*kulalensis*); Mbulu White-eye (*mbuluensis*); South Pare White-eye (*winifredae*); Taïta/Teita White-eye (*silvanus*)

Taxonomy. *Zosterops poliogastra* Heuglin, 1861, highlands of Ethiopia. Sometimes thought to form a superspecies with *Z. abyssinicus*, *Z. pallidus*, *Z. senegalensis* and *Z. vaughani*. Races *gerhardi* and *jacksoni* of *Z. senegalensis* have at times been included in present species, but seem closer to former species. Geographical variation quite well marked; each of the races *silvanus*, *kikuyuensis*, *eurycritotus*, *kulalensis*, *winifredae* and *mbuluensis* has been considered to be a full species. Eight subspecies recognized.

Subspecies and Distribution.

Z. p. poliogastrus Heuglin, 1861 – Eritrea, and Ethiopian Highlands (except W, SW) S to Addis Ababa (also Yavello) and E to Harar; and locally in mountains of SE Sudan (Imatong, Dongotona, Didinga).
Z. p. kaffensis Neumann, 1902 – W & SW Ethiopia.
Z. p. kulalensis J. G. Williams, 1948 – Mt Kulal, in N Kenya.
Z. p. kikuyuensis Sharpe, 1891 – C Kenyan Highlands from Meru district, Mt Kenya and Aberdare Mts S to Nairobi.
Z. p. eurycritotus G. A. Fischer & Reichenow, 1884 – N Tanzania (Mt Kilimanjaro region, Arusha, Mt Meru, Essimingo, Lössogono, Lolikissale).
Z. p. mbuluensis W. L. Sclater & Moreau, 1935 – S Kenya (Namanga Hill and Chyulu Hills) and N Tanzania (from Mt Hanang, Mbulu and Crater Highlands, Mt Ketumbeine and Longido E to N Pare Mts).
Z. p. silvanus J. L. Peters & Loveridge, 1935 – Mt Kasigau and Teita Hills, in SE Kenya.
Z. p. winifredae W. L. Sclater, 1934 – S Pare Mts, in NE Tanzania.

Descriptive notes. 11.5–12 cm, 11–11.3 cm (*silvanus*); 9–14 g. Nominate race has distinct yellow forehead and forehead extending to between eyes, white eyering 1–2 mm wide, narrow black line through lores and lower front edge of eyering; crown and upperparts green; flight-feathers and primary coverts blackish-brown, edged green to yellowish-green, tail dark brown with narrow green outer edges; chin and throat yellow, breast side and band across upper breast pale grey, flanks greyish-buff, centre of breast and belly white, sometimes tinged yellow, thighs and undertail-coverts yellow; axillaries pale yellow, underwing-coverts white

with yellow tinge; iris brown or hazel; bill black; legs slate to pale grey. Differs from *Z. abyssinicus* mainly in larger size, darker plumage, more yellow on forehead. Sexes alike. Immature resembles adult. Race *kikuyuensis* is rich green above, with very broad (3 mm) eyering, very broad and well-defined golden-yellow forehead band (to above lores and eyes), has centre of breast to undertail yellow, breast side and flanks dark green; *kaffensis* is like previous but with forehead as nominate, much narrower eyering (1–2 mm); *kulalensis* has relatively narrow eyering margined with black below and on lores, distinct yellow forehead, dark grey sides and flanks contrast with limited greenish-yellow of throat and upper breast, pale yellowish-white mid-ventral streak from breast to yellow vent, female only faintly yellowish-white on belly and paler grey on sides and flanks than male; *mbuluensis* has yellow forehead narrower and not sharply defined, merging with yellow-green of crown, eyering somewhat narrow (2 mm), golden-yellow below, paler green on sides; *eurycritotus* has very broad eyering, no yellow on forehead, mostly dark greenish below, some yellow on throat, yellow undertail-coverts; *winifredae* is smaller than preceding races, grey-bellied and similar to *kulalensis*, but darker above, forehead less yellow, darker and more blue-grey sides, mid-ventral stripe greyish-white, yellow undertail-coverts tinged green; *silvanus* is rather small, with very broad (4 mm) eyering but yellow restricted to supraloral band, belly grey. **Voice.** Song in C Kenya (race *kikuyuensis*) described as “three zhee zhee zhee zhee zhee zhee zhee”, in SE Kenya (*silvanus*) as a slow warbling “see tee tee tee, tee see tee see-chew...”. Typical buzzing and twittering calls from moving flock. Distinctive foraging calls include clear, slightly querulous but not buzzing “kweer-a-ree-ree” or “tree-tree, ter-ree-tee” or “kwerakwee-kwee-kwee”; foraging call in C Kenya (*kikuyuensis*) “whii-tu-tu-her-tu” or “whii-tew”.

Habitat. Highland forest, forest edge, bamboo and wooded gardens, *Euphorbia* and olive trees (*Olea*), eucalypt (*Eucalyptus*) and conifer woods; in NE Tanzania, race *winifredae* is found in the heath (*Erica*) vegetation at forest edge and in interior light gaps, but also in low (1 m) *Erica*. Found at 1380–3400 m, mostly above 1500 m. In dry season Mt Kulal race (*kulalensis*) found only in montane forest, where more abundant in glades than in closed-canopy forest; in wet season in forest and drier bush at lower altitudes, preferring young tree formations with thicker vegetation, and thus less restricted to mature forest than was previously thought.

Food and Feeding. Small berries, pieces of figs (*Ficus*), papaw (*Carica*) pulp; also invertebrates, especially aphids (Aphidoidea); also nectar (of exotic *Grevillea robusta*). Race *kulalensis* mainly frugivorous in dry season, insectivorous in wet season. Nestling diet small spiders (Araneae) and tiny caterpillars. In flocks of up to 30 individuals; *kulalensis* in larger flocks (up to 50 birds) in dry season, but in wet season flocks larger in morning and late afternoon.

Breeding. Nov–Apr in Sudan, Apr–Dec (mainly Apr) in Ethiopia, and Feb–Jun (mainly Apr–May) in E Africa; double-brooded in long season. No apparent territoriality; two nests may be close together. Nest built by both sexes, taking 7–10 days, a small cup 4.5 cm in diameter and 3.5 cm deep, neat inside, made of beard lichen (*Usnea*), moss, fine fibres and spider web, sometimes decorated externally with green moss and spider cocoons, slung between two stems, arms of a fork etc. in bush or tree, protected from rain and sun by overhanging foliage. Clutch 2–3 eggs, blue or white, 17–18 × 12 mm; incubation by both sexes, no information on duration; nestling period 15 days.

Movements. Mainly sedentary. In N Kenya, race *kulalensis* descends in dry season from montane habitat (1675 ha) on top of Mt Kulal to forest and drier shrub (7100 ha) at lower altitudes.

Status and Conservation. Not globally threatened. Locally common to rare. Race *silvanus* (sometimes treated as full species) previously considered Critically Endangered, subsequently downgraded to Endangered; a restricted-range taxon, present in Kenyan Mountains EBA. Following a study of this race in 1998–1999, population estimated at 7100 individuals; occurs in and adjacent to tiny areas (less than 3 km²) of forest remaining on Teita Hills and similarly small area on nearby Mt Kasigau, its main stronghold (very high density of 26 birds/ha, 80% of total population), but no interchange found between the hills and Mt Kasigau; despite abundance and capability of foraging far from forested areas, at risk because of further degradation of the core area. Race *kulalensis* (sometimes treated as full species) is Vulnerable; a restricted-range taxon, present in Mount Kulal Secondary Area; on Mt Kulal was abundant by 1980 in the 40 km² of forest, heavily penetrated and degraded by herds of cattle; population estimated at 10,000 individuals in Nov 1997. Race *winifredae* (sometimes treated as full species) is Vulnerable; a restricted-range taxon, present in Tanzania-Malawi Mountains EBA; in Oct–Nov 1992 was fairly common, with total of several thousands of individuals in four reserves, namely the Chombe Catchment Forest Reserve (143 km²), Mwala Forest Reserve (14 km²), and Kwizu and Chambogo Catchment Forest Reserves (combined 80 km²); these forests are under human pressure. Otherwise, race *kikuyuensis* is very common in the forests around Nairobi, on the Aberdares, and on Mt Kenya, and elsewhere local.

Bibliography. Barnes & Brooks (1997), Borghesio & Laiolo (2004), Borghesio & Ndag'ang'a (1999), Britton (1980), Butchart & Stattersfield (2004), Collar & Stuart (1985, 1988), Collar *et al.* (1994), David & Gosselin (2002a, 2002b), Diamond & Keith (1980), Fry *et al.* (2000), Heuglin (1861), Kalinganire *et al.* (2001), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1945a, 1945b, 1946), Mulwa *et al.* (2007), Nikolaus (1987), Pearson (1983), van Someren (1956), Stattersfield & Capper (2000), Williams & Arlott (1980), Zimmerman *et al.* (1996).

65. Mascarene White-eye
Zosterops borbonicus

French: Zostérops des Mascareignes **Spanish:** Antejitos de las Mascareñas
German: Maskarenenbrillenvogel
Other common names: Bourbon White-eye, (Réunion/Mascarene) Grey White-eye; Mauritius Grey White-eye (*mauritanus*)

Taxonomy. *Motacilla borbonica* J. F. Gmelin, 1789, Bourbon and Madagascar; error = Île Bourbon (Réunion).

Race *mauritanus* sometimes considered to represent a separate species. Very variable in overall colour, and nominate race polymorphic and with partly clinal variation. Two additional races described from Réunion, *alopekion* (Cilaos) and *xerophilus* (Étang Salé les Bains), appear to be colour morphs of nominate. Two subspecies recognized.

Subspecies and Distribution.

Z. b. borbonicus (J. F. Gmelin, 1789) – Réunion.
Z. b. mauritanus (J. F. Gmelin, 1789) – Mauritius.

Descriptive notes. 10.7–11.4 cm; male 8.2 g, female 7.9 g. Distinctive white-eye with white rump, no eyering; the only white-eye that characteristically cocks the tail. Nominate race has crown, back and upperwing-coverts slaty grey or brownish, rump and uppertail-coverts white; lores dusky, variable narrow whitish line above, ear-coverts lighter ashy than back; flight-feathers blackish, narrowly edged slaty, a little more hoary on primaries, tail feathers blackish, edged grey on outer webs, edged whitish on inner webs; cheek and chin hoary white, throat to breast ashy grey, abdomen whitish with slight ashy tinge, body sides and

flanks ashy grey, thighs and vent white with slight ashy tinge, underwing-coverts and axillaries white; obvious pale stripe running down sides of puffed-out breast and flanks (gives unusual “epaulette” effect); iris bright hazel to chestnut or dull brown; bill dull lead-colour, base of lower mandible paler; legs dull lead. Nominate race polymorphic: brown-backed with grey head in N & E, grey-headed with brown nape in S, and brown-headed and brown-backed in W & C parts of island; and others, with grey back and grey head, which rarely occur below 700 m but increase to 65–100% of population above 1300 m in N & E, and rarely below 1200 m in W; within and between each morph a complete range of colours, but with low proportion of intermediates; apart from plumage differences, morphs differ slightly also in weight and bill length (often related to sex and altitude), and grey morphs slightly larger than brown morphs, also other biometric differences recorded. Distinguished from sympatric *Z. olivaceus* and *Z. chloronothos* mainly by paler appearance, much greyer (not olive-green) plumage, and white rump. Sexes identical. Juvenile is like adult, but young fledgling has yellow gape. Race *mauritanus* has delicate bluish-grey upperparts, white cheeks, throat and underparts, slightly tinged with grey on forehead and breast, and washed rusty on side of body and flanks. **Voice.** Song on Réunion (nominate race) an elaborate loud warble; also an assemblage of sweet warbled phrases, “chip” notes, sputters and squeaks reminiscent of a catbird (*Dumetella*). Song on Mauritius (*mauritanus*) a whistled warbling. Calls include “plee plee plee” as contact; also varied “chee chee chee”, plaintive “eeee” or double “eeee-eee” (on Réunion), and soft inflected, slightly warbled “p-tree” or “p-tee” (on Mauritius).

Habitat. Scrub-forest, highland heath, evergreen forest, pine (*Pinus*) and casuarina (*Casuarina*) forest, gardens, natural forest at higher altitudes; also seasonally in exotic vegetation at lower elevations. Has adapted to man-made forest-like habitats, such as orchards, timbered gardens and plantations, also secondary forest, but absent from sparsely vegetated natural habitats, and cane fields, geranium fields, sparse dry thorn-scrub etc. On Mauritius visits tea plantations (for nectar), market gardens, wasteland, scrubby secondary growth with odd trees and town gardens for feeding.

Food and Feeding. Primarily insectivorous; also fruits and nectar. Insects include especially Hemiptera (*Flatopsis nivea* often taken), grasshoppers and crickets (Orthoptera), caterpillars and small butterflies (Lepidoptera). Fruits e.g. *Aphloia theiformis* at high altitudes, also exotic *Lantana camara*, *Schinus terebinthifolius*. Nectar (taken by probing and sometimes puncturing corolla base) mainly from the introduced species *Lantana camara*, tea (*Camellia*) and *Syzygium jambos*, but also native species e.g. *Eugenia mauritiana*, *Bertiera zaluziana*, *Sideroxylon*, *Gaetnera*; sweet sap oozing

On following pages: 66. Principe White-eye (*Zosterops ficedulinus*); 67. Annobon White-eye (*Zosterops griseovirescens*); 68. Malagasy White-eye (*Zosterops maderaspatanus*); 69. Chestnut-sided White-eye (*Zosterops mayottensis*); 70. Seychelles Grey White-eye (*Zosterops modestus*); 71. Mount Karthala White-eye (*Zosterops mouroiensis*); 72. Réunion Olive White-eye (*Zosterops olivaceus*); 73. Mauritius Olive White-eye (*Zosterops chloronothos*); 74. Yap Olive White-eye (*Zosterops oleagineus*).

from trees also taken. On Réunion more fruits eaten in winter (Jun–Jul), whereas fruits rarely eaten at high altitudes in summer; above 2000 m buds of *Philippia nontana* eaten where fruit-bearing plants absent, and when insects scarce (in winter). On Mauritius fruits less regularly eaten. Forages throughout year in noisy parties of 4–10 individuals, sometimes up to 20 (on Réunion), and 35 or more and once 81 (on Mauritius); on Mauritius these flocks sometimes joined by other species, such as *Z. chloronothos*, Mauritius Fody (*Foudia rubra*), cuckoo-shrikes (*Coracina*), monarchid flycatchers, and also introduced Red-whiskered Bulbul (*Pycnonotus jocosus*). Insects obtained by gleaning from foliage, by foraging among flowers, along twigs, on bark, probing in rotten wood, on the ground; aerial flycatching reported.

Breeding. Sept–Dec, occasionally to Feb, and adults feeding young observed in Aug on Réunion; Jul–Mar on Mauritius. Helpers feeding young reported for both races; nests sometimes in loose semi-colonial groups, no territoriality or nest defence, but breeding units reported as holding very small (c. 1 ha) territory. Striking white axillaries and rump important in courtship display. Nest on Réunion a small delicate cup of fine stems, covered in green moss when in foliage (e.g. casuarina branchlets), or with grey-white material (possibly lichen), and sometimes with dead leaves in more exposed areas, attached to twigs at 1–5 m in tree; on Mauritius a thin though robust structure made of moss, lichen, leaves or rootlets and (locally) dry grass, held together with spider web, lined with loosely coiled fine hairs, attached to supporting twigs in foliage towards end of a branch. Clutch 2–3 (occasionally 4) eggs on Réunion, 2 eggs on Mauritius, pale blue; no information on incubation period; fledging period 10 days. Longevity of ringed individual on Mauritius 4 years 11 months.

Movements. Resident. On Réunion, reports of some movement up and down 1000-m hills to visit flowering *Sophora* plants.

Status and Conservation. Not globally threatened. Restricted-range species: present in Réunion EBA and in Mauritius EBA. Common on Réunion, where population estimated at 556,000 individuals in 1967; although white-eyes have not suffered from habitat modification by humans, the balance of polymorphism on the island undoubtedly has been affected. Most common and conspicuous white-eye on Mauritius, locally reaching densities of 150 “pairs”/km²; reported numbers in native habitat substantially higher than those of all other native bird species combined. Main predator on Réunion is Madagascar Marsh-harrier (*Circus maillardi*); on Mauritius, a known predator is Mauritius Kestrel (*Falco punctatus*), but Red-whiskered Bulbul also considered responsible for nest losses. Avian malaria may limit the distribution of white-eyes outside undisturbed forest.

Bibliography. Buffon (1778), Cheke (1987b), David & Gosselin (2002b), Diamond (1987), Gadow (1884), Gill (1971a, 1973), Hansen *et al.* (2002), Horne (1987), Sinclair & Langrand (1998), Temple (1981), Warren *et al.* (2006).

66. Principe White-eye

Zosterops ficedulinus

French: Zostérops beeffigue **German:** Fahlbrillenvogel **Spanish:** Antojitos de Principe
Other common names: Sao Tome White-eye (*feae*)

Taxonomy. *Zosterops ficedulina* Hartlaub, 1866, hilly parts of Principe.

Closely related to and possibly forming a superspecies with *Z. griseovirescens*. Two subspecies recognized.

Subspecies and Distribution.

Z. f. ficedulinus Hartlaub, 1866 – Principe I, in Gulf of Guinea.

Z. f. feae Salvadori, 1901 – São Tomé I, in Gulf of Guinea.

legs brownish-grey. Sexes alike. Juvenile undescribed. Race *feae* is slightly darker and uniformly greenish above, including top of head, greyer below on throat, breast and flanks, with patches of tawny-rufous on posterior flanks. **Voice.** Powerful dawn song a monotonous and insistent, rapid series of 3–6 burry “ptirr” notes, last note more stressed; more complex song of burry, tinny and musical notes given during the day. Contact calls “prrip, prrip...”; flight calls high pitched weak “pink-pink-pink...”, and during foraging chipping notes with thin buzzes and dry tuneless “tyup” or “tyew” described.

Habitat. On São Tomé dense primary and degraded rainforest from sea-level to 1000 m, mainly above 400 m; also patches of dry woodland and isolated large trees in savanna. On Principe in forest and canopy of tallest trees in plantations in hilly interior.

Food and Feeding. Insects and berries. In pairs, family parties, and flocks of up to 20 individuals; often in mixed flocks with speirops (*Speirops lugubris* and *Speirops leucophoebus*), Sao Tome Prinia (*Prinia melleri*), Sao Tome Paradise-flycatcher (*Terpsiphone atrochalybeia*) and Newton’s Sunbird (*Anabathmis newtonii*). Forages in middle levels and in canopy. Gleans insects from twigs, leaves and other vegetation.

Breeding. Laying from Sept onwards, and fledglings seen in Feb. Nest a neat open cup slung under forked twig; clutch 3–5 eggs. No other information.

Movements. Resident; possibly some local movement on São Tomé.

Status and Conservation. **VULNERABLE.** Restricted-range species: present in São Tomé EBA and in Principe EBA. Rare to locally uncommon. Has declined seriously on Principe, where habitat destruction has been extensive, but was for unknown reasons rare in past century, with 2–3 specimens collected in 1920s, and none seen in 1970s; survives in the C massif, where it is mainly confined to primary forest, and more recently a flock was observed on R Papagaio; may still be present in SW of the island. Similarly, has declined worryingly on São Tomé, where it was common in 1920s, uncommon in 1970s, and generally rare and only locally quite common in 1990; seems to fluctuate in numbers, and is at risk from clearance of high-altitude rainforest for cocoa plantations.

Bibliography. Anon. (2007n), Atkinson *et al.* (1991), Bannerman (1914, 1948), Borrow & Demey (2001), Butchart & Stattersfield (2004), Christy & Clarke (1998), Collar & Stuart (1985), Collar *et al.* (1994), David & Gosselin

(2002b), Eccles (1988), Fry *et al.* (2000), Günther & Feiler (1985), Jones & Tye (1988, 2006), Keulemans (1866), Nadler (1993), de Naurois (1983), Stattersfield & Capper (2000).

67. Annobon White-eye

Zosterops griseovirescens

French: Zostérops d’Annobon **German:** Annobonbrillenvogel **Spanish:** Antojitos de Annobón

Taxonomy. *Zosterops griseovirescens* Bocage, 1893, Annobón.

Closely related to and possibly forming a superspecies with *Z. ficedulinus*. Monotypic.

Distribution. Annobón I (Pagalu), in Gulf of Guinea.

Descriptive notes. 12 cm; two birds 11 g. Top of head and upperparts are greyish-olive, with paler side of crown, sometimes a narrow creamy pale green to lemon-yellow supraloral line; conspicuous white eyering broader above than below and broken at front (and sometimes behind eye), black lores and dusky line below and behind eye; ear-coverts streaked greyish; flight-feathers blackish-brown, edged olive-green; central tail feathers olive-green, the rest blackish with broad olive-green fringes on outer webs; very pale sulphur-yellow on chin, throat, midline of belly and vent, otherwise buff below, greyer at side, with pale tawny-buff

flanks; axillaries and underwing-coverts white; iris light brown; bill blackish or horn-brown; legs brownish-grey. Sexes alike. Immature is like adult but slightly yellower below. **Voice.** Song remarkably melodious, a pleasant, quiet warble of indefinitely jumbled notes derived from flight call, reminiscent of song of a *Sylvia* warbler. Flight call a single “plic” or “tsip”, often several in quick succession; trilling “churr” when perched.

Habitat. Woody vegetation of all types, from moist forest, dry *Steganthus/Lanea* forest, savanna forest, and dense oil palm (*Elais guineensis*) and mango (*Mangifera*) plantations to small shrubs and trees around grassy cultivated patches of cassava (*Manihot esculenta*). Sea-level to highest peak, at 655 m.

Food and Feeding. Mainly small insects, especially ants (Formicidae); also small seeds. In pairs and in flocks of up to ten individuals. Forages from smallest bush to crowns of tallest emergent trees, but keeps mainly to lower strata in primary and regrowth forest.

Breeding. Laying Oct–Feb. Nest a small, neat, closely woven and quite robust cup of fine grass and vegetable fibres, placed among small twigs in small acacia tree (*Acacia*), cassava bush, or even in introduced “leafless” cactus *Rhipsalis* hanging on rock face in shady bouldery ground. Clutch 2 eggs, white, 18 × 13.5 mm. No other information.

Movements. Sedentary.

Status and Conservation. **VULNERABLE.** Restricted-range species: present in Annobón EBA. Abundant. Total population guessed at 7000–9000 individuals. The dominant bird species on the tiny island (17.5 km²) of Annobón, where the only other resident passerine is the Annobón race of Red-bellied Paradise-flycatcher (*Terpsiphone rufiventer smithii*). Population may even be growing with disturbance of vegetation. Nevertheless, it has a tiny global range, and any natural catastrophic events would put it at serious risk.

Bibliography. Anon. (2007n), Bannerman (1915b, 1948), Basilio (1957), Borrow & Demey (2001), Butchart & Stattersfield (2004), Collar & Stuart (1985), Collar *et al.* (1994), Fry (1961), Fry *et al.* (2000), Harrison (1990), Jones & Tye (2006), Sibley & Monroe (1990), Stattersfield & Capper (2000).

68. Malagasy White-eye

Zosterops maderaspatanus

French: Zostérops malgache **German:** Madagaskarbrillenvogel **Spanish:** Antojitos Malgache
Other common names: Madagascar White-eye; Kirk’s White-eye (*kirkii*); Hova (Grey-backed White-eye (grey-backed morphs))

Taxonomy. *Motacilla maderaspatana* Linnaeus, 1766, Madagascar.

Distinctive race *kirkii* sometimes treated as a separate species, or as a race of *Z. senegalensis*. Race *menaiensis* poorly defined and of uncertain validity; owing to its geographical isolation and different calls (which considered by some authors to be reasons for treating this as a separate species) it is probably best retained, pending further studies. Proposed form *hovorum* (Madagascar), formerly treated as a separate species, is not a valid taxon; original description was based on a single specimen of an aberrant form (with grey upperparts), two similar examples of which have since been found on Cosmolédo Atoll (SW Seychelles). Additional described taxa from Madagascar are *ampotakae* (a small form from Ampotaka, in dry SW plain) and *analogus* (a slightly larger montane form described from Manjakatomp, in Ankaratta Mts); both are treated as synonyms of nominate. Seven subspecies recognized.

Subspecies and Distribution.

Z. m. aldabrensis Ridgway, 1894 – Aldabra Atoll (possibly also still on Assomption), in SW Seychelles.

Z. m. menaiensis Benson, 1969 – Cosmolédo Atoll (Menai) and Astove, in SW Seychelles.

Z. m. kirkii Shelley, 1880 – Grand Comore (Njazidja), in NW Comoro Is.

Z. m. comorensis Shelley, 1900 – Mohéli (Mwali), in SC Comoros.

Z. m. anjuanensis E. Newton, 1877 – Anjouan (Ndzuani), in EC Comoros.

Z. m. maderaspatanus (Linnaeus, 1766) – Madagascar, and Glorioso Is (off NW coast).

Z. m. voeltzkowi Reichenow, 1905 – Europa I, in S Mozambique Channel.

Descriptive notes. 10–12 cm; averages 11.2 g (nominate), 7.6 g (*aldabrensis*), 8.8 g (*comorensis*), 8.3 g (*kirkii*). Nominata race has yellow-green forehead to nape and cheek, white eyering broken at front by blackish loreal line; upperparts, including most of upperwing, dark olive-green, sooty primaries with narrow green edges on outer half, mainly sooty to blackish-brown tail; chin and throat yellow, underparts pale grey, side of breast darker grey, flanks washed russet, yellow vent and undertail-coverts; iris reddish to light brown; bill black above, grey below; legs bluish to dark grey. Sexes similar. Juvenile is more greenish than adult, with eyering tinged yellowish, greyish-brown eye. Races differ mainly in plumage tones and in size: *aldabrensis* is somewhat smaller than nominate, and more yellow, less green, on upperparts, with paler side of breast sometimes washed brownish; *menaiensis* is similar to nominate, but a little paler; *kirkii* differs from others in having entirely yellow underparts; *comorensis* has green of upperparts paler, more yellowish, than nominate, rather brighter yellow on chin and throat, tending to extend more to chest, chest and abdomen more buffy,

less greyish, especially on flanks; *anjuanensis* is larger than previous and less markedly buffy on chest, abdomen and, especially, flanks, with chin and throat brighter yellow than in nominate; *voeltzkowi* is like nominate, but has white inner edges of secondaries slightly broader, lower back towards rump rather brownish-olive instead of olive-green, belly light greyish-buff, and undertail-coverts pale yellow (lighter than yellow of throat), also differs from previous subspecies in darker upperparts and weaker yellow stripe on forehead. VOICE. Song consists of reedy notes; song of race *kiriki* (from exposed perch) loud and melodious, similar to

that of a *Serinus* finch. Contact call a constant soft disyllabic "pec-u" or "wee tseet" or "tsit tsit", also gives harsher trill; *menaiensis* reportedly has thinner call than *aldabrensis*; *kiriki* has very wide range of call notes.

Habitat. All types of wooded areas, including all original undisturbed forest types, mossy forest, forest edge, scrubby woodland, subdesert brush, dry plains, afforested areas, secondary forest with *Ravenala madagascariensis*, wooded savanna, dry forest, eucalypt (*Eucalyptus*) woods, parks and gardens in towns and villages; from sea-level to 2300 m. No preference for particular trees but less common in mangroves, and race *aldabrensis* found in casuarina (*Casuarina*) trees. Occurs at forest edge at high elevations, but absent from heathlands of Mt Karthala (Grand Comoro), where *mouroniensis* occurs, although some overlap between the two species.

Food and Feeding. Mainly insects, especially beetles (Coleoptera), caterpillars, bugs (Hemiptera), Neuroptera, flies (Diptera), ants (Formicidae), also spiders (Araneae). Also some seeds (e.g. *aldabrensis* said to be fond of casuarina seeds), small fruits e.g. deep purple berries (5 mm in size), over-ripe figs (*Ficus*), bramble berries (*Rubus rosaeifolius*), fruits of *Peiper* shrub, and flowers and nectar. In rather loose monospecific flocks of up to 40 individuals, also three or more individuals in mixed-species flocks, where present species and Common Newtonia (*Newtonia brunneicauda*) may have role of nuclear species; participating in more than 50% of 47 flocks studied in 1989, and seen more often in mixed flocks than in single-species ones; associates most often with Common Newtonia, Souimanga (*Cinnyris sovimanga*) and Long-billed Green Sunbird (*Cinnyris notatus*), and Common Jery (*Neomixis tenella*), but also with Madagascar Paradise-flycatcher (*Terpsiphone mutata*), Cryptic Warbler (*Cryptosylvicola randrianasoloi*), Crested Drongo (*Dicrurus forficatus*), and Red-tailed (*Callicolius madagascariensis*), Blue (*Cyanolanius madagascarinus*) and Tylas Vangas (*Tylas eduardi*), among others. Has been recorded in same mixed flocks as *Z. mouroniensis*. Searches all levels of vegetation, particularly between 5 m and 10 m; frequents treetops and tops of shrubs, especially those flowering or fruiting. Gleans through branches for small insects.

Breeding. Mid-Sept to Mar, coinciding with wet season, with peak in Oct–Nov. Nest a firm deep cup made of *Casuarina* needles, grassy stems, grass-heads and bark fibre, with softer material (fine grass and rootlets) inside, a few bits of plant down and moss stuck on the outside, measurements (race *anjuanensis*) 45–80 mm deep and 70–95 mm wide externally, 35–60 mm deep and 50–70 mm wide internally; placed in shrub or in tree fork at 2–8 m above ground, on downward branch of *Macaranga* tree or similar in dense vegetation, or high up in fig tree. Clutch usually 2 eggs but up to 4 reported, pale blue-green, 15.3–16.4 × 12.3–12.4 mm (nominate), average 17.7 × 13 mm (*anjuanensis*). No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Common in Madagascar and the Comoros; common in the Seychelles, where it is one of the two most abundant landbirds on Aldabra, but less so on Cosmolé and Astove. Local population of race *aldabrensis* on Assomption I may have been wiped out after wholesale destruction of the island. Apart from nominate, each race has a tiny range and is therefore vulnerable. Introduced cats and rats (*Rattus*) may become a threat. The protection as a nature reserve and World Heritage Site should secure the future of Aldabra Atoll. Measures to secure the habitat of race *menaiensis* on Cosmolé Atoll should also be taken.

Bibliography. 69. Chestnut-sided White-eye

Zosterops mayottensis

French: Zostérops de Mayotte **Spanish:** Antojitos de la Mayotte
German: Dotterbrust-Brillenvogel
Other common names: Mayotte/Chestnut-flanked White-eye

Taxonomy. *Zosterops mayottensis* Schlegel, 1867, Mayotte, Comoro Islands. Probably related to *Z. senegalensis*. Sometimes lumped with extinct *Z. semiflavus* of Seychelles (which was smaller, slightly less yellow and had less bright yellow frontal bar), or considered a race of *Z. maderaspatanus*. Monotypic.

Distribution. Mayotte (Maore), including Petite Terre (Pamanzi I), in SE Comoro Is.

Descriptive notes. 11 cm; 9.9 g. Has forehead bright citrine-yellow, lores black, white eyering; crown and upperparts greenish-yellow; flight-feathers and tail blackish, edged greenish-yellow on outer web, remiges broadly edged white on inner web; bright citrine-yellow below, including underwing-coverts, flanks washed brownish-red; iris reddish-brown; bill dark blue to black, base of lower mandible grey; legs lead-grey, soles dull ochraceous. Sexes alike. Juvenile is greener, less yellowish, than adult on upperparts, duller below, with less extensive chestnut. VOICE. No detailed information available; reported to

produce vocalizations typical of the genus.

Habitat. Both forest and more open woodland, mangroves. More often seen in drier E side of Mayotte; less common in patches of rainforest.

Food and Feeding. Vegetable matter, insects, caterpillars, spiders (Araneae). Forages in small groups through trees and shrubs.

Breeding. Nest found in Oct, an open cup of very fine fibres, covered on outside with fine grass-heads and a little spider web, 70 × 70 mm externally, 40 mm deep and 45 mm wide internally; placed c. 2 m above ground in lateral fork of heavily foliated bush. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species; present in Comoro Islands EBA. Common on Mayotte, and fairly common on Petite Terre. The only white-eye present in its range. This species is less common than is the related *Z. maderaspatanus* (on Grand Comoro); reasons for this unknown, but possibly connected with the high densities of Frances's Sparrowhawk (*Accipiter francesii*) in forest habitat on Mayotte. As it is well adapted to man-made habitats, where insects and nectar abound, survival seems to be no problem. Numbers were randomly distributed over nine counting stations in 1992–1994.

Bibliography. Benson (1960), Forbes-Watson (1969), Gadow (1884), Louette *et al.* (2004), Milne-Edwards & Oustalet (1888), Sibley & Monroe (1990), Sinclair & Langrand (1998).

70. Seychelles Grey White-eye

Zosterops modestus

French: Zostérops des Seychelles **German:** Mahebrillenvogel **Spanish:** Antojitos de Seychelles
Other common names: Seychelles (Brown) White-eye

Taxonomy. *Zosterops modesta* E. Newton, 1867, Mahé, Seychelles.

May be related to *Z. olivaceus* and *Z. chloronothos*, to which it bears closest resemblance and with which it shares similar wing-flipping action and staccato calls; recent DNA studies, however, suggest *Z. maderaspatanus* as closest relative. Birds on Mahé on average larger (longer wing and tarsus) than those on Conception, with a 28% genetic difference recorded. Monotypic.

Distribution. Inner Is (Mahé and adjacent Conception), in NE Seychelles. Introduced on Frégate I, North I and Cousine I.

Descriptive notes. 10–11 cm; 11.5–13 g. Has inconspicuous white eyering with tiny gap at front; dark olive-grey to brown above, paler on yellowish-washed rump; throat dirty pale mustard-yellow, underparts pale grey, flanks with brownish wash, belly with faint yellowish wash; iris dark reddish-brown; bill blackish-grey; legs grey. Sexes alike in plumage, but male reported as sometimes smaller than female. Juvenile is similar to adult, but bill yellow in first few weeks, gradually changing to grey. VOICE. Song, from perch throughout day (most often at dawn during breeding season, and sometimes throughout day), varied

and pleasant, of variable complex phrases of high-pitched notes. Calls described as soft, brief, nasal "cheer" for contact (similar to those of *Z. borbonicus*), louder and more persistent when moving between trees and shrubs, also soft trilling note and clipped "tik tik" contact calls; also loud or soft 3-note or 4-note calls, and reportedly warbling incubation change-over calls; "chewik" and chattering trills as alarm.

Habitat. Thick-foliaged broadleaved trees and dense shrubs in well-wooded country, mixed secondary forest, especially where certain tall trees (e.g. *Albizia falcataria* and *Pterocarpus indica* on Mahé) have underlying or adjacent scrub layer, open woodland, gardens and areas with mature trees; prefers secondary habitat with alien trees and shrubs. On Conception in mixed woodland and open glaciis (rocky glades) with associated vegetation; on Mahé open woodland and gardens; on Frégate (introduced from Conception) also in mixed woodland but readily adapted to mixture of gardens, glaciis and rehabilitated coastal woodland. Found in residential areas on Mahé (La Misère, Grande Anse/Barbarons, Anse Boileau, Cascade). Most frequent at 300–500 m on Mahé, and common at all altitudes on Conception.

Food and Feeding. Diet largely based on invertebrates, and berries and seeds; nectar also taken. Recorded items include tiny insects such as ants (Formicidae), aphids, mealy bugs (*Pseudococcus*), small green caterpillars and crickets, as well as spiders; fruits include *Lantana camara* and cinnamon (*Cinnamomum*). Seen in family groups and in fast-moving flocks of 2–5 individuals on Mahé, and up to about twelve on Conception; also in mixed flocks with Red Foddes (*Foudia madagascariensis*) and Seychelles Sunbirds (*Cinnyris dussumieri*) on Mahé. Forages in scrub layer of secondary forest, as well as in tops of a large variety of native and exotic trees, including cloves (*Syzygium aromaticum*), cinnamon, *Tabebuia*, *Calophyllum* and *Albizia*; probes among leaves and into bark crevices, gleans and snatches insects from leaves. In general, does not have a strong preference for native trees, but on Conception several native small trees (e.g. *Premna serratifolia*, *Tabernaemontana coffeoides*, *Canthium bibracteatum*) play a very important role in diet. On Mahé, of 16 species of foraging tree, only two were indigenous and these were exploited in only 3% of observations.

Breeding. Oct–Apr (sometimes from late Jul). Co-operative breeder, helpers contributing to nest-building and brood-rearing duties; complex system with large nesting families of up to eight individuals (laying up to 7 eggs in one nest) discovered on Conception. Nest a flimsy cup made largely of grass, also containing strips of bark, small dead leaves, rootlets, strands of wool or cotton, and moss, attached by spider web to 2–4 small twigs 4–20 m above ground in dense cluster of leaves at end of almost horizontal branch; recorded nesting trees *Pterocarpus*, *Swietenia*, *Hevea*, clove and lichi (*Litchi*) on Mahé, cinnamon, cashew (*Anacardium*) and *Tabebuia* on Conception. Clutch (for groups with one female) 1–2 eggs, pale greenish-blue with very faint brown spots; incubation period 13–15 days; fledging period 11–15 days.

Movements. Exchanges between different subpopulations on Mahé shown by colour-ringing.
Status and Conservation. **ENDANGERED.** Restricted-range species; present in Granitic Seychelles EBA. Previously listed as Critically Endangered; recategorized in 2006 following successful conservation action. Global population estimated at 330–450 birds in 2006. Accurate census in 1999 estimated population of Conception at c. 280 (244–336) individuals; same method used in 2006 gave c. 230 (200–290) birds. On Mahé, presently occurs mainly in three tiny areas (La Misère, Upper Barbarons and Cascade), each less than 5 km² in extent. In 1906 was still abundant, and reported as not infrequent in mountainous parts of the island between 330 m and 700 m around central massif; most native forests had then been cleared but supported a scattered tree growth and often thickets of cinnamon bushes. Species not recorded after 1936 until beginning of 1960s (having been thought extinct), when a small flock of about a dozen was located in the cinnamon forest at La Misère. Extremely rare (the least common bird species) on Mahé, where has declined since mid-1970s from c. 100 birds, to c. 50 birds in mid-1990s, with 34–40 individuals counted in 1999; seems now to be stable or slightly increasing, with 50–60 birds in 2007. In Feb 1997 a population of this species was discovered on Conception, a small island off Mahé, inhospitable to man because of its steep slopes and absence of beaches or streams, and therefore rarely visited since abandonment

of its plantation in mid-1970s. Decline in numbers on Mahé is due mainly to predation by the arboreal black rat (*Rattus rattus*), Common Myna (*Acridotheres tristis*) and Seychelles Black Bulbuls (*Hypsipetes crassirostris*), which are absent or less abundant (myna) on Conception. Forestry practices and commercial tea-growing on Mahé reported to be incompatible with the species' needs in mid-1970s, and relative scarcity of native fruit trees on Mahé may have contributed to its decline. Most of Mahé population lies outside the Morne Seychellois National Park. Protection of population on dry island of Conception against fire, as well as disease, is desirable; brown rat (*Rattus norvegicus*) eradicated in 2007. Rat control undertaken at the two main breeding sites on Mahé since 2006. Although the populations of this white-eye on Mahé and Conception are genetically isolated, this limited differentiation is not considered of taxonomic importance, and mixing individuals from both populations in order to increase genetic variation may be beneficial for the species. As part of the Seychelles White-eye Recovery Programme, this species was introduced to Frégate I in 2001, and by 2007 a population of c. 100 birds had become established; in 2007, also introduced to North I (25 birds) and Cousine I (23 birds). Captive breeding recommended only as a last resort for Mahé birds. Eradication of introduced predators and further introductions to suitable, predator-free islands recommended in Species Action Plan.

Bibliography. Anon. (2007n), Butchart & Stattersfield (2004), Collar & Stuart (1985), Collar *et al.* (1994), Crook (1960), Feare (1975), David & Gosselin (2002b), Gerlach (1997, 2007), Greig-Smith (1978, 1979), Henriette-Payet (2007), Newton (1867), Rocamora (1997a, 1997b, 2008), Rocamora & François (2000), Rocamora & Richardson (2003), Rocamora *et al.* (2003), Sinclair & Langrand (1998), Skerrett & Bullock (1992), Skerrett *et al.* (2001), Stattersfield & Capper (2000), Vesey-Fitzgerald (1940).

71. Mount Karthala White-eye

Zosterops mouroiensis

French: Zostérops du Karthala

German: Karthalabrillenvogel

Spanish: Antejitos de la Gran Comora

Other common names: Comoro/Grand Comoro White-eye

Taxonomy. *Zosterops mouroiensis* A. Milne-Edwards and Oustalet, 1885, Grand Comoro. Monotypic.

Distribution. Mt Karthala, on Grand Comoro (Njazidja), in NW Comoro Is.

Descriptive notes. 11.8 cm; 9.9 g. Has white eyering; olive-green top of head and upperparts, somewhat darker on upperwing and tail; throat and undertail-coverts yellow, rest of underside rather dull yellowish-green; iris reddish-brown; bill and legs black. Sexes alike. Juvenile is duller and with smaller eyering than adult. **Voice.** Song is a mellow warble, "fi, fi, fi, pi, pi, pyo, pyo"; typical mellow "fee fee fee pee pee" whistles and buzzy notes as contact.

Habitat. Restricted to unstratified stunted woodlands (with canopy at 7–8 m), colonizing a recent lava flow, dominated by *Philippia*

comorensis heath (which grows to 5 m in its lower reaches, at 1700 m, and to half this size in summit area of Mt Karthala, an active volcano), but where broadleaf shrubs are also common. Mainly at 1750–2361 m, but also down to c. 1500 m, below which *Z. maderaspatanus* (of race *kiriki*) occurs.

Food and Feeding. Recorded food items small purple berries, also some insects (e.g. caterpillars). No other information.

Breeding. Of eleven males in Sept, ten were in breeding condition. One nest found, made of very fine grass, outside covered with moss, externally 85 mm deep and 90 mm wide, inner cup 45 mm deep and 55 mm wide, suspended between two thin stems 4 m above ground and 1 m from top of a *Philippia* bush; contained 3 eggs, pale blue, 20.2 × 15.4 mm. No other information.

Movements. Not known.

Status and Conservation. \ **VULNERABLE.** Restricted-range species; present in Comoro Islands EBA. Rare. In 1958 the species was still common, and even found in evergreen forest at 1700 m. In early 1980s considered not uncommon but localized, as restricted to a narrow band of heath vegetation on Mt Karthala, where 17 individuals located in 1985 in point-counts made during pre-breeding season at 1885 m. Here, it is very much threatened by habitat degradation, as a hiking road to the rim of the crater was constructed in 1980s, as well as by eruptions from the volcano itself. Its conservation status may in the future have to be upgraded to that of Endangered or even Critically Endangered.

Bibliography. Anon. (2007n), Benson (1960), Bijlens *et al.* (1987), Butchart & Stattersfield (2004), Collar & Stuart (1985), Collar *et al.* (1994), Louette (1988, 2001), Louette & Stevens (1992), Louette, Bijlens *et al.* (1989), Louette, Meirte & Jocuqué (2004), Louette, Stevens *et al.* (1988), Milne-Edwards & Oustalet (1888), Safford & Evans (1992), Sinclair & Langrand (1998), Stattersfield & Capper (2000), Stevens *et al.* (1992).

72. Reunion Olive White-eye

Zosterops olivaceus

French: Zostérops de la Réunion

German: Olivbrillenvogel

Spanish: Antejitos de Reunión

Other common names: Mascarene Olive White-eye, Olive White-eye

Taxonomy. *Certhia olivacea* Linnaeus, 1766, Madagascar; error = Réunion.

Forms a superspecies with *Z. chloronothos*; often considered conspecific, but the two differ strikingly in, especially, call and vocal behaviour. Monotypic.

Distribution. Réunion I.

Descriptive notes. 11 cm; 7.7–11.4 g. Dark white-eye with relatively long, decurved bill. Above, is dull dark olive-green, with blackish head and striking white eyering, rump brighter olive-green; grey below, browner on flanks, fading to yellowish on undertail-coverts; pale stripe running down side of puffed-out breast and flanks ("epaulette" effect); iris dark brown; bill and legs greyish. Distinguished from *Z. borbonicus* by darker plumage, obvious white eyering, dark rump and decurved bill. Sexes alike. Juvenile initially lacks white eyering, has green face uniform with rest of plumage. **Voice.** Song a loud warble with "tu" and "tchip" notes interspersed. Contact call a clipped "chip chip"; staccato call given especially in interactions around flowers; flight call "chuck chuck".

Habitat. Natural forest at higher altitude (except cloudforest in W), scrub-forest, heath. Scarce at 500 m and rare below that level; ranges up to 2300 m where *Hypericum* and *Sophora* flower.

Syzygium jambos etc. Reaches nectar by perching near the flower, or sometimes hovering in front, and probing into it from front; not observed to pierce the base. Insects sought by gleaning in foliage and probing in flowers; aerial flycatching sometimes observed. Occurs in isolated pairs, rather than in small flocks. Highly territorial in relation to flowers; vigorously defends especially the usually widely scattered *Hypericum* bushes.

Breeding. Jun–Jan. Clutch 2–3 eggs, pale blue-green. No other information.

Movements. Descends to lower elevations between Mar and May, but does not roam widely in lowlands. As flowering of foodplants is seasonal, vertical migration within mixed forest zone is necessary. After cyclones flowers are in short supply, and this species can appear at places where otherwise usually not seen.

Status and Conservation. Not globally threatened. Restricted-range species; present in Réunion EBA. Still reasonably common. Has become very rare in lowlands since 1920s, and has declined in mountains but much less so; population estimated at 154,000 individuals in 1970s, with a breeding distribution extending over 1500 km². Main predator is Madagascar Marsh-harrier (*Circus maillardi*).

Bibliography. David & Gosselin (2002b), Diamond (1987), Gadow (1884), Gill, F.B. (1970a, 1971a), Moreau (1957a), Sibley & Monroe (1990), Sinclair & Langrand (1998), Temple (1981), Warren *et al.* (2006).

73. Mauritius Olive White-eye

Zosterops chloronothos

French: Zostérops de Maurice

German: Mauritiusbrillenvogel

Spanish: Antejitos de Mauricio

Other common names: Olive White-eye (when treated as conspecific with *Z. olivaceus*)

Taxonomy. *Dicaeum chloronothos* Vieillot, 1817, no locality = Mauritius.

Forms a superspecies with *Z. olivaceus*; often considered conspecific, but the two differ strikingly in, especially, call and vocal behaviour. Monotypic.

Distribution. Mauritius.

Descriptive notes. 10 cm; 7.5–9 g. Rather dark white-eye with relatively long, decurved bill. Head to upper mantle grey, becoming olive-green on rest of upperparts, with uniform rump; paler below, tinged pinkish-buff on flanks, and becoming yellow on undertail-coverts; white eyering; iris dark brown; bill dark brown; legs pale horn to flesh-coloured. Distinguished from *Z. borbonicus* by noticeably decurved bill and obvious eyering. Sexes alike. Juvenile resembles adult. **Voice.** Song rather short and inconspicuous, hurried, consisting of warbled phrases interspersed with characteristic trilled call, repeated during several minutes; generally much briefer than song of *Z. borbonicus*, has been likened to that of a Dunnock (*Prunella modularis*). Contact call metallic "plik plik"; flocking calls e.g. "pit" during nectar-feeding, but silent when feeding on insects; flight call, agonistic calls and roosting calls also distinguished.

Habitat. Upland native forest with fairly even open canopy at 15–20 m, partly heavily degraded by guava (*Psidium*) and *Syzygium jambos*; found in the wettest forest (mainly inside 4000-mm isohyet) above 305 m; areas of dense guava avoided, but more open *S. jambos* thickets important sources of nectar and insects. Occurs also in the structurally quite different dwarf forests, but locally absent where canopy exceeds 5 m. Avoids gardens and invasive stands of woodland.

Food and Feeding. Nectar; also insects; possibly feeds also on sap of *Calophyllum eputamen*. More than 40 nectar foodplants recorded, favourites including endemic *Bertiera zaluzania*, *Sideroxylon puberulum*, *Sideroxylon cinereum*, *Labourdonnaia calophylloides*, and *Eugenia Syzygium* species, and introduced bottlebrush (*Callistemon citrinus*) and *Syzygium jambos*; native species of *Eugenia* and *Syzygium* visited assiduously, and even single flowers out of season are found. Insect prey include dragonflies (Odonata), beetles (Coleoptera), grubs, cocoon contents, adult insects up to 2 cm. Searches for insects through canopy foliage and bark, on branches, in herb layer, shrubs, saplings and fallen branches, and in inflorescences. Rarely hovers, but feeds restlessly in manner reminiscent of sunbirds (Nectariniidae) and sunbird-asities (*Neodrepanis*). Gleans items; aerial insects snapped up in flight. Small area around a favoured flower defended against other white-eyes. Suggested home range 20–30 ha; in areas rich in flowering species, seen to keep to home range of only 2 ha.

Breeding. Sept–Nov. During breeding season has large non-exclusive home range, but defends small area around nest-site. Nest completed within a few days, a cup made from leaf veins dressed externally with spider webs, lined with fibres, animal hair and especially feathers (unlike nest of *Z. borbonicus*), externally 63.4 mm wide, 80.3 mm long and 65.4 mm deep, inner cup 47.1 mm deep, placed 2–10 m above ground in tree fork. Clutch 2 eggs, rarely 3, pale blue; both sexes involved in incubation of eggs and brooding and feeding of young; incubation period 12–13 days; fledging period 14 days; adults perform "injured bird" distraction display near nest when young present; in one case juvenile fed by parents for c. 56 days, chased away at 61 days. Nesting success extremely low, at 7–17%, and five breeding pairs produced only a single fledgling each during three-year study; extremely severe nest predation by introduced crab-eating macaque (*Macaca fascicularis*) and black rat (*Rattus rattus*).

Movements. In non-breeding season wanders below usual lower altitudinal limit of 350–400 m (covering area of occupancy of 32 km² in 1993) over wide area of C plateau (area of occurrence 250 km²), including many relict patches of native vegetation; farthest in winter and at exceptional nectar sources. Long flights of up to 500 m often seen, sometimes over pine (*Pinus*) plantations, probably to reach favoured flowers.

Status and Conservation. **CRITICALLY ENDANGERED.** Restricted-range species: present in Mauritius EBA. Rare. Population fewer than 150 pairs, and declining. This species' mobility, extreme inconspicuousness and silent behaviour when not moving around make it very hard to count accurately. Found only in SW & C of the island. Continued degradation of native habitat (only 5% of native forest remains on Mauritius, all in a very degraded state), and nest predation by introduced Red-whiskered Bulbul (*Pycnonotus jocosus*), black rat, crab-eating macaque and Indian grey mongoose (*Herpestes edwardsi*) have reduced the population from 350 pairs in 1975 to c. 200 pairs by 1993, and 93–148 pairs in 2001. One-third of these survive in a 5-km² forested area to be included in Black River National Park, and highest densities (15–20 pairs/km²) were found between Montagne Cocotte and Piton Savanne, and native relicts of the Bois-Sec–Grand Bassin–Rivière du Poste area. Declines more severe in areas dominated by native vegetation than in those with substantial amounts of exotic *Cryptomeria* and *Pinus*; severe nest predation has possibly brought about a change in nest-site preference, as densely foliated introduced trees (especially *Cryptomeria japonica*) are unattractive to predators. Lengthy juvenile dependency period and fledging of only one young per nest limit productivity of a pair and make population more vulnerable to predation. On the other hand, this species' mobility may enable it to disperse more widely than do several of the other native forest birds, and allow immigrants to support dwindling populations in more remote areas. Translocation of individuals to predator-free island and targeted eradication of nest predators suggested as conservation measures.

(1970a, 1971a), Hansen *et al.* (2002), Horne (1987), Moreau (1957a), Nichols & Woolaver (2003), Nichols *et al.* (2004, 2005a, 2005b), Safford (1991, 1997), Sibley & Monroe (1990), Sinclair & Langrand (1998), Stattersfield & Capper (2000), Staub (1988), Temple (1974), Warren *et al.* (2006).

74. Yap Olive White-eye

Zosterops oleagineus

French: Zostérops de Yap **German:** Yapbrillenvogel **Spanish:** Antojitos de Yap
Other common names: Olive-coloured/Large Yap/Yap (Greater) White-eye, Yap Rukia

Taxonomy. *Zosterops oleaginea* Hartlaub and Finsch, 1872, Yap, Caroline Islands.

A fairly large, rather distinctive-looking taxon that has in the past been placed in a monotypic genus, *Kubaryum*, and was subsequently transferred to *Rukia*, where sometimes still retained;

however, DNA–DNA hybridization data indicate that it belongs in present genus. Possibly most closely related to *Z. semperi*. Monotypic.

Distribution. Yap, in W Caroline Is.

Descriptive notes. 12.5–13 cm. Has well-developed satin-white eyering interrupted at front by blackish loreal line, latter continuing under eyering; above, including forehead, generally brownish-citrine, flight-feathers and tail feathers blackish-brown with broad brownish edges; throat dull yellowish, becoming brownish-citrine (but paler than upperparts) towards upper breast, with centre of belly, flanks and remainder of underparts brownish-olive; iris reddish-white to reddish-brown; bill yellow-orange, darker on upper mandible; legs yellow-orange. Sexes similar, female perhaps darker than male. Juvenile undescribed. Voice. Me-

lodio song of monotonously repeated loud whistled phrases, pattern varying somewhat, but typically resembling the phrase “Tickle me, Peter” or “fickle-éé-feedle-dée”. Call a shrill harsh “cheee”.

Habitat. All types of forest, dense jungle, underbrush near swamps and other woody vegetation, including mangroves. Not confined to native vegetation.

Food and Feeding. No details of diet. Solitary, in small groups or, usually, in pairs. Generally forages in tops of small to medium-sized trees. Characteristically hangs with head downwards, exploring among leaves, flowers or fruits; especially fond of seed-pods of *Leucena* (tangen-tangen). Gleans items from foliage.

Breeding. No information.

Movements. Not known.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Yap Islands EBA. Confined to small island of Yap (less than 100 km²), where reported as rare. During a month's survey in 1940s, seen only twice. In 1970s was reportedly widely distributed, but more recently appeared to have become scarcer. In 1991 total population estimated at 19,619 individuals.

Bibliography. Anon. (2007n), Butchart & Stattersfield (2004), Collar *et al.* (1994), Engbring *et al.* (1990), Fisher (1950), Gadow (1884), Hartert & Finsch (1872), Mayr (1945b), Pratt *et al.* (1977, 1987), Sibley & Monroe (1990), Slikas *et al.* (2000), Stattersfield & Capper (2000).

Genus *WOODFORDIA* North, 1906

75. Bare-eyed White-eye

Woodfordia superciliosa

French: Zostérops de Woodford **Spanish:** Antejitos de Woodford
German: Woodfordbrillenvogel
Other common names: Woodford's/Rennell/Eyebrowed White-eye

Taxonomy. *Woodfordia superciliosa* North, 1906, Rennell, Solomon Islands. May form a superspecies with *W. lacertosa*. Monotypic.
Distribution. Rennell, in SE Solomon Is.

Descriptive notes. 14–15 cm; 22.5–37 g. Has bare black lores and circumorbital skin bordered by white band which extends narrowly across lower forehead; otherwise dull brownish-olive above, more brownish on top of head, upperwing more olive; flight-feathers and tail blackish-brown, primary P2 fairly short in length (between P7 and P9); chin and upper throat dirty whitish, side of breast and flanks pale olive with slight buffy tinge, fading towards centre of underparts, and with pale yellowish-brown wash on centre of belly and undertail-coverts; iris light brown; slightly decurved bill brownish-horn, with pinkish base;

legs slaty grey. Sexes alike. Juvenile undescribed. **VOICE.** Song, 30–10 minutes before dawn, seldom heard, soft and very quick, with narrow range around medium pitch, similar to that of *Zosterops rennellianus* but briefer, less fast and perhaps lower-pitched. Contact calls among the most commonly heard bird sounds of Rennell, a petulant “chip” note repeated very rapidly (8 per second), and a soft mellow note repeated more slowly (5 per second); alarm a hoarse “ghae-ghae-ghae”.

Habitat. Primary forest, forest edge, open woodland, second growth, gardens and coconuts, but not on very exposed perches; found on almost all islets of L Teganu.

Food and Feeding. Small insects, including caterpillars, also spiders (Araneae), also small land-snails. Many fruits taken, including *Macaranga*, *Ficus benjamina*, *Ficus adenosperma*, *Diospyros*, *Breynia cernua*, *Acalypha grandis*, *Dysoxylum caulostachyum*, and especially *Pipturus argenteus*; feeding in papaya (*Carica*) trees also reported. Small fruits swallowed whole, larger ones pecked at. In small groups of mostly three individuals, but up to six recorded; joins mixed-species flocks. Forages at all heights, but spends less time in canopy than in lower and middle storeys. Gleans from upper and lower surfaces of leaves; hops up vines, gleams while hanging upside-down.

Breeding. Oct–Nov. Nest cup-shaped, 50–75 mm in diameter, 50 mm deep, made from mostly dead and dry fine fibres, vines, twigs and coarse grass and few bits of green moss, lined with fine grass, slung in fork in twig 20–30 m above ground. Clutch 2 eggs, sometimes 1, plain white with faint greenish-blue tint, 19.5 × 14.5 mm. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Rennell and Bellona EBA. Very common and widespread. One of the three most common forest birds on the island, and the most abundant bird species of second growth and gardens.

Bibliography. Bradley & Wolff (1958), Diamond (1991), Doughty *et al.* (1999), Mayr & Diamond (2001), Mayr & Hamlin (1931), Mees (1969), Murphy (1929), Wolff (1976).

76. Sanford's White-eye

Woodfordia lacertosa

French: Zostérops de Sanford **German:** Sanfordbrillenvogel **Spanish:** Antejitos de Sanford

Taxonomy. *Sanfordia lacertosa* Murphy and Mathews, 1929, Santa Cruz Islands. Formerly placed in its own genus, *Sanfordia*, but resembles *W. superciliosa* sufficiently to be treated in same genus. May form a superspecies with *W. superciliosa*. Monotypic.

Distribution. Ndeni, in Santa Cruz Is (N of Vanuatu).

Descriptive notes. 15–16 cm. Has rather narrow white eyering, but off-white lores and some feathers below eye giving appearance of a large eyering; above, umber-brown, more rufous-brown on upperwing and tail; primary P2 fairly short in length (between P8 and P9); below, more or less cinnamon-buff with olive wash, particularly on throat; iris brown; bill straw-coloured; legs straw-coloured or light yellow. Differs from *W. superciliosa* mainly in head pattern, longer bill, and browner appearance. Sexes alike. Juvenile undescribed. **VOICE.** A typical “chip” note, uttered frequently during wandering in flocks.

Habitat. Degraded forest, primary forest, forest edge, secondary growth.

Food and Feeding. Pairs forage rather slowly in canopy and middle storey, sometimes feeding on fruits. No other information.

Breeding. No information.

Movements. Not known.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Vanuatu and Temotu EBA. Uncommon to fairly common.

Bibliography. Anon. (2007n), Butchart & Stattersfield (2004), Diamond (1991), Doughty *et al.* (1999), Dutson (2007b), Gibbs (1996b), Mayr (1945b), Mees (1969), Murphy & Mathews (1929), Stattersfield & Capper (2000), Stresemann (1931a).

Genus *RUKIA* Momiyama, 1922

77. Faichuk White-eye

Rukia ruki

French: Zostérops de Truk **German:** Trukbrillenvogel **Spanish:** Antejitos de la Truk
Other common names: (Large/Great) Chuuk/Truk White-eye, Truk Greater White-eye, Teardrop White-eye

Taxonomy. *Tephros ruki* E. J. O. Hartert, 1897, Chuuk Islands. Structurally and vocally similar to *Cleptornis marchei*. Monotypic.

Distribution. Chuuk Is (occurs on four islands in Faichuk Group), in C Caroline Is.

Descriptive notes. 14–14.5 cm. Has indistinct white eyering (white feathers developed under eye only), lores dull black; dark brownish-olive upperparts and underparts, primaries rather darker, more blackish-brown, than remainder of feathers; iris reddish-brown; bill black; legs orange-rufous. Sexes alike. Juvenile undescribed. **VOICE.** A loud lilting warble. **Habitat.** Dense old-growth stands of native forest, especially rich and well-developed forest above 400 m on Mt Winipot (Tol South I), where endemic poison tree (*Semecarpus kraemeri*) may play an important ecological role in this species' survival. Few records from

disturbed forest near native woods.

Food and Feeding. No details on adult diet. Young fed with small to medium-sized insects, including tan-winged moths (Lepidoptera), soft-bodied winged green Orthoptera, and black Diptera/Hymenoptera. Forages by probing among inner branches, limbs, leaf tangles and vines; favours *Ficus* and *Semecarpus*.

Breeding. Apr. One nest described, cup-shaped, 7.5 cm in diameter and 7 cm deep, thin-walled, woven with bark strips, moss and dried grass-like plant fibres, placed 20 m up in terminal leaf cluster in poison tree; contained single chick 2–4 days old; chick fed by both sexes, female doing more than male. No other information.

Movements. Not known.

Status and Conservation. CRITICALLY ENDANGERED. Restricted-range species: present in East Caroline Islands EBA. Rare; current population estimated at c. 500 individuals. In 1984 found to be locally common on Tol South (382 individuals), and rare on Onei (19), Paata (32) and Polle (93); total range only c. 4 km². Has always been uncommon, or at least local, since its discovery in 1895; one scientist who spent more than 14 months in Chuuk Is failed to see a single individual of this species. Possibly dependent on the native poison tree, but both that and the white-eye may be under threat from the expanding human population. This species could easily be exterminated by a catastrophic weather event such as a large typhoon.

Bibliography. Anon. (2007n), Baker (1951), Brandt (1962), Butchart & Stattersfield (2004), Collar *et al.* (1994), Craig (1999), Engbring *et al.* (1990), Hartert (1900a), Mayr (1945b), Mees (1969), Owen (1977), Pratt *et al.* (1987), Pyle & Engbring (1988), Sibley & Monroe (1990), Stattersfield & Capper (2000).

78. Long-billed White-eye

Rukia longirostra

French: Zostérops de Ponapé **Spanish:** Antejitos Piquilargo
German: Langschnabel-Brillenvogel
Other common names: Pohnpei/Ponapé (Greater)/Large Ponapé White-eye

Taxonomy. *Cynnirorhyncha longirostra* Takatsukasa and Yamashina, 1931, Pohnpei Island. Behaviourally similar to *Zosterops*. Name *R. sanfordi* is a synonym. Monotypic.

Distribution. Pohnpei, in EC Caroline Is.

Descriptive notes. 13 cm; 17.9 g. Distinctive, with long, thin and curved bill like that of a honeyeater (Meliphagidae); the only white-eye with a bill longer than the tarsus. Plumage is buffy olive above, slightly greener on head, brighter on rump and more buffish on upper-tail-coverts; narrow eyering; flight-feathers and tail feathers blackish-brown with olive to brownish margins, primaries and secondaries with whitish to brownish inner edges; below, much lighter, buffy, strongest on flanks, and with chin, throat and centre of underparts slightly tinged greenish-yellow; iris chestnut-brown; bill brownish-black, basal half of lower mandible

brownish with green tinge; legs pale yellow to yellowish-orange. Sexes alike. Juvenile undescribed. **VOICE.** Song a downslurred whistle followed by short warble and burry chatter, e.g. “peer-cheturde-tr-r-r-r-r”; described also as a musical, deep-throated sibilant. Contact call a loud series of clear downslurred whistles, “peer-peer-peer”, less nasal than calls of other white-eyes.

On following pages: 79. Golden White-eye (*Cleptornis marchei*); 80. Bonin White-eye (*Apalopteron familiare*); 81. Bicoloured White-eye (*Tephrozosterops stalker*); 82. Rufous-throated White-eye (*Madanga ruficollis*); 83. Grey-hooded White-eye (*Lophozosterops pinaiae*); 84. Black-masked White-eye (*Lophozosterops goodfellowi*); 85. Scaly-headed White-eye (*Lophozosterops squamiceps*); 86. Javan Grey-throated White-eye (*Lophozosterops javanicus*); 87. Yellow-browed White-eye (*Lophozosterops superciliosus*); 88. Crested White-eye (*Lophozosterops dohrtyi*); 89. Pygmy White-eye (*Oculocincta squamifrons*); 90. Spot-breasted White-eye (*Heleia muelleri*); 91. Thick-billed White-eye (*Heleia crassirostris*); 92. Mountain Black-eye (*Chlorocharix emiliae*); 93. Giant White-eye (*Megazosterops palauensis*); 94. Bioko Speirops (*Speirops brunneus*); 95. Principle Speirops (*Speirops leucophoeus*); 96. Black-capped Speirops (*Speirops lugubris*); 97. Mount Cameroon Speirops (*Speirops melanocephalus*); 98. Cinnamon Ibon (*Hypocryptadius cinnamomeus*).

Habitat. Secondary forest and primary forest in hills and mountains, above 600 m.
Food and Feeding. No details of diet. In small flocks. Forages quietly in canopy, often with *Zosterops cinereus*. Feeds among flowers of gum tree. Flocks dash rapidly and wildly through forest understorey.
Breeding. Birds with enlarged gonads in Dec and Feb; one immature specimen in Apr. No other data.
Movements. Not known.
Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in East Caroline Islands EBA. Widespread, but uncommon. Reported as very rare in 1931 and rare in 1947–48, but this species is inconspicuous, and its apparent rarity may be due to its being overlooked. Vulnerable to encroaching agriculture in its preferred and limited montane habitat, where nearly 90% of sightings were made in c. 10% of the land area. Has apparently declined: encounter rates (individuals per hour) in Pohnpei forest above 200 m were 25.0 in 1983 and 4.1 in 1994 (84% decrease), and below 200 m 2.6 in 1983 and 0.5 in 1994 (83% decrease).
Bibliography. Anon. (2007n), Baker (1951), Buden (2000), Butchart & Stattersfield (2004), Craig (1999), Lack (1971), Mayr (1945b, 1967), Mees (1969), Owen (1977), Pratt *et al.* (1987), Sibley & Monroe (1990), Stattersfield & Capper (2000).

Genus *CLEPTORNIS* Oustalet, 1889

79. Golden White-eye

Cleptornis marchei

French: Zostérops doré **German:** Goldhonigfresser **Spanish:** Antojitos Dorado
Other common names: Golden Honeyeater, Cleptornis

Taxonomy. *Ptilotis marchei* Oustalet, 1889, Saipan, Northern Mariana Islands. Was initially placed in now defunct genus *Ptilotis* within honeyeater family (Meliphagidae), with a new genus provisionally established for it in the event that it should prove more distinct. Much later, DNA analysis indicated the affinities of this species and also genus *Apalopteron* to current family, in which both were then incorporated. Closest to *Rukia*. Monotypic.
Distribution. Saipan and Aguijan, in S Northern Mariana Is.

Descriptive notes. 14 cm; 20.2 g. Unmistakable. Head is yellow to orange, with narrow pale eyering; back yellowish-green, wing and tail feathers fringed orange-yellow; golden orange-yellow below, washed cinnamon-red on flanks and undertail-coverts; iris dark brown; bill and legs orange. Sexes alike in plumage, but male longer-winged (wing 76–80 mm) and longer-billed than female (wing 71–73 mm). Juvenile has duller, paler plumage than adult, with areas of brownish-yellow on back and side of head, sometimes brownish-yellow streaks on breast; dusky bill, duller-coloured feet. **Voice.** Song described as an extended rambling warble, sound-

ing like “sée mé-can you sée mé-I can sée yô-can you sée mée...”. Flock calls include harsh, strident, raspy “tchup” or “schick” during swift flight, and quick loud whistle; begging call of juvenile a plaintive mellow whistle; twanging calls similar to that of Hermit Thrush (*Catharus guttatus*).

Habitat. Understorey of wide variety of wooded and semi-open habitats, including strand forest and suburban areas, but generally absent from sword-grass savanna; more common in native limestone forest than in disturbed habitats. Only bird species on Saipan that is not found in L. Susupe marshes.
Food and Feeding. Generalized diet. Mostly berries with hard pits, which are swallowed whole; also fruits of *Momordica* (also seeds), *Premna*, *Ficus*, *Melanolepis*, *Psychotria* (also nectar), *Artocarpus*, *Lantana* (also flowers), *Carica* and *Muntingia*, and nectar and/or flowers of *Pisonia*, *Erythrina*, *Morinda* and *Aidia*. Also invertebrates, picked from bark and leaves of trees; flying insects. Typically in family groups (with food-begging immatures) of 3–4 individuals, but sometimes travels in groups of up to twelve, frequently noisy; during foraging followed 1–2 m behind by Rufous Fantails (*Rhipidura rufifrons*), which seen to hawk insects disturbed from leaves by the white-eyes. Forages from ground to treetops, but predominantly in top outer portion of trees, mostly by gleaning and probing among (dead) leaves, on branches and on fruit. Despite its long legs, not a ground-feeder. Territorial, with countersinging between neighbouring pairs throughout day.

Breeding. Nests found in all months except Nov; song and food-begging observed throughout year, but apparently not during protracted dry season. Nest cup-shaped and unlined, composed primarily of casuarina (*Casuarina*) “needles”, grasses, vine tendrils and coarse hairs, placed 1.5–6.5 m above ground in tree, e.g. *Casuarina equisetifolia*, *Guamia mariananae*, *Cynometra*, *Leucena*, *Citrus*, *Maltighia* or *Randia*. Clutch 2 eggs, pale bluish-green, with reddish-brown blotches concentrated at wide end, 20.3 × 15.1 mm; incubation by both sexes equally, period 14 days; fledging period 10–12 days.

Movements. Not known.

Status and Conservation. CRITICALLY ENDANGERED. Restricted-range species: present in Mariana Islands EBA. Confined to Saipan (122 km²), where it is abundant, with density of 532 birds/km², and the even smaller island of Aguijan (4 km²), where population estimated to number 2000 individuals (573 birds/km²). In 1982, global population estimated to total of 55,522 individuals. Recently introduced brown tree-snake (*Boiga irregularis*) a major predator, and very likely to lead to massive decrease in this white-eye’s numbers. Extirpated from Tinian and Rota in prehistoric times.
Bibliography. Anon. (2007n), Bruce (1978), Butchart & Stattersfield (2004), Collar *et al.* (1994), Craig (1990, 1996), Craig & Beal (2001), Engbring *et al.* (1986), Hartert (1898b), Marshall (1949), Oustalet (1889), Pratt *et al.* (1987), Sibley & Monroe (1990), Slikas *et al.* (2000), Stattersfield & Capper (2000), Steadman (1999), Stinson & Stinson (1994), Stott (1947).

Genus *APALOPTERON* Bonaparte, 1854

80. Bonin White-eye

Apalopteron familiare

French: Zostérops des Bonin **German:** Boninhonigfresser **Spanish:** Antojitos de las Bonin
Other common names: White-eyed Honeyeater; Mukojima White-eye/Honeyeater (*familare*)

Taxonomy. *Ixos familiaris* Kittlitz, 1830, Boninsima = Muko-jima, north Bonin Islands. Initially described as a bulbul (Pycnonotidae), subsequently assigned to the babblers (Timaliidae) and then the Old World warblers (Sylviidae), and until recently included in honeyeaters (Meliphagidae). Recent DNA–DNA hybridization and field studies indicate closer relationships with present family, and especially with *Cleptornis marchei*. Two subspecies recognized.

Subspecies and Distribution.

A. f. familiare (Kittlitz, 1830) – N Bonin Is (on Muko-jima).

A. f. hahasima Yamashina, 1930 – S Bonin Is (Haha-jima, Mukô-jima, Hira-shima, Ane-jima, Imôto-jima and Mei-jima).

Introduced (*hahasima*) on Chichi-jima, in C Bonin Is.

Descriptive notes. 13.5 cm. Nominat race has yellow head with golden crown and distinctive triangular black eye patch which extends in thin line to well-defined black forehead; lores yellow, conspicuous white eyering interrupted by very thin black line at front and rear; upperparts olive-green with grey tinge, outer web of primaries tinged brownish, tail olive-brown; throat yellow, underparts pale yellow, greyish wash on flanks; iris brownish; bill and legs dark grey. Sexes alike. Juvenile is very like adult. Race *hahasima* very similar, but has yellowish-green tinge on upperparts, and larger bill and tarsus. **Voice.** Song, rarely heard (given almost exclusively during 20–30 minutes before sunrise), rather complex and melodious, “chew-i, chit-chit-pee, chot-chot-pee, ch-ee” or “tu-ti-ti, ti-titu-tuoo”, usually 1.8–2.3 seconds, in quality not unlike that of a bunting (*Emberiza*) or Siberian Blue Robin (*Luscinia cyane*); also song flights from perch. Calls include soft “pee-yu”, “weet” and “pit”, and explosive “tit-tit”; harsher “weet-weet” and “zhree-zhree” when mobbing.

Habitat. Found almost everywhere on Haha-jima, despite clearance of native forest: mountain and valley forest, low secondary forest, forest edge, bushes, plantations, gardens, near habitation, roadside brush and shrubs (especially *Leucaena glauca*), cultivated areas, pine (*Pinus*) woods, *Pandanus* on hillsides. Rare in dry low shrubs on windy peaks and ridges. Breeds in best patches of native forest (evergreen broadleaf forest dominated by *Schima* and *Artisia*, with well-developed but patchy undergrowth of bamboos, tall tree-ferns and tangled shrubs); secondary habitats used mainly for foraging outside breeding season.

Food and Feeding. Mainly soft fruits, such as papaya (*Carica*), *Acacia farnesiana*, bananas (*Musa*), mulberry (*Morus*) and others, also flowers. Also insects, especially ants (Formicidae), but also caterpillars, beetles and their larvae (Coleoptera, including curculionids), crickets (Orthoptera), flies (Diptera), homopteran bugs, Neuroptera larvae; spiders (Araneae); small reptiles. In one study, c. 50% of diet was plant material, from at least 15 species. Forages singly, in pairs and in small parties of 5–6 individuals; searches among twigs and leaves as other white-eyes, on trunks in manner of nuthatches (*Sitta*) and woodpeckers (Picidae), and on the ground in manner of *Erethacus* robins. This diversity of feeding ecology may have developed in absence of other small passerines; adapted for both an arboreal and terrestrial foraging (has long tarsi and strong toes and claws), the latter particularly in non-breeding season.

Breeding. Mar–Jun, mostly May, 1 record Feb, and young being fed by adults in Aug; sometimes double-brooded. Mating system little known, but year-long pair-bond suggested by observations of roosting birds in twos (probably pairs); apparently no territorial song, and may occur in small parties in breeding season. Both sexes participate in building nest, a crudely shaped deep cup, external diameter 98 × 103 mm and depth 72 mm, internal diameter 59 × 66 mm and depth 46 mm, outer layer of dead leaves, coarse grasses, pine needles and moss, some twigs, bark and plant down, inner wall mainly of long fibres, stems and rootlets, locally with goat wool and albatross (Diomedidae) feathers, placed 1–12 m (mean 6 m) above ground in tree, in one study 70% placed in dominant *Shima* trees, but introduced trees also utilized. Clutch 1–4 eggs, usually 2, pale greenish-blue with brown spots mainly at large end, 19–20 × 15–16 mm; incubation of eggs and feeding of chicks by both sexes, no information on duration of these periods.

Movements. Post-breeding dispersal throughout most of range, and in non-breeding season found almost everywhere on Haha-jima. Unconfirmed reports of birds moving from Haha-jima to other islands in the group in autumn and summer.

Status and Conservation. VULNERABLE. Nominat race probably Extinct. Historically reported from three island groups in the archipelago. In 1930 nominat race already extinct on Nakôdo-jima, in N group (Mukojima chain) of Bonins, when also last specimens taken on Muko-jima; not found in 1941 on latter island. S race *hahasima* known to survive in total area of less than 100 km², distributed across five or fewer sites in S group (Hahajima chain), with main stronghold on Haha-jima (little over 20 km²), where population estimated at maximum of 3000–4000 individuals in 1969 and about same in 1974; 3.3–4.5 pairs/ha in 1995/96. Status in C group (Chichijima chain) unclear; there were rumours in 1987 of its continued existence or, more likely, of its reintroduction on Chichi-jima. Decline in numbers of this species the result of historical clearance of primary forest, and presently tourism and infrastructural development pose continued threats to remaining secondary forest. On smaller islands in particular, introduced cats and rats (*Rattus*) could also be a serious threat; in addition, *Zosterops japonicus* was introduced in c. 1900–1910, and the two species share habitat and diet, but a study in 1995–1997 revealed no negative ecological interaction between the two species. This zosteropid has been protected as a National Endangered Species since 1993; Bonin Is, known also as the Ogasawara Is, are a National Wildlife Protection Area, established mainly for the conservation of the white-eye. Perhaps better regarded as Endangered.

(2007n), Brazil (1991), Butchart & Stattersfield (2004), Collar *et al.* (2001), Deignan (1958), Higuchi, Nakane & Maru (1993), Higuchi, Nakane & Suzuki (1984), Inskipp *et al.* (1996), Kawakami & Higuchi (2002, 2003), Kittlitz (1830), Morioka & Sakane (1978), Sibley & Monroe (1990), Sonobe (1982), Springer *et al.* (1995), Stattersfield & Capper (2000), Suzuki (1993), Suzuki & Morioka (2005), Suzuki *et al.* (1999), Yamashina (1930).

Genus *TEPHROZOSTEROPS* Stresemann, 1931

81. Bicoloured White-eye

Tephrozosterops stalker

French: Zostérops de Stalker **German:** Kakopibrillenvogel **Spanish:** Antojitos Bicolor
Other common names: Bicolored/Rufescent Dark-eye, Rufescent/Stalker’s/Karopi/Ceram White-eye

Taxonomy. *Tephros stalkerii* Ogilvie-Grant, 1910, Gunung Karopi, central Seram. Genus may be closely related to *Zosterops* (possibly closest to *Z. cinereus*), differing from it only in colour (complete absence of green and yellow pigments) and size (somewhat larger). Monotypic.
Distribution. W & C Seram (Ahiolo and Manusela), in S Moluccas.

Descriptive notes. 12–13 cm; male 17 g, female 20 g, unsexed 15–21 g. Plain white-eye with few obvious features. Plumage is rusty brown above, with slightly more rufous outer edges of blackish-brown remiges and rectrices; lores and ear-coverts slightly paler and more greyish; white below, tinged brown on flanks and thighs, pale yellowish tinge on undertail-coverts; axillaries pure white; iris reddish-brown to brown; bill dark horn-black; legs grey-blue. Sexes similar. Juvenile undescribed. **VOICE.** No information.

Habitat. Forest edge, in dense secondary growth and patches with epiphytes; scrub, edges of clearings; areas of overgrown cultivation. At 500–1200 m; mainly 650–950 m at Manusela.

Food and Feeding. Seeds, berries; insects, including beetles (Coleoptera). Singly and in twos, inconspicuous; often in mixed-species foraging flocks, particular with *Zosterops stalkerii*.

Breeding. Adult feeding young in Aug. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Seram EBA. Moderately common within its rather narrow altitudinal range.

Bibliography. Bowler & Taylor (1989a, 1993b), Coates & Bishop (1997), Inskipp *et al.* (1996), Mayr (1967), Mees (1953b, 1969), Sibley & Monroe (1990), Stattersfield *et al.* (1998), Stresemann (1914a), White & Bruce (1886).

Genus *MADANGA*

Rothschild & E. J. O. Hartert, 1923

82. Rufous-throated White-eye

Madanga ruficollis

French: Zostérops à gorge rousse

Spanish: Antojitos Golirrojo

German: Orangekehl-Brillenvogel

Other common names: Rufous-collared/Madanga White-eye, Buru Mountain White-eye, Rufous-throated Dark-eye

Taxonomy. *Madanga ruficollis* Rothschild and E. J. O. Hartert, 1923, Wa Fehat, Buru. Monotypic genus, with no obvious close relatives; perhaps closest to *Lophozosterops* and *Tephrozosterops*. Monotypic.

Distribution. W & C Buru (Mt Kapalatmada and Mada Range), in S Moluccas.

Descriptive notes. 13 cm. Has light greyish-olive crown, side of head and nape, paler on forehead and lores; rudimentary pale eyering consisting of very short scaly feathers; upperparts yellowish-green, remiges and rectrices browner with green edges; throat and upper chest bright cinnamon-rufous, rest of underparts dark greyish-olive, undertail-coverts yellowish-brown; iris black; bill blackish, paler base of lower mandible; legs pale brownish. Sexes alike but female considerably smaller. Juvenile undescribed. **VOICE.** No information.

Habitat. Montane forest at 820–1750 m, mainly above 1450 m; probably restricted to

small isolated pockets of elfin forest with strong epiphytic growth and stunted trees.

Food and Feeding. Few data; presumed to take invertebrates from bark and lichen. Forages in mixed-species flocks. Seen to climb up and down trunks in manner of a nuthatch (*Sitta*), for which pointed tail feathers and long strong toes appear to be adaptations.

Breeding. No information.

Movements. Not known.

Status and Conservation. **ENDANGERED.** Restricted-range species: present in Buru EBA. Uncommon and local. Four specimens collected in 1920s in mountains of W half of island. Revisited in 1990s, when two individuals observed in a mixed flock at Danau Rana, in far W; in 2006 a pair seen twice in C Buru. Although its montane habitat is supposedly secure, and the species is probably still common within its altitudinal range, habitat changes at Wa Fehat (noted in 1995), and its apparently very small population and range, make it very vulnerable. A nature reserve has been proposed.

Bibliography. Anon. (2007n), Butchart & Stattersfield (2004), Collar, Andreev *et al.* (2001), Collar, Crosby & Stattersfield (1994), Hartert (1924a), Inskipp *et al.* (1996), Mees (1969), Poulsen & Lambert (2000), Rheindt & Hutchinson (2007b), Robson (1996), Rothschild & Hartert (1923), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), White & Bruce (1886).

Genus *LOPHOZOSTEROPS* E. J. O. Hartert, 1896

83. Grey-hooded White-eye

Lophozosterops pinaiae

French: Zostérops à froc gris **German:** Pinaibrillenvogel **Spanish:** Antojitos Cabecigris

Other common names: Seram/Pinaia/Brown-breasted White-eye, Grey-hooded Dark-eye

Taxonomy. *Oreosterops pinaiae* Stresemann, 1912, Mount Binaija, central Seram. Monotypic.

Distribution. Mountains of C Seram, in S Moluccas.

Descriptive notes. 14 cm; 25–30 g. Very large white-eye. Head and neck are deep olive-grey, with slight brownish tinge on crown and ear-coverts, merging on nape into green mantle and side of neck; forehead and supraloral region dirty white, lores pale grey, broad white eyering interrupted by pale grey loreal streak; flight-feathers and tail feathers blackish-brown, broadly margined green (except on primary P2); throat and side of breast deep greyish-olive, somewhat paler on chin, and becoming paler on flanks, which are washed with buff, and dirty whitish on middle of abdomen; undertail-coverts bright yellow; iris light red-

dish-brown; bill black, base of lower mandible dark yellowish-brown; legs brown-grey. Sexes alike. Juvenile undescribed. **VOICE.** No information.

Habitat. Montane forest at limits of tree-fern forest, 1100–2450 m; most common at higher elevations.

Food and Feeding. Feeds on insect larvae, berries, small fruits and seeds. Singly and in pairs at lower elevations, where occasionally present in mixed-species foraging flocks; in flocks of up to 20 or more individuals at higher elevations. Frequents canopy; forages in densely foliated tree crowns and in thick growths of arboreal epiphytes.

Breeding. No information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Seram EBA. Fairly common but local.

Bibliography. Bowler & Taylor (1989a), Coates & Bishop (1997), Hartert (1920), Inskipp *et al.* (1996), Mayr (1967), Mees (1953b, 1969), Stattersfield *et al.* (1998), Stresemann (1914a, 1931a), White & Bruce (1886).

84. Black-masked White-eye

Lophozosterops goodfellowi

French: Zostérops de Goodfellow

Spanish: Antojitos Enmascarado

German: Mindanaobrillenvogel

Other common names: Mindanao/Apo/Goodfellow's White-eye

Taxonomy. *Zosterops goodfellowi* E. J. O. Hartert, 1903, Mount Apo, Mindanao, Philippines. Forms a superspecies with *L. squamiceps* and *L. javanicus*; extremely close to black-faced races (*frontalis* and *elongatus*) of latter species. Three subspecies recognized.

Subspecies and Distribution.

L. g. malindangensis (Mearns, 1909) – W Mindanao (Mt Malindang), in S Philippine Is.

L. g. gracilis Mees, 1969 – NE Mindanao (Mt Hilong-Hilong, in Diuata Mts).

L. g. goodfellowi (E. J. O. Hartert, 1903) – C & S Mindanao (Mt Kitanglad, Mt McKinley, Mt Apo, Mt Matutum, Mt Mayo).

Descriptive notes. 13.3 cm; male 19.5 g, female 20.7 g, unsexed 18.2–22.3 g. Nominat race has forehead and supraloral region grey-brown, indistinct pale eyering (almost non-existent), lores and line to below eye black, greyish ear-coverts; crown, side of head, nape and upperparts dull olive-green; remiges and rectrices blackish, all with dull green outer margins, flight-feathers with whitish inner margins; chin and throat dirty white, gradually changing into greenish-grey on breast, and pale lemon-yellow on flanks and undertail-coverts; iris reddish-brown; bill black; legs greyish-olive, soles yellowish. Sexes alike. Juvenile has

much paler underparts and duller upperparts. Race *malindangensis* is close to nominate but smaller, has crown more greenish-grey (not same colour as back), darker ear-coverts, and slightly more brownish tint in grey of forehead and above lores; *gracilis* is on average smaller (except for bill), has brownish-tinged crown, light supercilium, darker green upperparts. **VOICE.** Musical whistle, “tu-pik chu-beer” and “su si deer”, the two often uttered together in a series.

Habitat. Submontane and montane forest and forest edge, from 1250 m to 2400 m.

Food and Feeding. No details of diet. In parties and in mixed flocks with *Hypocryptadius cinnamomeus*, *Zosterops montanus* and Black-and-cinnamon Fantail (*Rhipidura nigrocinnamomea*). Forages at all levels in vegetation.

Breeding. Birds with enlarged gonads in Feb–May. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Mindanao and the Eastern Visayas EBA. Common to not uncommon, at least locally, e.g. common on Mt Kitanglad.

Bibliography. Delacour & Mayr (1946), Dickinson *et al.* (1991), Hachisuka (1930), Inskipp *et al.* (1996), Kennedy *et al.* (2000), Mayr (1967), McGregor (1909), Mees (1969), duPont (1971b), Rand & Rabor (1960), Sibley & Monroe (1990), Stresemann (1931a), Woods *et al.* (2003).

85. Scaly-headed White-eye

Lophozosterops squamiceps

French: Zostérops à tête rayée

Spanish: Antojitos Cabecirrayado

German: Schuppenkopf-Brillenvogel

Other common names: Streak(y)-headed Darkeye/White-eye, Celebes Grey-throated/Celebes Mountain White-eye, Scaly-crowned White-eye

Taxonomy. *Chlorocharis squamiceps* E. J. O. Hartert, 1896, Bonthain Peak, south Sulawesi. Forms a superspecies with *L. goodfellowi* and *L. javanicus*; race *heinrichi* resembles latter very closely. Six subspecies recognized.

Subspecies and Distribution.

L. s. heinrichi (Stresemann, 1931) – Tentolo-Matatin Mts, in NW Sulawesi.

L. s. striaticeps Riley, 1918 – mountains of NC Sulawesi.

L. s. stresemanni (van Marle, 1940) – Mt Ambang and Mt Soputan, in NE Sulawesi.

L. s. stachyrinus (Stresemann, 1932) – Latimojong Mts, in SC Sulawesi.

L. s. squamiceps (E. J. O. Hartert, 1896) – Bonthain Peak (Lompobatang Mts), in S Sulawesi.

L. s. analogus (Stresemann, 1932) – Mengkoka Mts, in SE Sulawesi.

Descriptive notes. 12 cm; 14–15 g. N nominate race has crown dark sepia, becoming lighter inwards, feathers having grey base, white shaft streak and white edges at tip, sides of head grey; upperparts olive-green; throat and upper breast whitish, feathers with very narrow sepia outer edges, greyish-white of lower breast changing smoothly into yellow below, with distinctly greener flanks; iris dark red-brown; bill black; legs bluish-grey or green, soles yellow. Sexes similar. Juvenile with crown tinged greenish, and perhaps slightly paler yellow underparts. Races vary mainly in size and in plumage coloration: *striaticeps* has

buffy-white throat, narrower white shaft streaks, and grey edges of crown feathers; *analogus* is smallest (with next race), has white throat lacking black scaly feather edges; *heinrichi* is smallest (with preceding race), has greyish-sepia crown with broad grey edges and inconspicuous white shaft streaks; *stresemanni* has more boldly patterned sepia crown, broadly bordered with grey and with both shafts and adjacent median parts of feathers boldly white; *stachyrinus* is largest race, similar to nominate but with broader white shaft streaks and no white edges at tips of crown feathers. Voice. Song a warbled series, lasting 4–5 seconds, consisting of loud, clear, sibilant high-pitched notes, repeated at intervals of 5–9 seconds (or much less frequently). Generally silent, but occasionally a harsh chirruping trill.

Habitat. Primary montane forest and forest edge and secondary growth, at 1000–2500 m; absent from fragmented bush zone of tallest peaks.

Food and Feeding. Diet includes fruits. In pairs and small groups; often in mixed-species foraging flocks in association with *Zosterops montanus*, *Zosterops atrifrons*, Sulawesi Leaf-warbler (*Phylloscopus sarasinorum*), Island Verditer-flycatcher (*Eumyias panayensis*) and Citrine Canary-flycatcher (*Culicicapa helianthea*), Rusty-bellied Fantail (*Rhipidura teysmanni*), and Yellow-sided (*Dicaeum aureolimbatum*) and Grey-sided Flowerpeckers (*Dicaeum celebicum*). Forages mainly in canopy, but ranges down to understorey. Appears to use probing techniques more than gleaning.

Breeding. No information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Sulawesi EBA. Generally widespread and common. Not uncommon in C Sulawesi; apparently of restricted distribution in NE Sulawesi. Occurs in Lore Lindu National Park.

Bibliography. van den Berg & Bosman (1986), Coates & Bishop (1997), Holmes & Philipps (1996), Inskipp *et al.* (1996), Mees (1969), Riley & Mole (2001), Rozendaal & Dekker (1989), Sibley & Monroe (1990), Stresemann & Heinrich (1940b), Watling (1983), White & Bruce (1986).

86. Javan Grey-throated White-eye

Lophozosterops javanicus

French: Zostérops javanais **German:** Javabrillenvogel **Spanish:** Antojitos de Java

Other common names: Grey-throated Dark-eye/Black-eye/Tufted-eye, Grey-throated(!)/Javan White-eye

Taxonomy. *Sylvia Javanica* Horsfield, 1821, Java.

Forms a superspecies with *L. goodfellowi* and *L. squamiceps*. Races appear to intergrade; also, a individual with characters typical of nominate race has been found within area occupied by *frontalis*. Three subspecies recognized.

Subspecies and Distribution.

L. j. frontalis (Reichenbach, 1852) – extreme W Java (Mt Karang, Mt Salak, Mt Gede-Pangrango).

L. j. javanicus (Horsfield, 1821) – Java except extreme W and extreme E.

L. j. elongatus (Stresemann, 1913) – extreme E part of Java (Mt Ijen) and Bali.

Descriptive notes. 13 cm. N nominate race has forehead, lores and supercilium creamy white, white eyering narrow below eye and slightly wider above; crown, side of head and nape dark olive-grey, upperparts olive-green; remiges and rectrices blackish-brown with olive-green outer margins; throat pale greyish, feathers slightly mottled yellowish-white; breast greyish-white, changing into yellow on belly, brighter yellowish-citrine on flanks and breast side; iris brown; bill greyish-black; legs greenish-yellow, grey or greenish-brown. Sexes similar. Juvenile has greenish tinge on crown and nape. Race *frontalis* has blackish loreal

patch, narrow at front, posteriorly as wide as eye, and broadly interrupting narrow white eyering, a narrow band of pale buff feathers (tinged ochre near nostril) runs from forehead to above anterior part of eye; *elongatus* is similar to previous, but has slightly larger bill (most pronounced on Bali), longer supercilium with less ochre tinge, and dark lores extending through eyering to just behind eye. Voice. Song composed of melodious whistles and call notes. Loud, high, long-drawn cheeping, rather throaty “turr”, “teerrrr-teerrrr”, or “chee-ee-weet-chee-ee-weeeet”.

Habitat. Forest, dense secondary growth, neglected tea plantations, farmland, in mountains above 900 m; most commonly seen in top zones of mountains.

Food and Feeding. Fruits and nectar; also beetles (Coleoptera) and caterpillars. Fruits taken from the trees *Myrica javanica*, *Eurya acuminata*, the herb *Polygonum chinense*, shrubs *Rubus lineatus*, *Rubus fraxinifolius*, *Rubus moluccanus*, *Schefflera lucescens*, *Gaultheria*, *Vaccinium varingiaefolium* and *Viburnum coriaceum*; nectar of the mistletoe *Scurrula lepidota*, and shrubs *Vaccinium varingiaefolium* and *Vaccinium laurifolium*. In pairs and small flocks; joins mixed-species flocks, especially those with Mountain Leaf-warbler (*Phylloscopus trivirgatus*), but also White-browed Shrike-babbler (*Pteruthius flaviscapis*), Sunda Warbler (*Seicercus grammiceps*) and others. Forages mostly in canopy of not too tall trees, high in forest edge and interior at lower elevations.

Breeding. Jan and Mar–Dec. Nest a rather solidly built spherical cup 6–9 cm in diameter, 4–14 cm high and 2.5–4.5 cm deep, of thin fibres, leaf strips, rootlets and the like, covered externally with various mosses, pale green beard lichen (*Usnea*) (this sometimes the most important nest material), usually firmly attached to fork or between various vertical branches in tree or shrub (e.g. *Anaphalis*

javanica) in or near dense forest, and usually high up but sometimes only a few metres above ground. Clutch 2 eggs, fine pale bluish-green or rather deep blue, 18.3 × 13.5 mm. No information on incubation and nestling periods.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Java and Bali Forests EBA. Common on mountains throughout Java. Very common above 1000 m on Bali. Occurs in Gunung Gede-Pangrango National Park.

Bibliography. Becking (1989), Docters van Leeuwen, H. (1929), Docters van Leeuwen, W.M. (1933), Hellebrekers & Hoogerwerf (1967), Holmes & Nash (1989), Hoogerwerf (1949, 1950), Inskipp *et al.* (1996), Kuroda (1933a), MacKinnon & Philipps (1993), Mees (1969, 1996), Sibley & Monroe (1990), Stattersfield *et al.* (1998).

87. Yellow-browed White-eye

Lophozosterops superciliaris

French: Zostérops à sourcils

German: Gelbbrauen-Brillenvogel

Spanish: Antojitos Cejiamarillo

Other common names: Eye-browed/White-browed White-eye, Yellow-browed Darkeye, Lesser Sunda Mountain White-eye

Taxonomy. *Zosterops superciliaris* E. J. O. Hartert, 1897, south Flores, Lesser Sundas.

Apparently closest to *L. dohertyi*. Two subspecies recognized.

Subspecies and Distribution.

L. s. harterianus (Rensch, 1928) – mountains of Sumbawa, in W Lesser Sunda Is.

L. s. superciliaris (E. J. O. Hartert, 1897) – mountains of Flores, in WC Lesser Sunda Is.

Descriptive notes. 13 cm. N nominate race has crown and upperparts dull olive-green, forehead and anterior part of crown tinged with fuscous; lores and broad superciliary stripe extending well behind eye pale yellow, accentuated by ill-defined blackish stripe from crown; side of head pale greyish-olive, narrow but complete white eyering; remiges and rectrices blackish-brown, broadly edged dull olive-green; dull yellowish-green below, most yellow on throat and centrally, greenest on sides; iris brownish-red; bill black; legs yellowish-grey. Sexes similar. Juvenile is duller than adult, less distinctly marked, and superciliary stripe not developed. Race *harterianus* has deeper yellow eyebrow than nominate. Voice. N nominate race gives rapid series of fairly high-pitched, bubbling, sometimes almost trilled, warbled notes (run together) interspersed with occasional brief “tchee-tchee”, the whole lasting for 6–17 seconds; also a ringing “peu-peu”.

Habitat. Mainly primary upper montane semi-evergreen rainforest; also casuarina (*Casuarina*) forest, logged and naturally degraded forest, forest edge, scrub, also very thin secondary growth; 1000–2140 m.

Food and Feeding. No details of diet. Usually in small groups, occasionally in larger parties, once a flock of 56 observed on Flores; often joins mixed-species flocks. Forages quietly in middle storey.

Breeding. Courtship feeding in Sept on Flores, and fledgling in Nov. A nest believed to belong to this species consisted mainly of narrow strips of bark and winged seeds of casuarina, built in fork of branch in casuarina forest. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Nusa Tenggara EBA. Common on Flores; thought to be much rarer on Sumbawa, but in recent survey found to be locally common, and presumably common in remaining montane forest. In view of its tolerance of logged and degraded forest, extent of forest remaining within its altitudinal range, and its refuge in higher-altitude montane forest, this species is thought not likely to be at any serious risk in the near future.

Bibliography. Butchart *et al.* (1996), Coates & Bishop (1997), Hartert (1897a, 1897b), Inskipp *et al.* (1996), Johnstone & Jepson (1996), Mees (1969, 2006), Pilgrim *et al.* (1997, 2000), Schmutz (1977), Stattersfield *et al.* (1998), Strange (2001), Verhoeve & Holmes (1999), White & Bruce (1986).

88. Crested White-eye

Lophozosterops dohertyi

French: Zostérops de Doherty

German: Schopbrillenvogel

Spanish: Antojitos Crestado

Other common names: Dark-crowned/Doherty's White-eye, Crested Dark-eye

Taxonomy. *Lophozosterops dohertyi* E. J. O. Hartert, 1896, Tambora, Sumbawa, Lesser Sundas.

Apparently closest to *L. superciliaris*. The short, rather inconspicuous crest and spotted eggs are unique within family. Two subspecies recognized.

Subspecies and Distribution.

L. d. dohertyi E. J. O. Hartert, 1896 – hills of Sumbawa and Satonda, in W Lesser Sunda Is.

L. d. subcristatus E. J. O. Hartert, 1897 – hills of Flores, in WC Lesser Sunda Is.

Descriptive notes. 12 cm. N nominate race has top of head blackish olive-brown, elongated crown feathers with sharply defined white dots in centres, spots becoming brownish and obsolete on hindcrown; narrow white eyering broken broadly at front, by black loreal streak, and narrowly at rear; blackish feathers at side of forehead, elongate yellowish spot behind eye, olive ear-coverts; upperparts, including upperwing-coverts, greyish-olive; remiges and rectrices blackish-brown with greenish outer edges; sulphur-yellow below, colour most intense on centre of belly and grading into yellowish-white on throat and chin; iris dark

brown; bill black; legs yellowish-grey. Sexes alike. Juvenile undescribed. Race *subcristatus* has shorter crest than nominate, paler crown sharply spotted only on forehead, yellow ear-coverts. Voice. On Flores (race *subcristatus*) distinctive and moderately rapid song of 14 clear, sweet whistles at even pitch, the series 5 seconds in duration, quite unlike typical white-eye notes and almost like those of *Turdus* thrush in quality; also a soft “tsip-tsip”.

Habitat. Primary semi-evergreen rainforest, tall secondary forest, wooded cultivation and scrub; degraded *Duabanga* forest and montane forest. Found in degraded forest only where closed canopy and extensive understorey remain. At 200–1400 m. Generally replaced by *L. supercilialis* above 1200 m.

Food and Feeding. No details of diet. Singly, in pairs and in groups of three or four individuals; often in mixed-species flocks with *Heleia crassirostris*. Forages quietly in understorey and dense scrub.

Breeding. Jul–Aug on Sumbawa; and Feb–Oct (peak May–Jun) on Flores. Clutch 2 eggs, sometimes 1 and rarely 3, light blue, sparsely to moderately dotted with variously sized coffee-brown spots, densest on blunt half, 17.9 × 13.6 mm. No other information available.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Nusa Tenggara EBA. Locally common in primary forest at 700–1000 m; generally scarce to rare in wooded cultivation and scrub. Optimum habitat for this species being lost at fast rate on Flores and Sumbawa, and it appears to be only moderately tolerant of degradation of habitat. Perhaps should be classified as Near-threatened.

Bibliography. Butchart *et al.* (1996), Coates & Bishop (1997), Hartert (1896, 1897a), Inskipp *et al.* (1996), Johnstone & Jepson (1996), Mees (1969, 2006), Pilgrim *et al.* (1997, 2000), Stattersfield *et al.* (1998), Strange (2001), Trainor (2002a), Verheijen (1964), Verhoye & Holmes (1999), White & Bruce (1986).

Genus *OCULOCINCTA* Mees, 1953

89. Pygmy White-eye

Oculocincta squamifrons

French: Zostérops pygmée **German:** Zwergbrillenvogel **Spanish:** Antejitos Pigmeo
Other common names: Pygmy Grey White-eye

Taxonomy. *Zosterops squamifrons* Sharpe, 1892, Mount Dulit, Sarawak, Borneo.

Genus closest to *Lophozosterops*. Monotypic.

Distribution. Hills and mountains of Borneo, ranging from Mt Kinabalu S along spinal chain to Mt Kenepai, and including Mt Magdalena, Kelabit Plateau, Mt Dulit, Hose Mts, Mt Penrissen, Long Laat, and Bangau.

Descriptive notes. 9–9.5 cm; three unsexed specimens 6.5–7.1 g. Plumage is olive-brown above, forehead with white-edged feathers (giving unkempt look); thin white eyering; greyish throat, yellowish-white underparts; iris greyish or buff-white; bill brownish-black; legs pale greyish or greenish. Sexes similar. Juvenile undescribed. Voice. Described as “chit-chit-chit”, or high-pitched “tsee-tsee...”.

Habitat. Hill forest and lower montane moss forest, especially edge vegetation, kerangas forest, sandy forest with dwarf vegetation, village clearings, secondary growth, dry scrub. Mostly above 800 m, and generally 550–1000 m, but

recorded to 2150 m; occasionally down to low altitudes (rarely to 50 m) in mixed dipterocarp forest.

Food and Feeding. Small fruits, small white and green berries, seeds; tiny insects also taken. Seen in flocks of 4–8 or more individuals; associates with White-bellied Erpornis (*Erpornis zantholeuca*), Chestnut-crowned Yuhina (*Staphida everetti*), other white-eyes and cuckoo-doves (*Macropygia*) when feeding on berries. Forages in crowns of tall trees, also in middle storey in edge vegetation; fast-moving, not settling anywhere for long. Uses foliage-gleaning in low growth. Will approach humans and cattle very closely in dense scrub.

Breeding. Males with enlarged testes in Jun and Jul. No other information.

Movements. Resident; wanders in search of fruiting trees.

Status and Conservation. Not globally threatened. Restricted-range species: present in Bornean Mountains EBA. Locally quite common, but inconspicuous. Fairly common in Kelabit Highlands.

Bibliography. Davison (1992), Hitoshi *et al.* (1996), Inskipp *et al.* (1996), Jenkins & de Silva (1996), MacKinnon & Phillipps (1993), Marsh (1989), Mees (1953b, 1954, 1969), Pfeiffer (1961), Sheldon *et al.* (2001), Smythies (1957), Smythies & Cranbrook (1981), Smythies & Davison (1999), Stattersfield *et al.* (1998), Wilkinson *et al.* (1991).

Genus *HELEIA* Hartlaub, 1865

90. Spot-breasted White-eye

Heleia muelleri

French: Zostérops de Timor **German:** Fleckenbrust-Brillenvogel **Spanish:** Antejitos de Timor
Other common names: Spot-breasted Dark-eye, Streak-breasted/Timor White-eye

Taxonomy. *H[eleia] Müller* Hartlaub, 1865, Timor.

Possibly forms a superspecies with *H. crassirostris*, but the two seem to be very well differentiated in plumage and vocalizations. Monotypic.

Distribution. Timor, in Lesser Sunda Is.

Descriptive notes. 13.5 cm. Has forehead and crown black with yellowish-green feather edges; lemon-yellow supercilium, a number of minute pale yellow feathers on eyelids (but not forming eyering), broad black lore stripe; black on nape gradually merging into uniform deep olive of upperparts; remiges and rectrices blackish-brown, broadly edged green; throat bright yellow, underparts yellowish-white with large dark grey spots, bolder on breast; iris red-brown; bill greyish-black; legs greenish-grey to grey-blue. Sexes alike. Juvenile is duller than adult, black crown mottling and dark breast spotting almost absent. Voice. Unmusical rattle lasting for 3–4 seconds, consisting of 10–20 very rapid mechanical notes initially rising and then falling; also a harsh but weak grating noise.

Habitat. Primary and tall secondary monsoon and evergreen forest, including some remnant patches, also woodland; appears to favour lower-lying areas with closed-canopy forest. Lowlands to 1300 m.

Wetar EBA. Uncommon and local, occasionally moderately common; apparently rare in E Timor, with only known recent sight record in Aug 1972. In W Timor found at all five major study sites in 1993, especially in evergreen forest at 1000 m. Although apparently not at immediate risk in W parts of range, further forest destruction could change this situation.

Bibliography. Anon. (2007n), Butchart & Stattersfield (2004), Coates & Bishop (1997), Collar & Andrew (1988), Gadow (1884), Inskipp *et al.* (1996), Mayr (1944a), Mees (1969), Noske (2003), Noske & Saleh (1996), Sibley & Monroe (1990), Stattersfield & Capper (2000), Stattersfield *et al.* (1998), White & Bruce (1986).

91. Thick-billed White-eye

Heleia crassirostris

French: Zostérops à bec fort **German:** Nacktaugen-Brillenvogel **Spanish:** Antejitos Picogordo
Other common names: Lesser Sunda Lowland White-eye, Sunda/Stripe-headed/Flores White-eye

Taxonomy. *Zosterops crassirostris* E. J. O. Hartert, 1897, south Flores, Lesser Sundas.

Possibly forms a superspecies with *H. muelleri*, but the two seem to be very well differentiated in plumage and vocalizations. Birds from Sumbawa perhaps slightly larger and with perhaps more cream colour on crown, sometimes separated as *junior* (described from Batu Dulang), but differences from Flores birds considered insufficient to warrant naming of geographical races. Monotypic.

Distribution. Sumbawa and Flores (Lesser Sunda Is).

Descriptive notes. 13.5 cm. Has creamy-white forehead, black forecrown with creamy-white feather edges, black on lores and broad ring below eye (forming blackish face mask), eyering consisting of tiny black feathers implanted on rim of eye, black ear-coverts; bare area below blackish, above and particularly behind eye; hindcrown and upperparts dark olive brown; plain underparts whitish-buff with very pale yellow tinge; iris brown-white to yellow; bill pale grey; legs reddish-grey. Differs clearly from *H. muelleri* in plumage pattern and in heavier bill. Sexes alike. Juvenile has uniformly buff forehead and crown. Voice. Song a very rapid

series of loudly whistled, almost trilled notes on even pitch, repeated at c. 4 notes per second, each bout lasting c. 6 seconds, more like song of a whistler (*Pachycephala*) than of a white-eye; described also as a mellow, melancholy whistle interspersed with single trilled notes, each phrase starting hesitantly, working up to trill at end; longer phrases have several trills separated by longer whistles, with abrupt changes in pitch. Contact call a quiet, deep, unobtrusive “chup...chup...”.

Habitat. Mainly primary and degraded semi-evergreen rainforest and moist deciduous monsoon forest; also degraded forest edge, dry forest and *Eupatorium* scrub. Wide altitudinal range, 50–2000 m.

Food and Feeding. No details of diet. Usually in groups of up to five individuals, also singly and in pairs; often in mixed-species flocks. Forages in understorey and lower middle storey. Gleans along slender branches and fine twigs.

Breeding. Adults with brood patch and carrying nesting material in early Aug on Sumbawa; season Mar–Oct (peak Apr–Jun) on Flores. Clutch 1–4 eggs, normally 2 or 3, usually white, occasionally pale blue, 19.1 × 13.9 mm. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Northern Nusa Tenggara EBA. Generally uncommon to rare; locally moderately common. Occurs in very low densities. Moderate tolerance of degraded and dry forest indicate that it is presently not at any immediate risk; because of great pressure from small-scale agriculture on forests in lower half of its altitudinal range, this species should be closely monitored.

Bibliography. Butchart *et al.* (1996), Coates & Bishop (1997), Hartert (1897a, 1897b), Inskipp *et al.* (1996), Mees (1969, 2006), Pilgrim *et al.* (1997, 2000), Stattersfield *et al.* (1998), Strange (2001), Trainor (2002a), Verheijen (1964), Verhoye & Holmes (1999), White & Bruce (1986).

Genus *CHLOROCHARIS* Sharpe, 1888

92. Mountain Black-eye

Chlorocharis emiliae

French: Zostérops à lunettes noires **Spanish:** Antejitos Ojinegro
German: Schwarzzring-Brillenvogel

Other common names: (Olive) Black-eye

Taxonomy. *Chlorocharis emiliae* Sharpe, 1888, Mount Kinabalu, Borneo.

Geographical variation somewhat clinal, from large, long-tailed and dark in N of range to smaller, relatively shorter-tailed and paler in S. Four subspecies recognized.

Subspecies and Distribution.

C. e. emiliae Sharpe, 1888 – Mt Tambuyukon and Mt Kinabalu, in N Borneo.

C. e. fusciceps Mees, 1954 – Maga Mts (S part of Crocker Range), in N Borneo.

C. e. trinitiae Harrison, 1957 – Mt Trus Madi, in N Borneo.

C. e. moultoni Chasen & Kloss, 1927 – mountains of N & W Borneo: Mulu, Murud, Tama Abu Range and Poi (Pueh) Range (in Sarawak) and Mt Niyut (in W Kalimantan).

Descriptive notes. 11–12 cm; one unsexed specimen 13.9 g. Nominative race has top of head and upperparts dark olive-green with distinct blackish cast (blackish very pronounced on crown, least so on rump); black lores connected to black ring around eye, this black mask bordered with lighter yellow area of variable width; below, plumage somewhat lighter and more yellowish than upperparts, especially centrally; iris brown; bill brown above, yellowish-orange below; legs dark yellowish-brown to blackish, soles yellow. Sexes alike. Immature has brown iris and dull orange to blackish bill. Races vary in darkness of plumage and in size: *trinitae* is like nominate, but brighter and more yellow, with almost pure yellow belly, more yellow at side of head; *moultoni* is smaller, relatively shorter-tailed, lighter, and more yellowish in colour; *fusciceps* is like last, but somewhat darker, more sepia-coloured on crown and forehead. Voice. Song, often heard in dawn choruses, a melodious “wit-a-wit, wit wit wheer”, not unlike that of a *Turdus* thrush. Twittering call notes “twit-u” or “stwet-u”, or “te-wio”; in flight jangling calls and a stuttering “guguguju”.

Habitat. Montane moss forest and stunted growth at higher elevations. On Mt Kinabalu above 3300 m predominantly heathers (*Erica*), conifers, rhododendrons (*Rhododendron*), pitcher plants, mosses, lichens, etc., mostly up to 10 m tall, with few trees in sheltered gulleys; at 3800–4200 m habitat becomes bare rock with little pockets and clefts with stunted heather, moss, and the like. Found throughout this habitat from treetops to near ground, and in dwarf clumps of heather close to bare summit. From 1650 m to 4000 m Mt Kinabalu; from 1250 m but chiefly above 1600 m on Mt Mulu; 1550–2600 m on Trus Madi, and 1850–2250 m on Tambuyukon.

Food and Feeding. Insects and vegetable matter. Insects preferred, include e.g. grasshoppers (Orthoptera), perhaps ants (Formicidae). Vegetable matter taken only very sparingly (even when stomach empty), includes small fruits (*Rubus*), nectar (*Schima*, pink to dark red flowers of *Rhododendron acuminatum* and *Rhododendron buxifolium*, *Eugenia*, and sometimes *Elaeocarpus*), possibly pollen; pierces flowers of *Rhododendron rugosum* in search of nectar. In pairs or in small flocks of up to five individuals. Forages in tree crowns and lower, down to small bushes. Insects taken from hanging inflorescences, bunches of new leaves, thick lichen and among foliage.

Breeding. Feb–Mar, Jun and Sept. Nest a rather flat compact cup of tendrils and coarse dead grasses with some lichens and staghorn moss (*Lycopodium*), heather roots incorporated, lined with finer grasses and moss fibres of brilliant orange colour (giving vivid and unusual effect); built at 1–8 m in fork in branches of *Leptospermum* tree in dense heath. No other information.

Movements. Some vertical movement; downhill movements during droughts, e.g. in 1983 recorded at 1500 m on Kinabalu.

Status and Conservation. Not globally threatened. Restricted-range species: present in Bornean Mountains EBA. Locally common; much the commonest bird species above 2300 m on Trus Madi and above 3300 m on Mt Kinabalu. Very localized in W of range (Mt Poi and Mt Niyut).

Bibliography. Allen & Berwick (1958), Argent (1985), Davison (1992), Davison & Chew (1996), Davison (1992), Harrison (1956a, 1956b), Hitoshi *et al.* (1996), Inskipp *et al.* (1996), Jenkins & de Silva (1996), MacKinnon & Philipps (1993), Mees (1954, 1969), Prieme & Heegaard (1988), Sheldon & Francis (1985), Sheldon *et al.* (2001), Smythies (1957), Smythies & Cranbrook (1981), Smythies & Davison (1999), Steinheimer (1999), Strange (2001).

Genus *MEGAZOSTEROPS* Stresemann, 1930

93. Giant White-eye

Megazosterops palauensis

French: Zostérops des Palau **German:** Bronzebrillenvogel **Spanish:** Antojitos de las Palaos
Other common names: Palau (Greater)/Large Palau White-eye

Taxonomy. *Cleptornis palauensis* Reichenow, 1915, Babeldaob, Palau.

Rather atypical member of the family. Has sometimes been placed in genus *Rukia*. Monotypic.

Distribution. Palau Is (Babeldaob, Urukthapel and Peleliu).

Descriptive notes. 13.5–14 cm. Large, relatively dull white-eye with heavy bill. Has pale yellowish supercilium from before eye, widening backwards, narrow indistinct pale yellow eyering, and dusky loreal area leading to dark greyish ear-coverts with irregular pale yellow mottling; dark fulvous olive above, crown feathers greyish towards bases (giving mottled appearance); pale fulvous olive below, flanks slightly more buffy; iris greyish to dark rufous-brown; bill pale brown above, orange-yellow below; legs tawny or olive-green, soles yellowish. Sexes alike. Juvenile undescribed. Voice. Song one of the most bizarre, some downward-inflected strained

whistles followed by long trill or rhythmic rattling, surging in intensity while simultaneously upslurred whistles, trills and descending siren-like slurs uttered polyphonically; altogether sounding like two canaries (*Serinus*) singing at same time. Calls include harsh scolding chatter, also loud grating calls during mutual chases; short sibilant downslurred whistle during feeding or in flight.

Habitat. Native forests and *Leucaena* thickets.

Food and Feeding. Caterpillars, ants (Formicidae); also fruits, and nectar from flowering trees. Reportedly lives solitary or in pairs, usually not travelling in flocks, although may apparently form flocks in Dec. Forages in tops of low trees and brambles, preferring upper part of tall vine-draped trees; also feeds in vine tangles close to ground.

Breeding. No information.

Movements. Not known.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Palau EBA. Fairly common to abundant on Peleliu in rela-

tively undisturbed jungle, common on Urukthapel. Apparently only one record from Babeldaob. Total population in 1991 estimated at 13,876 individuals. Absence from neighbouring islands of Palau Group (e.g. Koror, Eil Malk) difficult to explain. Population possibly declining as a result of gradual habitat loss. Introduction of predators could have serious adverse effects; in particular, arrival of brown tree-snake (*Boiga irregularis*), which has caused extinctions on other Pacific islands, would have devastating effect on present species' numbers.

(2007n), Baker (1951), Butchart & Stattersfield (2004), Craig (1999), Engbring (1988), Greenway (1958), Lack (1971), Marshall (1949), Mayr (1945b), Mees (1969), Owen (1977), Pratt, Bruner & Berret (1979, 1987), Pratt, Engbring *et al.* (1980), Reichenow (1915), Stattersfield & Capper (2000).

Genus *SPEIROPS* Reichenbach, 1852

94. Bioko Speirops

Speirops brunneus

French: Zostérops de Fernando Po

Spanish: Antojitos de Fernando Póo

German: Braunbrillenvogel

Other common names: Fernando Po Speirops

Taxonomy. *Speirops brunnea* Salvadori, 1903, Bioko.

Monotypic.

Distribution. Pico Basilé (Mt Malabo), in NC Bioko I (Fernando Póo).

Descriptive notes. 13–13.5 cm; 14–18.5 g. Has top of head dark brown, darkest on crown, pale narrow line at base of upper mandible, reddish tinge on nape and hindneck; cheek and ear-coverts greyish-brown; upperparts brown, less dark than crown, flight-feathers blackish-brown, edged rusty, tail feathers dark brown above and blackish below; underside brown, slightly paler than back, more greyish on chin and upper throat, and slightly paler on belly and undertail-coverts; underside of remiges dark grey-brown; iris dark; bill dark horn; legs dusky brown. Sexes alike. Juvenile undescribed. Voice. No song described. Various calls

include frequently uttered soft “peep” and rapid “trik-trik-trik” twitters during foraging, squeaky “tweet” in flight; also reported a long trill, “rrrrrrrruuu”.

Habitat. Open areas and clearings in fairly open lichen (not moss) forest, montane heathland scrub, and tree savanna; forest with *Hypericum*, *Pittosporum*, *Syzgium* and *Schefflera*. At 1900–2800 m.

Food and Feeding. Insects, including hairless caterpillars 10–25 mm long; also berries and seeds. In groups of 3–5 individuals, sometimes up to 30 together; often in mixed flocks with Green Longtails (*Urolais epichlorus*), Oriole Finches (*Linurus olivaceus*) and Western Mountain Greenbuls (*Andropadus tephrolaemus*). Forages at 0.5–6.5 m above ground; tends to keep in moderately leafy cover, out of direct sunshine.

Breeding. Birds in breeding condition in Oct and Dec. No other information.

Movements. Not known.

Status and Conservation. **VULNERABLE.** Restricted-range species: present in Cameroon Mountains EBA. Common on higher slopes. The commonest bird species in 50-km² area of lichen forest on Mt Malabo; absent from suitable forest in S part of the island. Surveys in late 1980s and mid-1990s indicated that this species is still present in small groups and that its habitat remains largely intact. It is thought, however, that it may be threatened by fires and by extensive forest clearance.

Bibliography. Anon. (2007n), Borrow & Demey (2001), Butchart & Stattersfield (2004), Collar & Stuart (1985), Collar *et al.* (1994), Eck (1995), Eisenraut (1973), Feiler & Nadler (1992), Fry *et al.* (2000), Pérez del Val *et al.* (1994), Stattersfield & Capper (2000), Wells (1968), Wolff-Metternich & Stresemann (1956).

95. Principe Speirops

Speirops leucophoeus

French: Zostérops de Principé

German: Silberbrillenvogel

Spanish: Antojitos Plateado

Other common names: Prince's Island/Principe Island Speirops

Taxonomy. *Parinia leucophoea* Hartlaub, 1857, Gabon; error = Principe.

Possibly belongs to the superspecies formed by *S. lugubris* and *S. melanocephalus*. Monotypic.

Distribution. Principe I, in Gulf of Guinea.

Descriptive notes. 12.5–14 cm; two specimens 14.7 g and 14.9 g. Has pale grey forehead, crown and nape, dark grey lores, very narrow white eyering, whitish cheek and ear-coverts, dark grey upperparts (considerable variation in amount and shade of grey in all these areas); flight-feathers dark brown, secondaries and tertials narrowly fringed olive-grey, tail dark brown; pale grey to greyish-white below, underside of flight-feathers shiny dark grey with whitish inner edges, underwing-coverts greyish-white; iris golden-brown; bill dark grey above, whitish below; legs pearl-grey, soles yellow. Sexes alike. Juvenile undescribed. Voice. Possible song a repeated series of rattling, tuneless notes, or perhaps fast, sibilant “whee-tsiu-tsiu-tseu” and “tsee-tsiu” or “tsiupti-ti-ti”. Calls include various high-pitched trills, rattles and single notes, e.g. a soft “rrrrrrr”, a short “tiup tiup”, also “tuctuctuctuctuct” flight call.

Habitat. Primary forest, but more commonly in forest regrowth, trees and bushes in farmland, and cocoa and coffee plantations shaded by large *Erythrina* trees. Lowlands.

Food and Feeding. Insects, spiders (Araneae), berries, possibly nectar and other vegetable matter. In pairs, and in parties of up to 15 individuals, keeping together closely. Forages mostly in middle

strata of vegetation at c. 8 m, also in undergrowth and canopy; restless and mobile, moving among leaves and foliage. Gleans leaves and other twigs in manner of a tit (Paridae).

Breeding. Mainly Jun–Jul (hatching), but records also of nest-building in Jan and laying in Sept. Nest a delicate loosely woven open cup 9 cm across and 6 cm deep, made from fine grasses and fine twigs or petioles, or dry twigs and moss, attached with moth-cocoon silk to twigs. Clutch 2 eggs, white, 19 × 16 mm. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Currently considered Near-threatened. Restricted-range species: present in Príncipe EBA. Frequent to common but somewhat local. In 1970s was still abundant at all altitudes, but may have declined since; evidence of local persecution and of a possible decline as a result of plantation development and pesticide use was found during a survey in 1987. Can still be found in groups of up to 15 birds in forest regrowth and cocoa plantations.

Bibliography. Anon. (2007n), Atkinson *et al.* (1991), Bannerman (1914, 1948), Borrow & Demeý (2001), Butchart & Stattersfield (2004), Christy & Clarke (1998), Collar *et al.* (1994), Dohrn (1866), Eck (1995), Feiler & Nadler (1992), Fry *et al.* (2000), Jones & Tye (1988, 2006), Keulemans (1866), Snow (1950), Stattersfield & Capper (2000).

96. Black-capped Speirops
Speirops lugubris

French: Zostérops de Sao Tomé **Spanish:** Antejitos de Santo Tomé
German: Trauerbrillenvogel

Other common names: Sao Tome Speirops

Taxonomy. *Zosterops lugubris* Hartlaub, 1848, São Tomé. Forms a superspecies with *S. melanocephalus*, and formerly considered conspecific, but morphologically and ecologically different; *S. leucophoeus* possibly belongs to same superspecies. Monotypic.

Distribution. Mountains of São Tomé I, in Gulf of Guinea.

Descriptive notes. 13.5–15 cm. Has forehead, crown and nape matt black, thin buffy line between nostril and lores; white lores and broad white eyering; upperparts dark greyish-olive; flight-feathers dark brown, edged olive, tail feathers blackish, fringed olive at bases; throat and underparts greyish-olive or buffy olive, indistinct whitish spots on chin and upper throat, whitish thighs, dull yellowish-olive undertail-coverts; underwing shiny grey with white shafts, creamy-white underwing-coverts; iris pale reddish-brown to brown; bill yellow-brown, culmen darker near tip; legs flesh-coloured. Sexes alike. Juvenile undescribed.

VOICE. Musical, whistled song, loud and powerful for so small a bird; mimics various other bird species. Contact call a short, dry trill (not whinnying like that of *Zosterops*); various other calls described as dry rattling, a high-pitched soft flight call, nervous trilling alarm, sharp “whseew”.

Habitat. Shady understorey of tall humid primary forest and secondary forest, patches of dry forest in savanna, around lakes and along watercourses, cocoa and coffee plantations; at all altitudes but mainly above 900 m.

Food and Feeding. Small berries, e.g. *Cestrum levigatum*, pieces of avocado (*Persea*), probably nectar; also insects, including caterpillars. In pairs, and in parties of 10–12, occasionally up to 25 individuals, which move from tree to tree; also in mixed flocks with *Zosterops ficedulinus*, Sao Tome Paradise-flycatcher (*Terpsiphone atrochalybeia*), Giant Weaver (*Ploceus grandis*), Newton’s Sunbird (*Anabathmis newtonii*) and Sao Tome Oriole (*Oriolus crassirostris*). Forages in lower strata at 5–10 m, sometimes down to 1 m above ground; also in herbaceous plants, on walls of old buildings and in dense bushes. Gleans items from leaves and twigs.

Breeding. Nest-building Dec to mid-Jan and eggs in Apr–Jun. Nest a delicate but quite thick-walled deep open cup, made from fine fibres, placed in forked twig 4 m up in lower canopy of *Chincona* tree. Clutch 2–3 eggs, white, plain or very finely speckled with grey, 19 × 13.5 mm. No other information.

Movements. Sedentary.

Status and Conservation. Not globally threatened. Restricted-range species: present in São Tomé EBA. Common to abundant throughout, especially at higher altitudes and perhaps in S of island; the dominant bird species on São Tomé. Formerly occurred also on I das Rolas, a tiny island (5 km²) off S coast, but now extinct there.

Bibliography. Atkinson *et al.* (1991), Bannerman (1948), Bocage (1891, 1904), Borrow & Demeý (2001), Christy & Clarke (1998), Eccles (1988), Eck (1995), Feiler & Nadler (1992), Fry *et al.* (2000), Gadow (1884), Günther & Feiler (1985), Jones & Tye (2006), Nadler (1993), de Naurois (1994).

97. Mount Cameroon Speirops
Speirops melanocephalus

French: Zostérops du Cameroun **Spanish:** Antejitos del Camerún
German: Kamerunbrillenvogel

Other common names: Cameroon White-eye/Speirops

Taxonomy. *Zosterops (Speirops) melanocephala* G. R. Gray, 1862, Mount Cameroon. Forms a superspecies with *S. lugubris*, and formerly considered conspecific, but differs morphologically and ecologically; *S. leucophoeus* possibly belongs to same superspecies. Monotypic.

Distribution. Mt Cameroon, in SW Cameroon.

Descriptive notes. 13 cm; 9–12.5 g. Has very dark brown, slightly glossy crown to nape, hindneck and side of head, greyish-white forehead and lores contrasting strongly with dark cap, very narrow white eyering; upperparts grey-brown, slightly greyer on rump; flight-feathers dark brown, all except outer primaries fringed whitish to olivaceous grey-brown; tail feathers dark brown above, blackish below; greyish-white chin and upper throat (contrasting with dark cheek), buffy grey below, more buff on flanks, with whitish thighs and pale grey vent; underwing silky white; iris pale brown to yellow, brownish-white or grey; bill yellowish or white, sometimes tipped pinkish; legs

white to pinkish-white or pale greyish-flesh. Sexes alike. Juvenile undescribed. **VOICE.** Song, very loud for size of bird, 2–2.5 seconds in duration, a sequence of staccato, tuneless, rising and falling notes, similar in quality to song of *S. leucophoeus*; another song type much richer, described as 7–8 sweet notes, first rising and then falling in pitch. A rattling “trrr” call and soft “cheep, cheep” calls also reported.

Habitat. More open parts of forest, forest clearings, thickets and bushy patches, avoiding denser closed-canopy areas, and generally confined to clearings in lower parts of range; at highest altitudes occurs in forest edge and

patches of vegetation in windswept grassland. At 1800–2750 m, sometimes to 3000 m.

Food and Feeding. Insects; also berries and other vegetable matter. Feeds singly, in pairs and in parties of 5–15 individuals; also in mixed flocks with White-bellied Crested-flycatcher (*Elminia albiventris*), Northern Double-collared Sunbird (*Cinnyris reichenowi*) and *Zosterops senegalensis*. Forages in canopy and middle levels. Actively inspects mossy holes, branches, leaves and twigs; tears apart fresh flowers and buds.

Breeding. Birds with enlarged gonads in Nov–Dec and Mar. No other information.

Movements. Resident; some vertical movement, e.g. seen at 1850–2800 m in Dec but less commonly at 1950–2150 m in Jan.

Status and Conservation. **VULNERABLE.** Restricted-range species: present in Cameroon Mountains EBA. Common; generally, not difficult for human observer to see c. 15 individuals in a day. This species is confined to a relatively narrow altitudinal belt in a small mountain range. Main threats are habitat destruction by natural fires and lava flows (active volcano); also fires set regularly by hunters, despite official management of the site by the Mount Cameroon Ecotourism Project.

Bibliography. Anon. (2007n), Bannerman (1948), Borrow & Demeý (2001), Butchart & Stattersfield (2004), Collar *et al.* (1994), Eck (1995), Eisentraut (1968, 1973), Feiler & Nadler (1992), Fry *et al.* (2000), Gadow (1884), Louette (1981), Stattersfield & Capper (2000), Stuart & Jensen (1986).

Subfamily HYPOCRYPTADIINAE
Genus *HYPOCRYPTADIUS*

E. J. O. Hartert, 1903

98. Cinnamon Ibon
Hypocryptadius cinnamomeus

French: Zostérops cannelle **German:** Zimtbrillenvogel **Spanish:** Antejitos Canelo

Other common names: Cinnamon Rufous-eye/White-eye

Taxonomy. *Hypocryptadius cinnamomeus* E. J. O. Hartert, 1903, Mount Apo and Mount Kitanglad, Mindanao, Philippines. True affinities unclear; may merit placement in separate family. Birds from Gandawan (on Mt Malindang) described as race *malindangensis* and those from Daggayan (in Misamis Oriental) as *pallidigula*, but differences from birds in rest of species’ range considered trivial. Treated as monotypic.

Distribution. Mountains of Mindanao, in S Philippines: recorded from Mt Malindang, Misamis Oriental (and coastal mountains at Daggayan), Mt Kitanglad, Mt Hilong-Hilong, Mt Apo, Mt Matutum, Mt Mayo.

Descriptive notes. 15 cm; male 28.3 g, female 30.1 g, 22 unsexed 24.7–31.5 g. Has top of head and upperparts entirely bright cinnamon, flight-feathers blackish-grey with cinnamon outer edges and inner webs; tail feathers largely cinnamon, mixed with grey (especially towards tips); chin, throat and breast light cinnamon, becoming paler on lower breast and flanks, with lower flanks and undertail-coverts pale buffy grey, centre of belly dirty white; iris reddish to pale yellowish-red; bill bluish-grey, blackish tip; legs bluish-grey. Sexes alike. Juvenile undescribed. **VOICE.** Call a soft whistle, “chuuu, pee chuuu” or “pee chuuu chuuu”, al-

most whining in quality, and often given continuously by several individuals together.

Habitat. Submontane and montane mossy forest and forest edge; above 1000 m.

Food and Feeding. Insects. In groups; also as core species in mixed flocks with *Zosterops montanus*, *Lophozosterops goodfellowi*, Black-and-cinnamon Fantail (*Rhipidura nigrocinnamomea*), Elegant Tit (*Periparus elegans*) and Mountain Leaf-warbler (*Phylloscopus trivirgatus*). Forages in all storeys of forest. Gleans prey from small branches and leaves.

Breeding. Birds with enlarged gonads Feb–May. No other information.

Movements. Not known.

Status and Conservation. Not globally threatened. Restricted-range species: present in Mindanao and the Eastern Visayas EBA. Common at least locally, e.g. on Mt Kitanglad. Probably reasonably common in all parts of range.

Bibliography. Delacour & Mayr (1946), Dickinson *et al.* (1991), Hachisuka (1930), Inskipp *et al.* (1996), Kennedy *et al.* (2000), Mayr (1967), McGregor (1909), Mees (1969), duPont (1971a, 1971b), Rand & Rabor (1960), Sibley & Monroe (1990), Stresemann (1931a), Woods *et al.* (2003).

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family PROMEROPIDAE (SUGARBIRDS)

- Medium-sized nectarivores with long, slender decurved bill, strong feet with sharp-clawed medium-sized toes, short rounded wings, very long tail; plumage brown above, more rufous crown and chest, yellow undertail-coverts.
- 23–44 cm (including elongated tail of 15–38 cm).

- Southern Africa.
- Mainly fynbos and protea scrub in montane areas.
- 1 genus, 2 species, 3 taxa.
- No species threatened; none extinct since 1600.

Systematics

The relationships of the sugarbirds are complex. The two species in the genus *Promerops* were first considered to be related to the Australian honeyeaters (Meliphagidae), a conclusion reached on the basis of tongue structure, nest construction and behavioural similarities. C. G. Sibley and J. E. Ahlquist, however, from their studies of egg-white protein in the 1970s, regarded the sugarbirds as specialized starlings (Sturnidae), but the egg-white protein was later reanalysed and found to be similar to that of the sunbirds (Nectariniidae). Ten years later, S. L. Olson and P. L. Ames proposed a transfer of this family to the thrushes (Turdidae) on the basis of the morphology of the syrinx, which was considered to be homologous to the "turdine thumb" of the thrushes. In a subsequent study, in 1994, M. R. Farquhar and colleagues compared the feather ultrastructure and skeletal morphology of the families Meliphagidae, Nectariniidae and Promeropidae. Their results indicated that it was not possible to clarify the taxonomic position of *Promerops* on the basis of these characters alone.

The sugarbirds have been treated by some recent authors as a subfamily, Promeropinae, of Nectariniidae, but others prefer to accord them family rank until further taxonomic evidence is forthcoming; the latter was, for example, the treatment adopted by P. A. R. Hockey and colleagues in the seventh edition of *Roberts Birds of Southern Africa*, published in 2005. The two species, the Cape Sugarbird (*Promerops cafer*) and Gurney's Sugarbird (*Promerops gurneyi*), are very similar to each other in many respects and form a superspecies.

During a long-term study investigating avian haematozoa in African birds, a blood parasite was found in Gurney's Sugarbird that was apparently indistinguishable from *Leucocytozoon annelobiae*, a form known from the Little Wattlebird (*Anthochaera chrysoptera*) of the Meliphagidae. *Leucocytozoid* parasites are supposedly specific to a host family, and on this basis the sugarbird parasite was named as a new species, *L. deswardti*. The presence of what appeared to be the same parasite in African sugarbirds and Australasian honeyeaters has prompted some speculation on the origins and evolution of these birds, which could have shared a common ancestor before becoming separated by continental drift some 40 million years ago. However, recent work on the DNA of haematozoa reveals that while some are indeed host-specific, others are mobile across lineages, so the debate continues.

Very recent molecular work indicates that the sugarbirds appear to have no close living relatives. It shows them as an old

lineage, basal to a sizeable clade of passerines, Passeroidea, which includes the sunbirds, leafbirds (Chloropseidae), sparrows (Passeridae), buntings (Emberizidae), and wagtails and pipits (Motacillidae), amongst others. Much still remains to be discovered and agreed upon, but in the meantime there certainly appears to be a good case for retaining the sugarbirds in their own separate family.

Morphological Aspects

Both sugarbirds resemble a large, long-tailed sunbird. They have mostly streaky brownish plumage with yellow undertail-coverts, while bill and legs are black. The brown, floppy tail of the Cape Sugarbird is exceptionally long, with a maximum length of 38 cm. The female of this species has a shorter tail, and the sexes can be easily separated in the field by this character alone. The tail of Gurney's Sugarbird is noticeably shorter than that of the Cape Sugarbird, with a maximum length of 19.3 cm for males and about 15.5 cm for females, while the tail of some unsexed individuals of Gurney's Sugarbird measures less than 11 cm.

In terms of plumage, the Cape Sugarbird typically shows a dull brown breastband which is variable in colour, but not so solidly red nor so richly chestnut as the breast of Gurney's Sugarbird. In addition, the Cape Sugarbird has a pale creamy forehead and crown, whereas Gurney's has a chestnut-red forehead and crown. Immatures of both species have browner plumage and are shorter-tailed than adults; furthermore, they lack the bright yellow on the undertail-coverts, which are, instead, olive-yellow.

The skull anatomy of *Promerops* was described by W. J. Bock, who compared it with those of sunbirds and honeyeaters. The sugarbird skull was found to be similar to that of the meliphagids, with no unique or special homologues in cranial osteology. The tongue of the sugarbirds is similar to that of the honeyeaters, and this similarity is believed to be the result of convergent evolution. Both families possess a tongue which is long and protrusible, and which differs from that of other species groups in being distally almost tubular and in having a brush-like tip divided into four parts, unlike the split tip found in, for example, the sunbirds. The tongue tapers gradually from its base, and the tip of the tongue is flexible, as is the case also with meliphagids and other nectar-feeding birds that have a frilled-tipped tongue. The tubular, frilled tongue strongly resembles that of the meliphagids, having evolved

Sugarbirds are fairly large nectarivorous passerines of the southern African shrublands. They have a complex and uncertain evolutionary history, and have variously been treated as relatives of the sunbirds (Nectariniidae), starlings (Sturnidae), honeyeaters (Meliphagidae) or thrushes (Turdidae). Molecular evidence has suggested that they may share a divergent lineage with two enigmatic monotypic African genera: *Arcanator* (Dapple-throat) and *Modulatrix* (Spot-throat), but the latest results appear to refute this, concluding that the sugarbirds have no close living relatives; they emerge as basal to a large, diverse clade of passerines, and would appear to be of ancient origin. Both sugarbird species look rather like overgrown sunbirds with streaky brown plumage, black legs, yellow undertail-coverts and a long tail. The spectacular tail of the male **Cape Sugarbird** is the longest in the family. It is particularly conspicuous in aerial displays during which males undulate dramatically several metres above the top of the vegetation. The sexes are highly dimorphic in tail length, the tails of females being much shorter. This species is restricted to the South African Fynbos biome, mostly within the Western Cape Province, where it is common. It is particularly fond of Protea flowers, and often occurs where these are cultivated or grown ornamentally, for example at the Kirstenbosch National Botanical Gardens.

adaptively for nectar-feeding. The brush-tipped tongue of the sugarbirds also exhibits other adaptations. First, the narrow and slightly concave bristles collect and channel the nectar by capillary attraction into a central trough; second, the long and numerous bristles at the tip of the tongue can be spread out in several directions, enabling nectar to be collected from a wider area within a flower. The tongue musculature is consistent with a hypothesis that the Promeropidae may have evolved from the Meliphagidae.

The long decurved bill of the sugarbirds is likewise adapted for nectar-feeding, and resembles that of the sunbirds. In Nectariniidae, the longer-billed species are more efficient in reaching nectar in flowers than those with a shorter bill; in most species, males have a longer bill than females, and are regarded as more effective pollinators of flowers than females; and males, with the longer bill, tend to be larger than females and are also aggressively dominant over them. In both sugarbird species, the bill of the males is longer than that of the females, and the former are able therefore to force the bill more easily into protea (*Protea*) inflorescences than can the shorter-billed females. The mean culmen length of male Cape Sugarbirds is 3.1 cm, longer than that of male Gurney's Sugarbirds, which is 2.9 cm. The former species is adapted to exploit the fynbos Proteaceae, most of which have closed involucre bracts. Most of the grassland protea species along the Drakensberg escarpment and in Zimbabwe have open involucre bracts, and Gurney's Sugarbird, with its shorter culmen, is better adapted for foraging on them.

An interesting adaptation in the wing of the sugarbirds involves modified primary feathers, which have a large bulge or lobe on the outer vanes. This specialized modification affects primaries P5–P7 of Cape Sugarbirds and primary P6 of Gurney's Sugarbird. The bulges on the primaries are responsible for the audible “frrt-frrt-frrt” sounds produced during flight and in aerial displays, and a wider primary bulge is thought to produce a louder sound during display-flights. Males with a wider P6 bulge and with greater wing and tail lengths may be older, and the modification of the primaries might thus fulfil a function in sexual selection.

Gurney's Sugarbirds moult their primary feathers mainly during the period from October to March. The primaries are replaced descendantly, from the outer feathers to the inner ones, while the secondaries are replaced ascendantly, from the inner wing inwards towards the body. It is interesting that the wing moult of Gurney's Sugarbird coincides with the species' breeding season, when much energy is required for the successful rearing of young. As male sugarbirds need long tail feathers for territorial defence and display, tail moult occurs over a protracted period throughout the year; the moult proceeds from the central rectrices towards the outermost feathers. Cape Sugarbirds moult their primaries from October to January or later, before their breeding season starts in April.

Sugarbirds have fairly strong toes, and remarkably sharp claws, as many a bird-ringer has discovered! These are important in facilitating access to flowers, but also lead the birds into some conflict with human activities (see Relationship with Man).

Habitat

Both sugarbirds live in close association with protea scrub, where they are dependent on nectar for food. The genus *Protea* belongs in the Proteaceae, a plant family virtually confined to the Southern Hemisphere. Africa is home to well over 100 species of protea, 91 of which grow naturally in southern Africa; of these, 71 are found in the coastal region of the Cape.

The Cape Sugarbird is resident in the Fynbos biome, which is centred on the Western Cape Province of South Africa and extends eastwards into the Eastern Cape. Its search for nectar has led to its becoming adapted also to cultivated gardens and protea nurseries. This sugarbird's range has not contracted much, although it is rarer at the easternmost limit, in the Amatole Mountains, where protea populations, especially those of *Protea subvestita*, have been eradicated by veld fires.

The geographical range of Gurney's Sugarbird extends eastwards along the mountains of the Eastern Cape to the KwaZulu-Natal midlands and farther up the escarpment in Mpumalanga and the northern provinces. Further, isolated populations occur

in the Soutpansberg, Blouberg and Waterberg ranges, in Limpopo Province, where they occupy areas with protea species. The subspecies *ardens* of Gurney's Sugarbird occurs from the Nyanga Mountains to the Chimanimani Range in easternmost Zimbabwe and adjacent Mozambique, where it is common, for example, in protea nurseries. Gurney's Sugarbird is associated mainly with *Protea roupelliae* woodland at altitudes mostly above 1800 m. It is common also in *Protea caffra*, *Protea gaugedi* and vegetation with other protea species in the eastern parts of South Africa.

General Habits

Both members of this family occur solitarily, in pairs or in family parties, although it is often the case that apparently solitary individuals are, in fact, accompanied by a mate, which is hidden in nearby foliage. Small groups of up to a dozen or so individuals are sometimes observed outside the breeding season. Sugarbirds are active throughout the year, the males often chasing one another and occasionally chasing off females. Both species are strong fliers, flying directly and with little, if any, undulation, but it becomes increasingly undulating during social interactions. When returning to a perch on a bush, they land with an upward “flip-jump”, a movement made without any apparent slowing down or breaking of the flight.

Studies of the Cape Sugarbird, the better-known of the two species, have revealed that the birds typically alternate periods of active feeding with periods of rest and of socializing, when many individuals come together. The species is very lively for a couple of hours early in the morning, after which it becomes silent and disappears deep inside a protea bush, where it dozes and preens for some time. This pattern of behaviour is repeated through the day. Sugarbirds are less active during the middle part of the day, remaining silent and hidden in the protea bushes, although they may give away their presence by vocalizations or by indulging in chasing activities. Furthermore, they seem to dislike wind, and tend to keep within cover for longer periods on windy days than on calm ones. The extremely long tail of the Cape Sugarbird is blown sideways or up and above the bird's head by the strong winds that are typical of the fynbos habitat.

At dusk, following a short bout of noisy social interaction involving conspicuous perching and chasing, the sugarbirds drop down into the lowest branches of a protea bush, where they spend the night. Partners roost together, and communal roosting by small groups is not uncommon. In some locations, flocks of several hundred individuals sleep together.

The male spends much time perched prominently on a bushtop, foraging actively at flowers and flicking its wings, but it spends as much or more time within the thick, dense foliage of protea bushes. Characteristically, it dives from its bushtop perch down into cover, and later, after a variable period, it shoots up and out of the thickest foliage and back to its perch. It moves at speed and, when leaving its bushtop perch, it makes a slight jump before darting over and downwards; on returning to its perch, it again makes a slight jump before alighting. During the breeding season, male sugarbirds spend most of the time perched on top of their favourite protea bush, from where they deliver their characteristic jangling territorial advertising songs (see Voice) for long spells, with interruptions for foraging or preening.

When a sugarbird is in relaxed posture, the head is sunk into the shoulders and the bill pointed slightly upwards. When alert, it lifts the head somewhat higher. Comfort behaviour performed by sugarbirds includes bill-wiping on perches, especially after feeding on insects, and indirect head-scratching, in which the leg is raised behind and over the lowered wing to reach the head.

Cape Sugarbirds have been observed to bathe, and they usually do so in dew, or in protea foliage made wet by dew or rain. They are particularly fond of bathing after heavy rain. The bathing individual makes a series of plunges into the leaves, dipping its head into the wet foliage and fluttering the wings in order to splash moisture over the plumage. There are extremely few observations of the bathing behaviour of Gurney's Sugarbird, but the basic details appear to differ little from those applicable to the Cape Sugarbird.

Gurney's Sugarbird

differs from the Cape Sugarbird (*Promerops cafer*) in having a more solidly and richly coloured breastband. Its forehead and forecrown are also chestnut-red, rather than pale creamy, and its tail is noticeably shorter, reaching a maximum length of only some 19 cm in males, as opposed to 38 cm. The nominate race, pictured here, occurs in northern and eastern South Africa, with a major population distributed along the Drakensberg escarpment. The race *ardens* occurs to the north, in Zimbabwe and adjacent Mozambique. Both forms are associated with the common open-country flowering plants of the region, such as proteas and aloes. The individual pictured here is visiting a flowering *Aloe arborescens*, an important plant in horticulture and medicine.

Voice

Sugarbird songs are a series of grating, twanging, creaky and clicking notes, which are delivered from the top of a bush or other perch, and also from the interior of a bush. Both species use the songs mainly to advertise their territories. The song of the Cape Sugarbird is a jumble of harsh, grating notes which are interspersed with "chit-chit-chit" calls and longer rambling "tschaak-tschaak" or "chee-chee" notes. Some authors describe it as resembling the sound made by a squeaky or rusty gate or as having a twangy quality similar to that of the call of the Fork-tailed Drongo (*Dicrurus adsimilis*). The song of Gurney's Sugarbird, on the other hand, is less grating than that of its congener and is a faster, rapid high-pitched jumble of twittering and twanging notes, but it does have the same rambling, squeaking qualities. A song bout of Gurney's Sugarbird often lasts for five minutes or more, and sessions of singing can continue for 20 minutes.

The "threat song" of the Cape Sugarbird is similar to the advertising song, but is faster and more intense. Females also utter a soft sibilant song, which is shorter than that of males. Cape Sugarbirds' calls are varied, and include a loud, tinny "tcheek-tcheek" and a rapid, repeated "skedge-skedge" ending with slurred drongo-like or starling-like nasal sizzling. Gurney's Sugarbirds also utter short stuttering "chit-chit" notes for long spells, most often when they are excited, and these are interspersed with hurried, loud "churrs" and hard chatters. The "chit-chit" notes increase in tempo, and both sounds serve as advertisement and also indicate anxiety.

Both species have a harsh alarm call, as well as other high-pitched ones. Cape Sugarbirds give a mild, high-pitched "tweet-tweet" call and flutter the wings when excited, this call becoming shorter and more explosive when the sugarbird's anxiety increases. They also emit a single harsh, wheezy sound which resembles the sound of cloth being ripped, "ssrrr-ssrrr". The alarm calls of Gurney's Sugarbirds are similar to those of its congener but are harsher in quality, "skirrit skirrit" or "skirr-sik", repeated several times. Alarm calls are given also by captured individuals when held in the hand or when being extracted from mist-nets; in these circumstances, other males respond to such calls by flying towards the site of the net and may even be captured when flying in the direction from where distress calls are coming.

Although by definition not vocalizations, the mechanical sounds made by the modified feathers in the wings and tail likewise constitute significant and characteristic components of the birds' acoustic repertoire (see Morphological Aspects, Breeding).

Food and Feeding

The diet of both sugarbirds consists of the nectar of flowers, together with small insects and spiders (Araneae). Flowers regularly visited by Cape Sugarbirds in the fynbos include several species of protea, but the sugarbird shows a preference for, mainly, *Protea repens*, *P. lepidocarpodendron*, *P. neriifolia*, *P. laticolor* and *P. longifolia*, along with other plant genera such as *Leucospermum* and *Mimetes*, notably *L. conocarpodendron*, *M. fimbriifolius* and *M. hirtus*. In the Mediterranean-type climate in which they are found, these species have a winter flowering season which is at its peak between April and August. The sugarbirds also visit both natural and cultivated heathers (*Erica*), *Watsonia* and red hot pokers (*Kniphofia*), as well as aloes (*Aloe*), tree-fuchsia (*Halleria lucida*), Cape honeysuckle (*Tecomaria capensis*) and alien invaders such as eucalypt species (*Eucalyptus*) and sisal (*Agave sisalina*).

The Cape Sugarbird is an important pollinator of the above-mentioned fynbos protea species. It will make several probes in one single inflorescence before moving on to the next one, whereby pollen, which becomes attached to the sugarbird's forehead, is transferred to the next inflorescence and pollination occurs. The brush-type flowers of *Protea* and *Leucospermum* provide perches with many large inflorescences and unopened flowers which serve as potential landing platforms. When a Cape Sugarbird forages on protea inflorescences, it usually perches on top of them, leans down into the flower to reach the nectaries, and "sucks" or probes

for nectar between stamens or bracts. When foraging on *P. multibracteata*, it perches on top of the flower and probes on the far side of the mass of stamens. *Protea lepidocarpodendron* has a more cylindrical flowerhead with densely packed florets, as also does *P. neriifolia*, and the sugarbird leans far down on the side of the flower and probes through bracts from the outside. When foraging into inflorescences, the head and the front half of the sugarbird's body disappear from view as it reaches into the deep cup of the protea. During a feeding session, the bird visits more than one flowerhead of any one bush or tree.

Nectar is low in protein and amino acids, and the sugarbirds must therefore supplement their diet with animal food in the form of arthropods. In a study of the Cape Sugarbird's energy requirements, it was found that *P. repens* inflorescences contained high concentrations of reduced sugars but were low in proteins and amino acids, and the sugarbirds consequently had to visit a very large number of flowers on a daily basis in order to satisfy their energy requirements. The sugarbirds supplement their diet with insects, mostly beetles (Coleoptera) and ants and bees (Hymenoptera), taken from the protea flowers. It was mainly these insect orders that were found in the *P. repens* inflorescences utilized as a food source by Cape Sugarbirds. K. M. Calf and her co-workers raised the question of whether sugarbirds foraged for insects from the inside or the outside of protea flowers, and whether the insects are ingested accidentally or on purpose, but these matters remain to be resolved. Sugarbirds also catch small flying insects such as flies (Diptera), moths (Lepidoptera) and aphids (Aphidoidea) by flying into the air to heights of up to 10 m, snapping up the prey and then returning to the perch to consume it.

In South Africa, Gurney's Sugarbirds forage almost exclusively on the nectar of *Protea roupelliae* in its mountain habitat, and during the winter they visit *Aloe arborescens* blooms on mountain cliffs and in cultivated areas. In some places, they seem not to move away from protea patches, especially in localities where sufficient flowers are available for them. They also feed on nectar of the proteas *P. laticolor*, *P. gagedi*, *P. caffra* and *P. subvestita*, most of which occur in association with *P. roupelliae*, and that of several grassland and forest-margin species, such as *Greyia radlkoferi*, *Greyia sutherlandii*, tree-fuchsia, *Watsonia* and *Kniphofia*. In cultivated areas, during the winter months, they exploit several species of aloe, primarily *A. arborescens*, and of protea, mainly *P. neriifolia* and *P. repens*, as well as introduced Australian bottlebrush (*Callistemon viminalis*) and eucalypts. When feeding at *P. roupelliae* inflorescences, Gurney's Sugarbird perches on the top of the flower, which does not have closed involucral bracts, and probes with quick movements of the bill for nectar. It then moves in a clockwise direction while inserting its bill repeatedly into different parts of the flower. During a feeding session, the sugarbird tends to remain among the flowers of a single bush, but it will also fly to other protea bushes in the vicinity. Females of this sugarbird have frequently been observed to probe for nectar in closed inflorescences by forcing the bill between the floral bracts.

Invertebrates taken as food by Gurney's Sugarbird consist mainly of beetles, bees and ants, while spiders make up a small proportion of the diet. The beetle portion consists mostly of scarabaeid species such as *Tanaos sanguineus* and *Cyrtothyrea testaceogutta*, which occur in large numbers in *P. roupelliae* inflorescences. Sugarbirds, during their feeding activities, have been seen to take honeybees (*Apis mellifera*) at aloe inflorescences, nectar-feeding being temporarily interrupted in order to catch the bee. The remains of honeybees have been recorded in stomach contents of sugarbirds in both mountainous and suburban localities. As an offshoot of their nectar-feeding, sugarbirds are important for transferring tiny flower mites between plants, and large populations of mites can live in the birds' nasal cavities.

Breeding

Both sugarbird species are socially monogamous, nesting exclusively in protea trees. They are very similar to each other in details of the nest, the lining of which incorporates protea fluff or seeds, in clutch size, generally consisting of two eggs, and in details of

The male **Cape Sugarbird** is highly aggressive at the onset of the breeding season, often chasing intruders from the territory. He is usually seen perching prominently atop a bush or a protea flower, from where he delivers his characteristic song. The vocal repertoire of both sugarbirds is remarkably variable. Their primary songs tend to be a weird series of grating, twanging, creaky and clicking notes.

The most complex renditions are given by males, but females also sing with a softer, more sibilant version of the same. Both species also have characteristic alarm calls, one harsh and grating, likened to the sound made by tearing cloth, and others high-pitched and varying in intensity. They are also known to give various hissing, wheezing and musical notes of unknown function.

[*Promerops cafer*,
Kirstenbosch National
Botanical Gardens,
Cape Town, South Africa.
Photo: Andy & Gill Swash]

the nestling development. The males of both species are very aggressive at the onset of the breeding season, guarding their territories against intruders. The male usually sits on a prominent perch on top of a bush or on a protea flower, from where it delivers its highly characteristic jumbled series of jangling notes (see Voice). Through the day the males perform impressive display-flights, that of the Cape Sugarbird being particularly striking, by rising to heights of 10 m or more and then flying in a series of undulations during which it produces a clacking noise by jerking the long tail feathers up and down. During these aerial displays the male utters its territorial song, a harsh, grating and scratchy "tschaak-tschayli-chitchit".

In the winter-rainfall area of the Western Cape, the Cape Sugarbird's peak egg-laying period is from mid-April to the end of May. Here, *Protea lepidocarpodendron*, locally a dominant species, has an extended flowering season, while farther away across the Cape Flats, in the Hottentots Holland Mountains, *P. neriifolia* has an earlier peak in flowering, and the sugarbirds there consequently commence breeding earlier; the ranges of these two proteas do, however, overlap extensively. The peak breeding season for Gurney's Sugarbird in South Africa is between November and February, coinciding with the peak flowering period of *P. roupelliae*. This species tends to breed later in the season in KwaZulu-Natal, in the Eastern Cape Province of South Africa and in Zimbabwe, where observations of nesting from late summer to early winter all seemed to be correlated with flower availability of protea species. Recently fledged young, still dependent on the adults, were captured in Mpumalanga during mid-winter, in June, egg-laying having therefore taken place during late April or early May. These late breeding attempts were possibly triggered by the arrival of suitable conditions, when sufficient protea nectar was available after high rainfall in the surrounding mountainous areas.

Calf and co-workers compared the territorial behaviour of the two sugarbird species during the breeding season and found that Cape Sugarbird territories were smaller than those of Gurney's Sugarbird. This was because the former contained a higher tree density and a greater diversity of protea species. Cape Sugarbirds are highly territorial during the breeding season, and defend resources for themselves, their mates and their offspring. This territory ownership was found to be male-based, and the territory sizes and locations of males varied slightly when males returned in the subsequent season to their territories. Severe weather conditions and predation are the main influences in mating and reproductive success. Even so, male Cape Sugarbirds defending larger territories achieved greater reproductive success than did those with smaller territories.

In the protea-grassland areas where Gurney's Sugarbirds occur, territory sizes were observed to change in response to inflorescence and arthropod availability and to associated increased competition from other males in adjoining territories. This species' territory sizes have been observed to decrease during the middle part of the breeding season, November–December, when more protea inflorescences and insects are available, and to increase again nearer the end of the breeding season, in January–February, when fewer resources are available for the sugarbirds. Fewer territorial sugarbirds are present at the end of the breeding season, and low inflorescence availability may result in larger territory sizes. The changes in sugarbird territory sizes documented in the study by Calf and colleagues were confirmed in the Lydenburg area of Mpumalanga, where seasonal densities at selected protea clumps were high during October–November and, again, lower at the end of the breeding season, in February–March. Fire in protea grassland also influences sugarbird densities, as bushes are damaged by fire, and the sizes of clumps therefore also determine sugarbird territory sizes.

The combination of large territory sizes and low food availability leads Gurney's Sugarbirds to expend large amounts of energy in moving between inflorescences of several bushes within the territory. The reduced availability of nectar and arthropods may also be a contributing factor in the finding that territories of Gurney's Sugarbird are larger than those of Cape Sugarbirds, which results in the former being subject to heavier energy constraints with regard to mating and reproductive success than are experienced by Cape Sugarbirds. It was noted also that, within

one and the same population, male Gurney's Sugarbirds with a longer tail and a wider bulge on the sixth primary feather (see Morphological Aspects) defended larger territories with more protea inflorescences available and achieved greater success than did younger, shorter-tailed males with a narrower primary bulge.

As both sugarbird species are highly territorial during the breeding season, they will drive individuals of both their own species and other potential competitors out of their respective territories. The Cape Sugarbird gapes widely if another bird approaches too close to it, and harsh alarm calls are then uttered. Gurney's Sugarbird will fly at speed towards other birds, such as *Ploceus* weavers, and will chase them in flight with rapidly beating wings, and they have also been seen to attempt to chase larger bird species such as Red-winged Starlings (*Onychognathus morio*). Both sugarbird species have been observed to behave aggressively towards Malachite Sunbirds (*Nectarinia famosa*), although C. J. Skead mentioned that Gurney's Sugarbird would tolerate Malachite Sunbirds on the same bush, and that, if the two species met on the same flower, it was the sunbird that had to give way to its larger, more aggressive food competitor. At Lydenburg, in Mpumalanga, D. H. de Swardt observed that Gurney's Sugarbird displaced a sunbird from its flower on a protea bush by "jumping" towards the sunbird and chasing it away, usually while uttering aggressive alarm calls and other vocalizations.

The nest-sites favoured by sugarbirds provide protection against the inclement conditions of the winter and summer thunderstorms. The nest is placed in the centre of a thick-leaved protea bush, where it is sheltered from the elements. Cape Sugarbirds prefer protea bushes, such as *P. eximia*, *P. grandiceps* and *P. neriifolia*, the large leaves and dense foliage of which provide shelter and protection against the wind. Nearly all South African nests of Gurney's Sugarbird are in a *P. roupelliae* bush or solitary tree,

Sugarbirds consume a large quantity of nectar, along with a range of small insects and other arthropods. The bills of both species are adapted for extracting nectar, being long, slender and slightly decurved. **Gurney's Sugarbird** has a shorter bill than the Cape Sugarbird (*Promerops cafer*), perhaps related to food-plant differences. In particular, it has been noted that many protea species in the Fynbos biome tend to have closed involucral bracts, whereas most of the protea species found along the Drakensberg escarpment have open ones. The shorter bill of Gurney's Sugarbird is thus perhaps adapted to these more accessible sources of nectar. Although the bill of the female, shown here, is shorter than that of the male, it remains long enough to reach nectar sources in a wide range of flowers, including this Aloe.

When a **Cape Sugarbird** forages on protea inflorescences, it typically does so by perching on top of the flower and probing for nectar between stamens or bracts. It extracts the nectar through an unusual brush-like tongue, similar to those of probably unrelated nectarivores, such as honeyeaters (*Meliphagidae*). Sugarbirds are often forced to reach far down into the deep cup of a protea in search of nectar, at which time the head and the front half of the body may disappear from view, as seen here. On species with more cylindrical flowerheads and densely packed florets, the nectaries are accessed by probing through bracts from the outside; this is an example of nectar predation rather than pollination.

situated on the periphery of a protea clump, and usually located on the south-western aspect of the tree. Nests are in most cases well hidden among the protea leaves, either situated in a fork of a branch or among small branches, or built on to the base of an old inflorescence with a cluster of terminal twigs surrounding it.

The nest of *Promerops* is an open cup, built mainly from twigs of *Cliffortia* species, heath stems and dry grass, and compactly lined with coarse but soft, dry protea seed down or fluff. Other nest materials used by Gurney's Sugarbirds include *Widdringtonia nodiflora* and *Stoebe vulgaris*, and this species sometimes utilizes additional available material from the surrounding forest margins and streams; for example, the dry pinnules of bracken (*Pteridium aquilinum*) were used on the outside rim of one nest. When constructing the nest, Cape Sugarbirds will take advantage of fynbos restios (*Restionaceae*) such as *Leptocarpus paniculatus* and *Thamnochortus fruticosus* growing in the immediate vicinity, and they will also incorporate *Helichrys* species (*Asteraceae*) in the structure. Once the basic structure is complete, the female uses her body to shape the nest until a rough cup is formed. Nests of Cape Sugarbirds, with an average internal depth of 60 mm, are deeper than those of Gurney's Sugarbirds, which have a corresponding measurement of about 40 mm. Old or unused nests are wind-buffed and blown out of the tree, and the seeds in the nests are dispersed by wind, or rain, to germinate.

The female builds the nest and collects most of the material, but the male may occasionally visit, perhaps contributing a few items; it is suspected that the females also choose the nest-site. Construction of the Cape Sugarbird's nest takes an average of eight days, and the lining of the nest takes a further three days, the first egg being laid one to five days after the nest has been completed. Few comparable data are available for Gurney's Sugarbird, most nests of which are built within five to 15 days.

Sugarbird clutches consist mostly of two eggs, although there are rare instances of three-egg clutches being laid by Cape Sugarbirds. The second egg is laid usually on the second day, or within 48 hours after the first one. Sugarbirds generally have one brood in a season, but the Cape Sugarbird is occasionally double-brooded; both species commonly lay replacement clutches. The egg is an elongate oval in shape, and it varies from being

pale coffee-coloured to being dull salmon-pink, with dark brown spots and scrawls. The dark spots and blotches are spread all over the egg, but they tend to form a ring around the broad end. The eggs of Gurney's Sugarbird are more cream to buffy brown in colour. With both species, it is the female alone that incubates the eggs, and she leaves the nest only for short feeding bouts, these breaks in incubation occurring mostly in the early morning or late afternoon. The incubation period for both species is 16–17 days, incubation starting when the clutch is complete.

Hatching in Cape Sugarbird nests takes place mostly during the early hours of the day or in the late afternoon; the parents carry the empty eggshells away. On hatching, the sugarbird nestling has pinkish skin with blackish-grey down on the head, back and wing areas, and the eyes are closed. The base of the culmen is of a pale orange-flesh colour with a thick yellow gape-flange, and the tip of the bill is blackish. At an age of five days, the blackish-grey down on the head, back and wings becomes longer and darker. The skin darkens and the feather tracts start to develop, while a thicker yellow gape-flange starts to become apparent at the base of the pinkish bill. At seven to nine days, the primary and secondary feather tracts develop and start to break through the feather pins. The nestling's eyes start to open, and they are fully open on the ninth day, when the bill starts to look curved and becomes blackish, but with the lower mandible still flesh-coloured. From the eleventh day onwards, the soft down is replaced by feathers with buffy-brown edges, the scales of the tarsi become fully developed and are glossy black, and the culmen lengthens, with the upper mandible blackish and the lower mandible flesh-coloured. Body feathers have now replaced the downy feathers, and the wing feathers, having broken through the pins two days before, are now longer. From the 19th day, the primaries, the brownish-edged secondaries and the tail feathers are almost fully grown, but there are still few down feathers on the body; the dark brownish coloration of the breast and crown is similar to that of adults, but with a few downy feathers remaining between the reddish feathers.

The female Cape Sugarbird broods the chicks from time to time during the day until they are six days old, and at night until they are 14 days old. The duration of the development period of the chicks of both species varies between 17 days and 23 days.

Young start to leave the nest on the 19th day, on average. The offspring remain for a few days in the nest tree, where they probably also sleep for a night or two, and fly short distances after the adults, which feed them for as much as a further three or four weeks.

Sugarbird nestlings are fed mainly with small, winged insects, including small beetles, which are brought to the nest by both parents, the female making more feeding visits than the male. Cape Sugarbirds deliver food to the nest every 10 minutes or so, with more visits in the morning and late afternoon, while the frequency of visits to the nest by Gurney's Sugarbird is more varied, up to every 22 minutes. When the adult alights on the nest, the nestlings respond by craning the neck, with the bill held wide open, begging for food. When the young become larger, they merely stand on their heels. With both species, nest sanitation is maintained by both sexes, which carry away faecal sacs to nearby bushes up to 5 m from the nest-site.

Breeding success is rather variable for the Cape Sugarbird in the studies available to date. The majority of nest failures recorded were the result of predation by other birds, rodents, mongooses (Herpestinae) and snakes. In addition, the introduced Argentine ant (*Linepithema humilis*) is known to attack and kill small chicks of this species. It has been suggested that the breeding success of Gurney's Sugarbird is associated with food availability, but further research is needed in order to determine if this really is the primary limiting factor in breeding.

Limited information is available on the longevity of sugarbirds. De Swardt and W. J. Peach analysed the ringing data (see Movements) for Gurney's Sugarbird, from which they estimated a survival rate of 80.7% and an average life expectancy of 4.8 years. These authors concluded that the "average" sugarbird could survive beyond seven years of age. The oldest Gurney's Sugarbird was resighted after 13 years, having been recaptured 3 years earlier when it was 10 years of age. The oldest Cape Sugarbird recorded in ringing studies was 14 years and six months when it was recaptured.

Movements

Both sugarbird species are resident, but in the non-breeding season they are itinerant, undertaking short-distance movements in response to the flowering phenology of important foodplants in their distributional ranges. For example, there are movements of Cape Sugarbirds to the coastal plains, where they track *Leucospermum conocarpodendron* in September–March, during the austral spring and summer, and to hillsides where *Protea repens* is in bloom during the winter months of May–August. Movements of between 27 km and 44 km have been recorded for Cape Sugarbirds, and one individual moved 365 km.

In the case of Gurney's Sugarbird, a seasonal pattern of vertical movement between the *P. roupelliae* populations in the mountains and nearby suburban areas has been observed in a Mpumalanga town. One individual was recovered 37 km north-east from the locality where it was initially captured. Juvenile Gurney's Sugarbirds disperse a few kilometres from the natal territory, and two were recaptured more than six years later. In some areas they are sedentary, especially where there are botanical gardens and protea nurseries where nectar is available all year. During the past twenty years, in Mpumalanga, it has been observed that in years with high rainfall the protea flowering period is prolonged, while in years with lower rainfall fewer flowers are available and the sugarbirds then disperse into the mountain valleys and to nearby towns.

Both sugarbird species also move in response to fires, which are of frequent occurrence in their protea habitat. The birds return to such sites only when their foodplants have matured, or else they move to unburnt protea clumps.

Since the 1950s, more than 7300 Cape Sugarbirds have been ringed, most of them in the Western Cape, and more than 800 recoveries or recaptures have been obtained. Fewer Gurney's Sugarbirds have been ringed, although the total exceeds 1000 individuals, the majority of these, 760, in the Lydenburg area of Mpumalanga. Some 210 recaptures and recoveries of this species have been obtained, most of them again from Mpumalanga.

Their foraging ecology means that sugarbirds probe several times into each flower, and visit several flower heads per tree or bush, before moving on to another plant. Each time they probe a flower, pollen attaches to the forehead, as demonstrated by the yellow dusting on the face of this Cape Sugarbird. When it moves to a new plant, this bird will transfer pollen to another inflorescence, perhaps fertilizing the carpel. For this reason, sugarbirds play a vital role in pollinating a wide variety of flowering plants, many of them highly threatened, in the Fynbos biome and the montane grasslands of south-east Africa.

[*Promerops cafer*, Caledon, South Africa. Photo: Roland Seitre]

Relationship with Man

The South Western Cape floristic region hosts the largest concentration of fynbos plant species, which are endemic in this region, and includes some very rare and even endangered species. Moreover, the protea plants are important not only for the Cape Sugarbird and other nectarivores as a food source, but also for local farmers and others, through the export trade in cut flowers. In this region alone, the plants provide South African farmers with a total annual income of more than 60 million rands, in an industry that employs more than 4000 farm workers. Fynbos plants are nowadays harvested from protea plantations, while a smaller number are still harvested from natural mountain fynbos where Cape Sugarbirds and other nectarivores are common. Although no direct competition between sugarbirds and man occurs, it is known that sugarbirds can damage protea inflorescences considerably while foraging on them. Damage is caused mainly when they probe flowers for nectar and their sharp claws leave scratch marks on the nearest leaves, making the flowers unsuitable for the export market. Several commercially important protea species, mainly *P. cynaroides*, *P. magnifica* and *P. grandiceps*, are damaged in this way, whereas less damage is caused to *Leucospermum* species. Several measures have been used in attempts to prevent sugarbirds from harming flowers, the principal ones of which are the chasing-away of the birds, covering the flowers in bags, placing plastic strips on bushes, and the installation of systems broadcasting bird sounds. A few isolated instances of poisoning have been reported, but, as the sugarbirds are legally protected species, any incidents of poisoning must be

reported and the persons responsible prosecuted. Happily, it appears that poison is no longer used as a control measure by protea farmers, who now, instead, actually welcome birdwatchers into their plantations. Bird-capturing, and also bird-ringing, operations can easily be conducted, but these are generally ineffective in terms of removing the birds permanently from the protea plantations. In the Drakensberg escarpment, in KwaZulu-Natal, several farmers have started to establish protea plantations, concentrating their efforts mainly on the grassland protea species. In such plantations, Gurney's Sugarbirds are, as might be expected, often proving to be common.

In contrast to the possible harm inflicted on plants by sugarbirds, these birds play a significant role in the pollination of plants. The Cape Sugarbird is important as a pollinator of fynbos protea species, as well as other plant species, including cultivated ones (see Food and Feeding). Gurney's Sugarbird plays a similar part in the pollination of, especially, *P. roupelliae* in the higher-lying habitats which it occupies.

The two members of the genus *Promerops* are much sought-after species in birding circles, especially because they occur only in certain isolated localities and in conservation areas. The Cape Sugarbird's limited distribution in the fynbos means that birdwatchers wanting to observe it are normally taken only to particular localities in the Western Cape with reasonable access, such as the Kirstenbosch National Botanical Gardens, the Cape of Good Hope Nature Reserve and other protected areas. In the Drakensberg range, where Gurney's Sugarbird is localized, the Sani Pass area, adjacent to Lesotho, is one of the best-known destinations for birders wishing to see this sugarbird and other high-altitude bird species.

Status and Conservation

Both members of the family are found only in southern Africa, where they are common within their restricted ranges. Cape

Sugarbirds are less common in extreme eastern parts of their distribution, where, in the past, they overlapped in range with Gurney's Sugarbird. The latter is uncommon at its southernmost limit in South Africa, but is common farther north along the escarpment in KwaZulu-Natal and Mpumalanga. Gurney's Sugarbird is noted as being absent especially in areas where protea species are rare, and it probably goes undetected in many fairly inaccessible mountainous areas. It is less common in Zimbabwe, and exists as localized populations in the Waterberg, Blouberg and Strydpoort mountain ranges of Limpopo Province, in northern South Africa. The overall geographical ranges of the two species appear not to have changed dramatically during the past few decades.

Cape Sugarbird densities vary from up to 20 pairs per square kilometre, as found near Port Elizabeth, in the Eastern Cape, to four individuals in 100 ha of strandveld fynbos vegetation in the Western Cape. In mountain fynbos, densities of 2–4.1 birds/ha are recorded, while densities in cultivated protea stands are even higher. In *Protea roupelliae* habitats in Mpumalanga, Gurney's Sugarbird reaches estimated densities of 4.6 birds/ha, and more than 20 individuals of this species have been captured at single sites where sufficient inflorescences were available. The subspecies *ardens* of Gurney's Sugarbird is estimated to number a few thousand individuals in Zimbabwe, where it is common in protea nurseries.

The main conservation problems facing both species are loss of habitat through development, fires in fynbos or grassland, and the afforestation of protea savanna. Protea veld in fynbos is being gradually replaced by such developments as agriculture, and coastal lowland fynbos is being destroyed by developers for the building of holiday homes and through water impoundment. In addition, the illegal persecution of sugarbirds by poisoning or shooting in areas where protea flowers are cultivated for commercial trade has been a cause for concern. The appropriate management of the Cape Sugarbird fynbos habitat requires that fire, preferably during March and April, be on a frequency cycle of between 10 and 15 years. This is necessary in order to maintain as many protea species as possible in the fynbos habitat. In the Eastern Cape, uncontrolled fires have eradicated large areas of *Protea subvestita* populations in the Amatole Mountains, an area where the two sugarbird species historically co-occurred. Hot fires in late summer kill the growing tips of grassland proteas, leading to total crown loss, as *P. roupelliae*, unlike other proteas, does not resprout. Block-burning in *P. roupelliae* populations during the autumn months, in April/May–June, on a three-year rotation, or after the first spring rains in August/September, has been suggested as a means of ensuring that suitable habitat is available for sugarbirds, but such methods too must be applied with great caution and the implications for other species of plant and animal given full consideration.

Both sugarbird species live in socially monogamous pairs and breed once or twice a year. The nests, built exclusively by the female, are untidy cup-shaped structures of twigs, bracken, rootlets and other plant fibres. The nest of the Cape Sugarbird is placed 1–2 m up in a protea bush and lined with soft plant down. A clutch of two eggs is typical. After an incubation period of around 17 days, the chicks hatch and are then brooded by the female, and fed by both sexes for a further 17–21 days until they fledge. The fledglings remain on the natal territory, being fed by their parents, normally for another 21 days or so.

PLATE 37

PLATE 37

Family PROMEROPIDAE (SUGARBIRDS) SPECIES ACCOUNTS

Genus *PROMEROPS* Brisson, 1760

1. Cape Sugarbird

Promerops cafer

French: Promérops du Cap **German:** Kaphonigfresser **Spanish:** Mielero-abejaruco de El Cabo
Other common names: (Cape) Long-tailed Sugarbird

Taxonomy. *Merops cafer* Linnaeus, 1758, Cape of Good Hope, South Africa. Forms a superspecies with *P. gurneyi*; some evidence of former hybridization between the two in Eastern Cape. Monotypic.

Distribution. S South Africa (Western Cape, SW & S Eastern Cape).

Descriptive notes. 24–44 cm (including elongated tail of up to 38 cm); male 30.5–43.5 g, female 26–39 g. Medium-sized passerine with long, somewhat decurved bill, and long to exceedingly long, graduated tail. Male has forehead and crown grey-brown, black malar stripe bordered by white moustachial stripe and chin; upperparts brown, streaked blackish, rump and uppertail-coverts olive-green with faint black streaks; tail very long, 12–38 cm (during moult in Oct and Nov shorter, sometimes similar to female length), dark brown; primaries P5–P7 with rounded bulge on inner webs, narrow outer webs emarginated; breast rufous-brown, rest of underparts buffish-white, dusky streaks on lower breast, belly and flanks; undertail-coverts

bright yellow; iris dark reddish-brown; bill black; legs dark brown to blackish. Differs from *P. gurneyi* in having longer tail, duller crown, less rusty-tinted breast. Female is similar to male but smaller, with shorter tail (8–18 cm). Immature is duller than adult, colours of breast and belly not well demarcated, undertail-coverts pale brown, no flank streaks, gape bright yellow, tail short. Voice. Song consists of grating, chirping, chipping and twanging notes, “k-swip-chirring-ka-swip-chik-chik”, varying in intensity. Also various hissing and musical notes; rasping alarm call, also harsh wheezing alarm note likened to sound of cloth being torn. Mechanical noises made by male in display, using modified feathers of wings and tail (see pages 488, 492).

Habitat. Proteoid shrublands in fynbos; also suburban gardens, and in areas where alien plants e.g. eucalypts (*Eucalyptus*) and agaves (*Agave*) present. Attracted to artificial environments with year-round food supply, such as botanical gardens. Sea-level to mountains.

Food and Feeding. Nectar of several fynbos *Protea* species (mainly *P. repens*, *P. lepidocarpodendron*, *P. neritifolia* and others) and of *Leucospermum* (e.g. *L. conocarpodendron*), *Mimetes* and *Aloe*; also that of heaths (*Erica*) and *Tecomaria*, *Watsonia*, red hot poker (*Kniphofia*), agaves and eucalypts; and visits several introduced species, e.g. eucalypts and bottlebrush (*Callistemon viminalis*). Insects eaten include mainly beetles (Coleoptera), bees (Hymenoptera) and flies (Diptera), with ants (Formicidae), wasps (Hymenoptera), aphids (Aphidoidea) and moths (Lepidoptera) less frequent; spiders (Araneae) also taken.

Breeding. Season mainly Apr–Jul in SW of range and later, Jun–Jul, in E, coinciding with *Protea* flowering season; sometimes double-brooded. Socially monogamous, but some extra-pair copulations occur; loosely colonial nester, but strongly territorial. Nest built by female, taking 5–10 days, an untidy cup made from twigs, bracken (*Pteridium*) and rootlets, lined with brown-coloured plant down from dead flowerheads, placed 0.25–2.4 m above ground in forked branch, hidden by foliage, in protea bush (e.g. *P. eximia*, *P. grandiceps*, *P. neritifolia*) or in *Leucadendron*, heath, *Rhus* or other woody plant; territory small, 0.2–0.4 ha. Clutch 2 eggs, rarely 3, occasionally 1; incubation by female (starting with second egg), period 17 days; chicks brooded by female, fed by both sexes, nestling period 17–21 days; young fed by parents for c. 21 days after leaving nest. Breeding success 33–60–80% in three studies, nest failures due mainly to adverse weather conditions (driving rain, low temperatures), and to predation by other birds, rodents, mongooses (Herpestinae) and snakes; also, small chicks sometimes attacked and killed by introduced Argentine ants (*Linepithema humilis*). Maximum recorded longevity in ringing studies 14 years 6 months.

Movements. Non-migratory, but undertakes local movements occur in response to flowering seasons of foodplants, e.g. those of *Leucospermum conocarpodendron* on coastal plains (Sept–Dec) and *Protea repens* on hillsides (Jun–Aug); moves into sandplain fynbos on W coast in spring and early summer, in order to exploit flowering by procumbent sandveld pincushions (*Leucodendron hypophyllocarpodendron*, *L. tomentosum*, *L. parile*, *L. rodolentum*); also moves in response to fire, and returns to previously burnt areas once foodplants mature. Often returns to same area after local movements. In SW of range, ringed individuals recorded moving up to 365 km. Records of vagrants in C South Africa (S Free State) thought to be result of drought conditions in Eastern Cape. One bird seen 40 km offshore from Cape Point, heading out to sea.

Status and Conservation. Not globally threatened. Locally common. Densities in mountain fynbos 2–4.1 birds/ha and up to 20 pairs/km²; 14 birds/ha in cultivated protea stands. Serious long-term threats are destruction of coastal lowland fynbos for development and agriculture, and invasion by alien plants; other threats include elimination of seed regeneration of proteas by overly frequent burning, alien-plant infestation in mountains, and water impoundment. Damage to flowers caused by sugarbirds in commercial protea plantations is generally minimal, but can sometimes lead to persecution. Present species is an important pollinator of proteas. Occurs in several protected areas in mountain ranges of Cederberg, Swartberg and Outeniqua, and also in Cape of Good Hope Nature Reserve, Tsitsikama National Park and Kirstenbosch National Botanical Gardens. Altogether, 5000–10,000 individuals reckoned to be present in at least 34 protected areas, out of a total population of 10,000–100,000 birds.

2. Gurney’s Sugarbird

Promerops gurneyi

French: Proméròps de Gurney **Spanish:** Mielero-abejaruco de Gurney **German:** Natalhonigfresser

Other common names: Natal Sugarbird, Gurney’s/Natal Long-tailed Sugarbird, Chestnut-headed Sugarbird

Taxonomy. *Promerops gurneyi* J. Verreaux, 1871, KwaZulu–Natal, South Africa.

Forms a superspecies with *P. cafer*; some evidence of former hybridization between the two in Eastern Cape. Races separated geographically, and perhaps ecologically isolated; research required on possible taxonomic implications. Two subspecies recognized.

Subspecies and Distribution.

P. g. ardens Friedmann, 1952 – E highlands of Zimbabwe and adjacent W Mozambique (Chimanimani Mts).

P. g. gurneyi J. Verreaux, 1871 – N & E South Africa from Limpopo Province (isolated populations) S along Drakensberg escarpment.

Descriptive notes. 23–29 cm; male 30–46.5 g, female 23–43 g. Medium-sized passerine with long, somewhat decurved bill and long, graduated tail; deep russet crown and breast. Male nominate race has forehead to nape rich chestnut, black lores, short white supercilium, grey-brown ear-coverts, white moustachial stripe, indistinct thin brown malar stripe; upperparts grey-brown, streaked darker, rump and uppertail-coverts yellowish-olive with faint black streaks; tail long, 11–19.3 cm, dark brown; primary P6 with rounded bulge on inner web (bulge width 13.1–16.1 mm, usually widest on older males), and narrow outer web

emarginated; throat whitish, breast russet, belly and flanks whitish with brown streaks, undertail-coverts bright yellow; iris dark hazel to reddish-brown; bill and legs black. Female resembles male but somewhat smaller, with shorter bill, shorter tail (8.3–13.6 cm), primary edge smaller (9.8–12.2 mm in width) or lacking. Immature is duller than adult, secondaries edged brownish, breast greenish-russet, undertail-coverts greenish-yellow, tail relatively short; gape-flange yellow for few months after leaving nest. Race *ardens* is somewhat darker than nominate, rump greener, less yellowish, uppertail-coverts tinged greenish, breastband richer and brighter chestnut, flanks more heavily streaked. Voice. Song a jumbled series of rapid high-pitched twittery and twanging notes, “swip-cheek-cheek-cha-wing-king-ching”. Also short “sa-weep-chi-chi” calls for long spells, especially when excited. Harsh “sskirrit” alarm call. Mechanical noises made by male in display, using modified feathers of wings and tail (see pages 488, 492).

Habitat. Nominative race mainly in montane scrub dominated by protea (*Protea*) species; distribution coincides with that of *Protea roupelliae* in grassland. Recorded also in mixed *P. roupelliae*–*P. caffa* veld, but absent in lower-altitude areas of *P. caffa* (e.g. mountain ranges in Gauteng Province). Has become resident in protea nurseries; a non-breeding visitor to aloes (*Aloe*) in gardens. N race (*ardens*) occurs in areas dominated by proteas and brachystegia (*Brachystegia*), sometimes in riparian woodland; favours drier, W-facing slopes with abundance of flowering shrubs, e.g. *Protea*, *Sirelitzia*, *Erythrina*.

Food and Feeding. Nectar, mainly of proteas (*Protea roupelliae*, *P. caffa*), *Greyia radikoferi* and *G. sutherlandii*, tree-fuchsia (*Halleria lucida*), *Aloe* (e.g. *A. arborescens*), *Watsonia*, red hot poker (*Kniphofia*) and eucalypts (*Eucalyptus*), and including cultivated proteas, aloes and other flowers; also insects, mainly beetles (Coleoptera) and bees and ants (Hymenoptera); also few spiders (Araneae). Large numbers of beetles (including *Tanaos sanguineus*) associated with *P. roupelliae* inflorescences were found in stomach contents.

Breeding. In South Africa, season mainly Sept–Feb, occasionally in other months (Jun–Jul), coinciding with flowering of main foodplant (*Protea roupelliae*); in N of range (race *ardens*) recorded in Jul, Oct and Apr. Socially monogamous, but some extra-pair copulations may occur; solitary nester, territorial. Nest built by female, taking 5–15 days, an open cup made from stems and leaves of e.g. bracken (*Pteridium aquilinum*), *Helichrysum* and heath (*Erica*), lined with fine material and with fluffy, brown-coloured protea seeds, placed 1.7–2.7 m (up to 8 m) above ground in protea tree or at edge of clump, mostly in old floral bract; territory large, 2.5–3 ha (changing in response to inflorescence and arthropod availability). Clutch 2 eggs (occasionally only 1 reported, but possibly incomplete); incubation by female, period 16–17 days; chicks brooded by female, fed by both sexes, nestling period 19–23 days; young fed for further 20 days after leaving nest. Breeding success in South Africa 46.1% (Mpumalanga) to 55.5% (Free State), failures attributed to adverse weather conditions (rain), predation, and desertion of nest by adults. Maximum recorded longevity at least 13 years; estimated annual survival 80.7%.

Movements. Primarily resident, with local dispersal and short altitudinal shifts. Disperses from protea areas during winter months, mainly after peak Oct–Feb flowering period of *Protea roupelliae*, but also in response to veld fires. Short-distance altitudinal migrant between low-lying town areas and higher parts of mountains in E South Africa, individuals returning to same mountain localities in summer, mean distance moved 7 km; one moved 37 km to E. Seasonal movements during winter, especially in Drakensberg escarpment to midlands. Resident populations in protea nurseries augmented by non-breeding visitors during winter months.

Status and Conservation. Not globally threatened. Locally common; uncommon in SC Eastern Cape (Amatole Mts), where *Protea subvestita* populations destroyed by uncontrolled fires. Probably under-reported, as it inhabits mountainous terrain. In N South Africa (Mpumalanga), mean density 4.6 birds/ha and more than 20 birds/ha recorded in *P. roupelliae* woodland with sufficient inflorescences. Race *ardens* estimated to number a few thousand individuals in Zimbabwe, where common in protea nurseries. Main threats to species are uncontrolled grassland fires in protea savanna and afforestation of grassland habitat; management of protea grassland therefore a priority. Sometimes causes damage in commercial protea-farming areas in KwaZulu–Natal, which can lead to control measures being introduced. Present species is an important pollinator of plants. Occurs in several protected areas, e.g. in Marakele, Golden Gate and Drakensberg National Parks and in Blyde River Canyon and Amatole Forest Complex, all in South Africa; in Zimbabwe, race *ardens* protected in Nyanga and Chimanimani Mountain National Parks.

Class AVES

Order PASSERIFORMES

Suborder OSCINES

Family MELIPHAGIDAE (HONEYEATERS)

- Tiny to very large, typically slender passerines with variably long and usually decurved bill, short to long tail; generally drab plumage, often with conspicuous wing patches of yellow or white, many with areas of bare facial skin or wattles.
- 9–50 cm.

- Australasia and Oceania, and marginally Oriental Region.
- Rainforest, sclerophyll forests and woodlands, shrubland, heath, grassland, mangroves.
- 42 genera, 175 species, 375 taxa.
- 8 species threatened; none extinct since 1600.

Systematics

The honeyeaters (Meliphagidae) comprise one of the most characteristic, numerous, speciose and widespread components of the Australo-Papuan bird fauna. Although centred in Australia and New Guinea, the group has outliers westwards to the Moluccas and Bali, north to the Northern Mariana Islands and Micronesia, and east through New Zealand and the south-western Pacific to Samoa and Tahiti. Two recently extinct genera, *Moho* and *Chaetoptila*, once thought to have been honeyeaters but apparently unrelated to the Meliphagidae, occurred in the Hawaiian Islands. Excluding the Hawaiian species, there are at least 42 genera and 175 species in the family as currently constituted.

The first extensive classification of the honeyeaters was that of H. F. Gadow in 1884, in Volume 9 of the *Catalogue of the Birds in the British Museum*. Gadow placed them together with the sunbirds (Nectariniidae) in a larger grouping, Cinnymorphae. He recognized three subfamilies: Myzomelinae, with *Myzomela* and *Acanthorhynchus*; Meliphaginae, comprising 20 genera; and Zosteropinae, the last containing the white-eyes, which are now segregated as the family Zosteropidae, and two honeyeater genera, namely *Melithreptus* and *Plectorhyncha*. Within Meliphaginae, species were placed in generic combinations that are considerably different from those used in the latter half of the twentieth century and up to the present day.

It was the 1967 classification of F. Salomonsen in J. L. Peters's *Check-list of Birds of the World* that introduced the generic circumscriptions and names that have been employed until just recently. Salomonsen accepted 39 genera. Unfortunately, there was no supporting document to accompany the linear sequence which could have explained the classification adopted. The reasons for several aspects of this sequence, and its implied association of genera, were not obvious, and some details of the arrangement were confusing. The classification of H. E. Wolters, in 1979, included 49 genera. Both Salomonsen's treatment and that of Wolters contained several genera that have subsequently been removed to other families.

Although a few papers went beyond mere linear classifications for small subsections of honeyeaters, K. P. Koopman's revision of the genus *Myzomela* being one example, there was no major attempt to address the evolution and diversification of the Meliphagidae within a broader framework until R. Schodde, in 1975, scrutinized the Australian taxa within the context of the whole family. He proposed that, among Australian honeyeaters,

the larger-bodied forms retained more ancestral characters than the smaller ones. Those considered to be the most generalized honeyeaters, the *Melidectes*, *Pycnopygius* and *Ptiloprora* species, were centred on the cool rainforests of the New Guinea highlands and were at the bases of two major lineages. Schodde identified one lineage comprising many larger-bodied forms, such as the genera *Melidectes*, *Pycnopygius*, *Anthochaera*, *Philemon*, *Acanthagenys*, *Entomyzon*, *Manorina*, *Meliphaga*, *Lichenostomus* and *Melithreptus*. The other lineage contained smaller-bodied honeyeaters, many with a thin, curved bill, and included the genera

The family Meliphagidae contains 175 species spread across 42 genera. The core of honeyeater distribution lies in Australia and New Guinea, but the family also extends north to Micronesia, west to Wallacea and east through New Zealand into Oceania. The genus *Acanthorhynchus* is endemic to Australia and contains two small, fairly long-tailed species with long, slender decurved bills. Both are attractively plumaged and sexually dichromatic, the **Western Spinebill** particularly so. The striking adult male is adorned with black, white, grey and rufous, while the female is much less distinctively marked.

[*Acanthorhynchus superciliosus*, Cheyne Beach, Waychinicup National Park, Western Australia, Australia. Photo: Drew Fulton]

Ptiloprora, *Phylidonyris*, *Acanthorhynchus*, *Certhionyx*, *Conopophila* and *Lichmera*. There were also genera of uncertain affinity, such as *Timeliopsis*, *Glycichaera*, *Melilestes* and *Myzomela*, which could not be easily placed in one lineage or the other.

Honeyeaters are diverse in size and morphology. They include species that are nectarivorous, insectivorous or frugivorous, or, more commonly, combine nectar-eating and insect-eating. Many species have a long, narrow, decurved bill, adapted for the procuring of nectar. The most striking feature of honeyeaters is the tongue, which is prolonged and protrusible. The tip of the tongue of most meliphagids is modified into a brush (see Morphological Aspects). The morphological analyses undertaken by W. J. Bock and H. G. Morioka revealed significant variation in the structure of the palate and the ectethmoid-mandibular articulation across the family.

Traditionally, the Meliphagidae were linked with the sunbirds, the white-eyes and other nectarivorous birds. Several lines of molecular evidence, including the studies by C. G. Sibley and J. E. Ahlquist of DNA-DNA hybridization, the various protein-electrophoretic studies of L. Christidis and Schodde, and the various DNA-sequencing studies of P. G. P. Ericson and colleagues and F. K. Barker and colleagues, have indicated that the honeyeaters belong to an Australo-Papuan clade, which also includes the pardalotes (Pardalotidae), thornbills (Acanthizidae), bristlebirds (Dasyornithidae) and Australasian fairy-wrens (Maluridae). The meagre fossil record of honeyeaters has been summarized by W. E. Boles. Fossils of Quaternary age have been found in Australia, New Zealand, the south-western Pacific and Hawaii. The oldest known fossils are from the Late Tertiary of Australia, and are of Pliocene and Miocene age. Some of these Pliocene specimens are represented by tarsometatarsi that resemble those of modern members of the genera *Meliphaga* and *Lichenostomus*.

Several molecular and biochemical studies undertaken in the decades since the late 1980s have changed our understanding of the composition of the Meliphagidae. In particular, MacGregor's Honeyeater (*Macgregoria pulchra*), a New Guinea species formerly classified as a bird-of-paradise and placed in the family Paradisaeidae, is now known to be a honeyeater, and the Australian chats, herein separated as the family Ephianuridae (see HBW12, pages 612-626), should likewise be included in Meliphagidae. The affinities and systematics of these are discussed in greater detail later in this section.

All of the other changes have involved the removal of species from the family, and are given brief mention here. The affinities of the New Guinea longbill genus *Toxorhamphus* have for long been controversial. This genus was aligned by some authors with the sunbirds in Nectariniidae and by others with the honeyeaters. On the basis of morphological characteristics, the other New Guinea longbill genus, *Oedistoma*, was generally considered to be part of the honeyeater assemblage. The history of classification of these two genera has been well summarized by Sibley and Ahlquist. Grooved nostrils and a quadrid tongue were originally given as some of the characters for including *Toxorhamphus* and *Oedistoma* in the Meliphagidae. The studies by Sibley and Ahlquist, Christidis and colleagues and Barker and colleagues have provided strong evidence for concluding that the four species of *Oedistoma* and *Toxorhamphus* are not honeyeaters but are, instead, part of the berrypecker complex (Melanocharitidae).

The African sugarbirds (*Promerops*) have at various times been included in the thrush family (Turdidae), in the starlings (Sturnidae) and, more commonly, in the honeyeaters, the last-mentioned treatment being based largely on the morphology of the corneous tongue and its associated musculature, as described by Bock. Other treatments for the sugarbirds have included the placing of them with the sunbirds (Nectariniidae) or in their own monotypic family, Promeropidae. Both data derived from DNA-DNA hybridization and data from DNA-sequencing have indicated that the sugarbirds are not related to the honeyeaters. Although the DNA-DNA hybridization data suggested links between the sugarbirds and the sunbirds, the DNA studies of Barker and colleagues indicate that they are, in fact, part of a basal African passeroid assemblage.

The Golden White-eye (*Cleptornis marchei*), confined to the Northern Mariana Islands, was traditionally treated as a honey-

eater, but behavioural and ecological observations by H. D. Pratt strongly indicated that it was, in reality, a white-eye. Both the studies of Sibley and Ahlquist and the mitochondrial-DNA sequence data of M. S. Springer and colleagues have corroborated Pratt's suspicions. In vocalizations, *Cleptornis* is most similar to the genus *Rukia* from the Caroline Islands. Another zosteropid previously treated as a honeyeater is the Bonin White-eye (*Apalopteron familiare*), restricted to the islands of that name, south of Japan. This species had at different times been assigned also to the bulbuls (Pycnonotidae) and the babblers (Timaliidae). Although several characters, including tongue structure, bill, and nest and eggs, were cited by H. G. Deignan in support of its honeyeater affinities, interpretation of this evidence was ambiguous. Nevertheless, field observations of the Bonin White-eye by H. Morioka and T. Sakane identified similarities in ecology and behaviour to the other white-eyes. The mitochondrial-DNA data of Springer and colleagues supported the view that this species is not a honeyeater but is, indeed, a white-eye, and most closely allied to the Golden White-eye. The eggs of the two are very similar, and it has been suggested that these two species, along with the white-eye genus *Rukia*, comprise a single genus, for which the name *Apalopteron* has priority.

An interesting case is that of the Stitchbird (*Notiomystis cincta*). This New Zealand species, known also as the Hihi, has generally been treated as a honeyeater, albeit an unusual one. Following analyses of DNA sequences and a re-evaluation of several behavioural and skeletal characters, however, A. C. Driskell and her colleagues separated the Stitchbird into its own monophyletic family, Notiomystidae. According to their DNA-based phylogeny, and that of J. G. Ewen and his colleagues, the Stitchbird is most closely allied to the New Zealand Wattlebirds (Callaeidae), although the two groups diverged from one another some 34 million years ago.

As with the above genera that have been found not to be honeyeaters, recent work has revealed that the Hawaiian genera *Moho* and *Chaetoptila* are likewise not meliphagids. Unfortunately, all five species in these two genera, the Kauai O'o (*Moho braccatus*), Oahu O'o (*Moho apicalis*), Bishop's O'o (*Moho bishopi*) and Hawaii O'o (*Moho nobilis*) and the Kioea (*Chaetoptila angustipluma*), are now considered extinct (see Status and

The genus *Pycnopygius* comprises three medium-sized, rather nondescript meliphagids from New Guinea. All have a medium-length, marginally decurved bill, and are broadly grey-brown in plumage. The **Marbled Honeyeater** and its congeners are superficially similar in appearance to friarbirds (Philemon), a characteristic that is thought to be by design rather than coincidence. Several honeyeater species, as well as several orioles (Oriolidae), mimic the larger, more aggressive friarbirds in order to feed undisturbed by their side.

[*Pycnopygius cinereus marmoratus*, Ubaigubi, EC New Guinea. Photo: William S. Peckover]

Conservation). Using DNA extracted from museum specimens collected in the 1800s, R. Fleischer and his colleagues found no support for the placement of these Hawaiian genera within the family Meliphagidae, or even within the "parvorder Corvida" as defined by Sibley and B. L. Monroe. They found both *Moho* and *Chaetoptila* to be members of the "parvorder Passerida", forming a divergent lineage within an unusual clade containing three other avian families, namely the waxwings (Bombycillidae), the silky-flycatchers (Ptilonotidae) and the Dulidae, the last consisting of a single species, the Palmchat (*Dulus dominicus*). These two Hawaiian genera are convergent in morphology, behaviour and ecology with the Australasian honeyeaters, but they remain unique taxonomically, possibly to the level of family. They are not derived from South Pacific ancestors, in common with the other Hawaiian endemics other than the Elepaio (*Chasiempis sandwichensis*), which has been shown by the DNA study of C. E. Filardi and R. G. Moyle to be allied to the monarch-flycatchers (Monarchidae) centred on the Australo-Papuan region.

There have been no recent attempts to recognize subfamilies and tribes within the honeyeaters. Morphological assessments have focused on limited character bases and have produced little general consensus. A particular difficulty is the fact that circumscription of several genera is still unresolved. In placing the Australian chats (Epthianuridae) within the honeyeaters, Schodde and I. J. Mason treated these as a separate subfamily, Epthianurinae, on the basis of a few apparently divergent skull characters. The DNA findings of Driskell and Christidis, however, clearly place the Australian chats deep within the honeyeaters. The extensive DNA-sequencing study of relationships of largely Australian and New Guinean genera undertaken by Driskell and Christidis identified five major assemblages. Apart from one, which is monogeneric, these assemblages comprised a mixture of large-bodied and small-bodied genera. Although several critical genera and species were not included in the study, the assemblages identified are probably the best reflection of higher relationships within the Meliphagidae and form the basis of the classification currently adopted here. The main divergence from this is that, in the present arrangement, the Australian chats are excluded, having already been treated as a separate family, Epthianuridae.

Assemblage 1. The DNA-sequence data have identified the Eastern Spinebill (*Acanthorhynchus tenuirostris*) and the Western Spinebill (*Acanthorhynchus superciliosus*) as the sister-group to the rest of the honeyeaters examined to date. Schodde and Mason suggested that the spinebills resembled the genera *Myzomela* and *Certhionyx* in certain features of the skull and palate. They noted, however, that the spinebills comprise one of the more distinctive genera of honeyeaters in terms of external morphology and behaviour, as well as in having tomial toothings of the bill and an extensively tubed tongue. Having one basal group of honeyeaters with two species and a single genus restricted to the heathlands and woodlands of eastern and southern Australia, while the other basal group comprises the remaining 173 species and 41 genera and ranges throughout Wallacea, Australasia and the Pacific, is an intriguing biogeographical and evolutionary scenario. Driskell and Christidis suggested that the honeyeaters arose during the mid-Tertiary, when heathlands were widespread in Australia. The two species of spinebill are very similar to each other and are considered to represent eastern and western replacements, respectively, of a single superspecies. In terms of genetic differentiation the two are in fact quite distinct, with a level of divergence similar to that observed between distinct subgenera of honeyeaters. This indicates that the two spinebills diverged several million years ago, but that they have retained a strong degree of similarity in morphology and plumage pattern.

Assemblage 2. In complete contrast to the spinebill group, the second assemblage is the largest in terms of genera and species. It is distributed throughout Australia, New Zealand, New Guinea and possibly the Solomon Islands, the last depending on the affinities of taxa not yet subjected to DNA analysis. Within this assemblage, one intriguing clade identified by the DNA-sequencing analyses of Driskell and Christidis comprises the New Guinean *Pycnopygius*, the arid-adapted Australian *Certhionyx* and the New Zealand endemics *Prosthemadera* and *Anthornis*. DNA analysis of other Melanesian and Polynesian honeyeater genera

The **Tui** is the only member of the genus *Prosthemadera*. It is endemic to New Zealand and its offshore islands. One of the larger honeyeaters, the Tui is morphologically distinctive, having broad, rounded wings and tail, strong legs and feet, and a sturdy, slightly decurved bill. The wings are modified with notches in the eighth primary; only adults have the notches and those of males are larger than those of females. The notches enable the Tui to produce a variety of whirring wing noises in aggressive and courtship displays.

The Roving Tortoise Photos]

may help to elucidate the origins and evolutionary history of this biogeographically challenging pattern. The three species of New Guinean *Pycnopygius*, the Plain Honeyeater (*Pycnopygius ixoides*), the Marbled Honeyeater (*Pycnopygius cinereus*) and the Streak-headed Honeyeater (*Pycnopygius stictocephalus*), are rather nondescript meliphagids having superficial resemblances to the smaller friarbirds (*Philemon*), as well as to the Tawny-breasted Honeyeater (*Xanthotis flaviventer*) and the quite unrelated Brown Oriole (*Oriolus szalayii*). According to J. M. Diamond, the tendency for some smaller species of honeyeater and oriole to develop similarities in overall appearance to larger species is a form of mimicry that allows the smaller species, in this case *Pycnopygius*, to feed alongside the larger, more pugnacious ones, in this case friarbirds and orioles (see Morphological Aspects, Voice). In such instances, external morphology is a poor indicator of systematic relationships. DNA-sequencing information aligns *Pycnopygius* with the Pied Honeyeater (*Certhionyx variegatus*) of Australia. These two genera are, in turn, linked to a clade that comprises the Tui (*Prosthemadera novaeseelandiae*) and the New Zealand Bellbird (*Anthornis melanura*), both confined to New Zealand. Until recently, *Certhionyx* was considered to include a further two species, the Black Honeyeater (*Sugomel nigrum*) and the Banded Honeyeater (*Cissomela pectoralis*), generally aligned with the Pied Honeyeater owing to similarities in external appearance, all three having black-and-white plumage, a small body and a longish decurved bill. DNA-sequencing studies, however, indicate that the three are unrelated and that each belongs to a different assemblage, the Pied Honeyeater being part of "assemblage 2", the Black Honeyeater belonging to "assemblage 4" and the Banded Honeyeater lying within "assemblage 5". Consequently, *Certhionyx* is a monotypic genus comprising only the Pied Honeyeater. Morphology provides few clues to the affinities of the Pied Honeyeater; the body shape and bill type are more reminiscent of *Phylidonyris*, and the small blue wattle below the eye has some similarity to the eye skin of *Manorina* and *Melithreptus*. To date, no strong shared morphological features have been found that link the Pied Honeyeater with *Pycnopygius*, *Prosthemadera* and *Anthornis*.

According to molecular-clock estimates based on the data of Driskell and her colleagues, the Tui and the New Zealand Bellbird diverged from each other about 3 million years ago, follow-

ing a single colonization event in New Zealand. Morphologically, the two species are quite distinctive and, if it were not for their shared biogeography a close relationship between the two would not be obvious. The two genera do, however, have similarly patterned eggs. The extinct Chatham Islands *Anthornis* taxon *melanocephala* is generally considered a subspecies of the New Zealand Bellbird, but it was treated as a separate species, the "Chatham Island Bellbird", by R. Holdaway and his colleagues, a decision based on a broad acceptance of the phylogenetic species concept. The Chatham Island Bellbird had yellow eyes, whereas all other forms have red eyes, and it was, moreover, the largest of all subspecies, but determination of whether it represented a separate species requires more detailed examination.

Due to superficial similarities in facial pattern, the genera *Meliphaga*, *Lichenostomus*, *Xanthotis*, *Guadalcanaria*, *Oreornis* and *Foulehaio* have been thought to be closely related. Driskell and Christidis, however, found that, rather surprisingly, *Meliphaga*, *Lichenostomus*, *Xanthotis* and *Foulehaio* appeared not to be closely related; *Meliphaga* and *Lichenostomus* were part of assemblage 2 but not as sister-clades, while *Xanthotis* and *Foulehaio* were part of assemblage 5 but, again, not as sister-lineages.

The Guadalcanal Honeyeater (*Guadalcanaria inexpectata*) is a large grey meliphagid with a dusky malar line and an elongated yellow plume on the side of the neck. These characters have prompted several authors to associate this species with *Meliphaga* and *Lichenostomus*, and it was placed in the former genus by Salomonsen. Nevertheless, the DNA-based studies have revealed that plumage patterns are poor indicators of generic affinities within the honeyeaters, suggesting that *Guadalcanaria* is best retained as a genus of indeterminate affinities pending DNA analysis.

Both the protein-electrophoretic study of Christidis and Schodde and the DNA-sequencing analyses of J. A. Norman and colleagues identified two major lineages within *Meliphaga*. The "lewinii group" consists of Lewin's Honeyeater (*Meliphaga lewinii*) and the Yellow-spotted Honeyeater (*Meliphaga notata*) from Australia and the Puff-backed Honeyeater (*Meliphaga aruensis*) from New Guinea. These three replace each other geographically, and even where Lewin's and Yellow-spotted Honeyeaters meet, in north-eastern Queensland, they largely replace each other altitudinally. The Puff-backed Honeyeater has been found to comprise two genetically distinct forms, one of which is

restricted to the extreme south-east of its range; in terms of genetic distance, the two forms have diverged from each other to the same extent as have Lewin's and Yellow-spotted Honeyeaters. The second main lineage, the "analoga group", comprises the Scrub Honeyeater (*Meliphaga albonotata*), Hill-forest Honeyeater (*Meliphaga orientalis*), Mimic Honeyeater (*Meliphaga analoga*), Tagula Honeyeater (*Meliphaga vicina*), Graceful Honeyeater (*Meliphaga gracilis*), Spot-breasted Honeyeater (*Meliphaga mimikae*), Forest Honeyeater (*Meliphaga montana*), Yellow-gaped Honeyeater (*Meliphaga flavirictus*), White-lined Honeyeater (*Meliphaga albilineata*) and Streak-breasted Honeyeater (*Meliphaga reticulata*). DNA distances revealed the existence of two further species in this assemblage. The Kimberley Honeyeater (*Meliphaga fordiana*), from the Kimberley region of north-western Australia, is specifically separable from the White-lined Honeyeater, which is now confined to Arnhem Land, in northern Australia. The Graceful Honeyeater is restricted to north-eastern Australia and the Trans-Fly region of New Guinea; those populations in south-eastern New Guinea formerly treated as conspecific with it are now separated as the Elegant Honeyeater (*Meliphaga cinereifrons*). Of particular uncertainty have been the taxon *stevensi*, from the northern watershed of south-eastern New Guinea. On the basis of plumage patterns and proportions, it has been aligned with either the Mimic Honeyeater or the Elegant Honeyeater. The DNA-sequence data reveal that both morphological assessments may have been correct as, in reality, the birds till now labelled as *stevensi* include individuals of both species, and the two species co-occur at least in part of this zone. The Streak-breasted Honeyeater, from Timor, has been difficult to place taxonomically because it has *Lichenostomus*-like dusky rictal stripes and *Meliphaga*-like flared yellow ear-tufts. Other traits, such as broad white-shafted ventral striping and streaked ear-tufts, suggest affinities with *Lichmera* or *Trichodere*. The DNA-sequence data place this species within *Meliphaga*, as sister to the White-lined and Kimberley Honeyeater group, and such an association is consistent with the geographically close proximity of Timor to north-western Australia. Within *Meliphaga*, closely related species occupy disjunct distributions and replace each other geographically or altitudinally, this presumably being a mechanism for minimizing competition between ecologically similar forms. Norman and her colleagues

The 15 species in the genus *Meliphaga* are classic, medium-sized honeyeaters, as befits a genus that gives the family its name. In *Meliphaga*, the bare facial skin that is typical of the family is restricted to a swollen and extended gape line that runs back from the bill to below the eye. The genus is also characterized by a pale ear-covert patch, although many are less extensive and less prominent than that of the **Elegant Honeyeater**. This species is endemic to New Guinea and was formerly considered conspecific with the Graceful Honeyeater (*M. gracilis*).

[*Meliphaga cinereifrons*
cinereifrons,
near Brown River,
SE New Guinea.

found that co-distributed lineages tended to be phylogenetically distant and co-existed by segregating vertically within the habitat or through horizontal segregation in the form of habitat differentiation. Consequently, the predominantly allopatric distributions observed among recently evolved *Meliphaga* species suggest that most speciation events have been initiated through physical isolation mechanisms of single habitats, such as mountain uplift, flooding of basins or aridification.

The genus *Lichenostomus* comprises 20 species that have elongated ear and upper-neck plumes and a lined face. They are very homogeneous in terms of body shape and bill shape, and their centre of diversity is the sclerophyll forests of Australia. On the basis of plumage patterns, Christidis and Schodde recognized six species groups, or subgenera: the “*Caligavis* group”, comprising the Black-throated (*Lichenostomus subfrenatus*), Obscure (*Lichenostomus obscurus*), Bridled (*Lichenostomus frenatus*), Eungella (*Lichenostomus hindwoodi*) and Yellow-faced Honeyeaters (*Lichenostomus chrysops*); the “*Gavialis* group”, with the Singing Honeyeater (*Lichenostomus virescens*), the Varied Honeyeater (*Lichenostomus versicolor*) and the Mangrove Honeyeater (*Lichenostomus fasciolaris*); the “*Stomiopetra* group”, with the White-gaped Honeyeater (*Lichenostomus unicolor*) and the Yellow Honeyeater (*Lichenostomus flavus*); the “*Nesoptilotis* group”, containing the White-eared Honeyeater (*Lichenostomus leucotis*) and the Yellow-throated Honeyeater (*Lichenostomus flavicollis*); the “*Lichenostomus* group”, comprising the Yellow-tufted Honeyeater (*Lichenostomus melanops*), the Grey-headed Honeyeater (*Lichenostomus keartlandi*) and the Purple-gaped Honeyeater (*Lichenostomus cratitius*); and the “*Ptilotula* group”, consisting of the Yellow-plumed (*Lichenostomus ornatus*), Grey-fronted (*Lichenostomus plumulus*), Fuscous (*Lichenostomus fuscus*), Yellow-tinted (*Lichenostomus flavescens*) and White-plumed Honeyeaters (*Lichenostomus penicillatus*). Only two of these species, the Black-throated and Obscure Honeyeaters, are endemic to New Guinea, and two others, the Varied and Yellow-tinted Honeyeaters, are shared between Australia and New Guinea. All of the remaining 16 species are restricted to Australia. There has been occasional taxonomic debate on whether the Fuscous and Yellow-tinted Honeyeaters should be treated as a single species, but the current consensus is

that the two do not intergrade where they meet, and they are ecologically and morphologically quite distinct. J. Ford argued that the Varied and Mangrove Honeyeaters should be combined as one species because of introgression where their distributions abut. The presumed area of introgression is, however, limited and patchy, and it appears to consist of transient colonies, and the two are retained as separate species. Populations of the Varied Honeyeater in New Guinea divide into two plumage types: those of the south and south-east resemble the Varied Honeyeater of northern Australia, whereas those of northern New Guinea and the Western Papuan Islands resemble the Singing Honeyeater. Further work on the matter of species relationships and circumscription in this complex is clearly warranted. Although the occasional argument has been put forward for treating the form *cassidix* as a separate species, the “Helmeted Honeyeater”, it is now firmly established as a race of the Yellow-tufted Honeyeater.

Still in New Guinea, the Orange-cheeked Honeyeater (*Oreornis chrysogenys*), found in subalpine regions in the west of the island, has sometimes been placed in *Lichenostomus*. It has a distinctive bicoloured ear patch and yellowish throat, which are suggestive of the patterns displayed by some members of *Lichenostomus*, in particular the Black-throated and Obscure Honeyeaters, with which it has sometimes been linked. The calls of the Orange-cheeked Honeyeater are said to be similar to those of the Black-throated Honeyeater.

DNA-sequence data have strongly indicated that the White-fronted Honeyeater (*Purnella albifrons*) is not a member of the genus *Phylidonyris*, in which it has hitherto always been placed. While it is part of assemblage 2, the other species generally associated with *Phylidonyris* are split between assemblages 4 and 5. The closest affinities of the White-fronted Honeyeater appear to be with *Lichenostomus*, *Manorina* and *Melidectes*. This is an extremely novel arrangement of its relationships. Nevertheless, the presence of a small bare red wattle behind the eye of the White-fronted Honeyeater is reminiscent of the triangular bare skin patches behind the eye of *Manorina*, which are red in the Bell Miner (*Manorina melanophrys*) and yellow in the other three species.

The composition of the genus *Melidectes* is far from resolved. It comprises a heterogeneous assemblage of medium-sized honeyeaters with a long, often stout bill and various degrees of coloured facial skin. Nine species are confined to the mountains of mainland New Guinea, and a tenth occurs in the Bismarck Archipelago. The Bismarck Honeyeater (*Melidectes whitemanensis*) is a moderately large, drab honeyeater with a long, curved bill and a narrow area of bare skin below and behind the eye. Its generic placement has had a chequered history. Salomonsen kept this species in a monotypic genus, *Vosea*, while Wolters placed it in *Melidectes* presumably because of its long bill. Diamond placed the Bismarck Honeyeater in *Melidectes* and suggested that its affinities lay closest to the Sooty Honeyeater (*Melidectes fuscus*). T. Iredale separated the Sooty Honeyeater, the Long-bearded Honeyeater (*Melidectes princeps*) and the Short-bearded Honeyeater (*Melidectes nouhuysi*) as the genus *Melionyx*, a decision based on several aspects of morphology, behaviour and nidification that differed from those of other members of *Melidectes*. Both Wolters and B. J. Coates followed this arrangement, but most other authors have not. Compared with the other members of *Melidectes*, these three species are darker, have a relatively slender bill and have much smaller areas of bare skin. The Long-bearded and Short-bearded Honeyeaters are eastern and western representatives of a superspecies, and some authors have suggested that they could be conspecific. They are the only members of the group that have a throat beard. The next group comprises the Cinnamon-browed Honeyeater (*Melidectes ochromelas*), the Vogelkop Honeyeater (*Melidectes leucostephes*), Belford's Honeyeater (*Melidectes belfordi*), the Yellow-browed Honeyeater (*Melidectes rufocrissalis*) and the Huon Honeyeater (*Melidectes foersteri*). Wolters placed all of these in a genus *Melirrhophetes* and retained *Melidectes* solely for the Ornate Honeyeater (*Melidectes torquatus*). Driskell and Christidis provided DNA-sequence data for three species of *Melidectes*, and their analyses placed the Cinnamon-browed and Belford's Honeyeaters together, followed by the Ornate Honeyeater, in keeping with generally accepted practice. Separate species status for the

The genus *Lichenostomus* contains 20 species, of which the **Grey-fronted Honeyeater** is one of 16 restricted to Australia. The members of this group are all morphologically rather similar, and are characterized most notably by having elongated plumes on the ear-coverts and upper neck, as well as a lined face. While some honeyeater genera have contrastingly coloured panels on the folded wing, among *Lichenostomus* species this is the exception rather than the rule. The bright yellow-olive fringes to the remiges in the Grey-fronted Honeyeater are thus relatively unusual for the genus. This genus is centred on Australia's sclerophyll forests.

[*Lichenostomus plumulus*, Australia.
Photo: Drew Fulton]

Cinnamon-browed Honeyeater is well established, whereas the other four form a superspecies with various degrees of hybridization among the forms. The Vogelkop Honeyeater was recognized as a separate species by Salomonsen, but he incorporated the other three within Belford's Honeyeater, although noting that the Yellow-browed and Huon Honeyeaters could comprise an additional species. At issue is the extent of hybridization between the forms, which is well detailed by Coates, and also by Diamond in his study of the birds of the New Guinean Eastern Highlands. Belford's and Yellow-browed Honeyeaters interbreed readily where they meet, and some of the resultant hybrid populations have even been assigned subspecific names. Pure populations of each species are very distinct. Belford's Honeyeater has a prominent patch of pale blue bare skin above, behind and below the eye, though this is lemon-yellow in the race *schraderensis*, and all have a small white gape wattle. The Yellow-browed Honeyeater likewise has a white gape wattle, but the bare skin around the eye is more extensive and pale greenish in colour, and there are small orange-red wattles on each side of the throat. Whether the two comprise one or two species requires more detailed study. The Huon Honeyeater further complicates the picture in that it has blue facial skin in common with Belford's Honeyeater but orange-red throat wattles as in the Yellow-browed Honeyeater. Most authors align the Huon Honeyeater with the Yellow-browed Honeyeater. Within Belford's Honeyeater, Coates noted that, in south-eastern New Guinea, the subspecies *brassi* and the nominate race occupy the same geographical range but are altitudinally separated, the former living in the middle mountains at up to 2800 m, whereas the nominate race is found in the high mountains from 3000 m to 3800 m. The two apparently do not intergrade but, rather, replace each other abruptly. Whether or not they represent separate species merits further investigation.

Sibley and Monroe, following a suggestion by Schodde, included the San Cristobal Honeyeater (*Meliarchus sclateri*) in *Melidectes*, although most other authors have continued to retain it in the monotypic *Meliarchus*. K. C. Parkes argued for a close affinity between it and the Spiny-cheeked Honeyeater (*Acanthagenys rufogularis*) from Australia on the grounds of apparent similarities between them in bill shape and plumage. Although this suggestion has not been given serious consideration, further DNA-based research on the matter is warranted, given that *Melidectes* and *Acanthagenys* have been identified as being part of the same clade by the DNA study of Driskell and Christidis.

The Australian miners in the genus *Manorina* have been aligned with *Melithreptus* by Schodde and Mason, primarily on account of the pattern of development of the ectethmoid-mandibular articulation of the palate. The DNA-sequence data of Driskell and Christidis, however, clearly placed these two genera in widely separated assemblages, thereby indicating that apparent similarities in this articulation are convergent. *Manorina* appears to be most closely related to New Guinean *Melidectes*. Within the genus *Manorina*, there has been considerable debate as to whether the restricted-range and Endangered Black-eared Miner (*Manorina melanotis*) is merely a subspecies or an ecological colour morph of the more widespread Yellow-throated Miner (*Manorina flavigula*), and the various arguments have been well summarized by Schodde and Mason. Despite extensive hybridization in parts of their ranges, ecological and morphological assessments support the recognition of two discrete species. Moreover, unpublished data from DNA-sequence analysis by Norman and colleagues indicate that the two have diverged from each other as much as they have from the Noisy Miner (*Manorina melanocephala*). The three form a recently diverged group of species which is sister to the more divergent and morphologically distinctive Bell Miner.

The Spiny-cheeked Honeyeater has sometimes been included in the wattlebird genus *Anthochaera*, with which it shares some palatal and cranial features. Its levels of DNA-sequence divergence, however, are consistent with its generic separation, hence its placement in the monotypic *Acanthagenys*. Within the wattlebirds proper, two subgroups have generally been recognized. The first consists of the Little Wattlebird (*Anthochaera chrysoptera*) and the Western Wattlebird (*Anthochaera lunulata*), which lack wattles, have conventionally feathered and streaked

cheeks and utter clanking territorial calls; the second contains the Red Wattlebird (*Anthochaera carunculata*) and the Yellow Wattlebird (*Anthochaera paradoxa*), which are wattled, have cheek patches of scaly whitish feathering and deliver rasping coughed territorial calls. The Regent Honeyeater (*Anthochaera phrygia*) was previously placed in its own genus *Zanthomyza* (sometimes erroneously emended to "*Xanthomyza*"). The DNA-sequence data, however, clearly place it among the wattlebirds, where it is most closely allied to the Red and Yellow Wattlebirds. Although the Regent Honeyeater lacks wattles, it does have bare cheeks and its territorial call is very reminiscent of that of the Red Wattlebird, as is its posture when calling. The similarity in territorial calls was interpreted by P. A. Veerman as being mimicry, but it now appears to be a shared evolutionary feature. The Western Wattlebird has sometimes been treated as a subspecies of the Little Wattlebird, but the DNA-sequencing study of Driskell and Christidis and the morphological-based assessments of Schodde and Mason have indicated that the two are separate species.

Assemblage 3. After the first assemblage, the third is the next-smallest in terms of number of species. It is restricted to Australia, New Guinea and possibly the Solomon Islands, the last depending on the affinities of taxa not yet included in DNA analyses. Three biogeographically coherent groups are apparent. The first contains the genera *Ramsayornis* and *Conopophila* from northern Australia and southern New Guinea, and the second consists of *Timeliopsis*, *Melilestes*, *Melipotes* and *Macgregoria* from New Guinea. The third group contains the Australian genera *Epthianura* and *Ashbyia*, both of which have been treated in a separate family, Epthianuridae, but should be transferred to the present family.

According to Schodde and Mason, the Brown-backed Honeyeater (*Ramsayornis modestus*) and the Bar-breasted Honeyeater (*Ramsayornis fasciatus*) exhibit similarities to *Myzomela* in such features as straight palatines, narrow and reduced ectethmoids and nasal bars. The DNA data of Driskell and Christidis indicate that these characters are convergent. *Ramsayornis* is very closely linked with *Conopophila*, which resembles it in the architecture of the skull and palate, differing primarily in its larger and more elongate temporal fossa. While the circumscription of *Ramsayornis* has been straightforward, this has not been the case with *Conopophila*. Although the Rufous-banded Honeyeater (*Conopophila albogularis*) and the Rufous-throated Honeyeater (*Conopophila rufogularis*) are universally regarded as sister-taxa, their affinities with the Grey Honeyeater

The rise to prominence of DNA-sequencing technology has revolutionized taxonomy. Traditional classification methodologies had resulted in the White-fronted Honeyeater being situated in the genus *Phylidonyris* for decades. Molecular data, however, have revealed such classification to be erroneous, and the species is now placed in its own monotypic genus, *Purnella*.

The White-fronted Honeyeater is a medium-sized meliphagid with a long, slender, decurved bill, and a long, sloping forehead. As is the norm in the family, *Purnella* shows sexual dimorphism, males being larger than females.

[*Purnella albigrons*, Gluepot Reserve, South Australia, Australia. Photo: Cheryl Ridge]

(*Conopophila whitei*) are far less well established. The Grey Honeyeater is a nondescript, poorly known honeyeater that is often placed in a monotypic genus, *Lacustroica*. No DNA data exist for this enigmatic species, and its retention in *Conopophila* is largely a matter of convenience, rather than being based on evidence. The placement of the Painted Honeyeater (*Grantiella picta*) in *Conopophila* by Salomonsen is totally negated by the genetic evidence; there appears to be no close association between the two genera. The affinities of the Painted Honeyeater are discussed below, in the final paragraph of this section.

Before the DNA evidence, a close association between the genera *Timeliopsis*, *Melilestes*, *Melipotes* and *Macgregoria* had not been proposed, as each is morphologically distinct from the others. *Timeliopsis* comprises two nondescript species of honeyeater, the Olive Straightbill (*Timeliopsis fulvigula*) and the Tawny Straightbill (*Timeliopsis griseigula*), the placement of which within Meliphagidae has been questioned. The tongue of *Timeliopsis* is particularly broad and shallowly grooved, with a shortened brush-like tip. Often, the genus has been placed near the start or the end of the systematic sequence, next to the longbill genus *Oedistoma*, which is now known to be a berrypecker belonging in Melanocharitidae. Despite their non-honeyeater superficial appearance, the straightbills are nevertheless clearly nested well within the Meliphagidae. The decision of Schodde and Mason to place the Green-backed Honeyeater (*Glycichaera fallax*) within *Timeliopsis*, on the grounds of apparent similarities in skull profile as well as in the maxillo-palatine process and tongue, is not supported by the DNA data. The Green-backed Honeyeater is, in fact, part of "assemblage 4".

With its exceptionally long, curved bill, *Melilestes* is another New Guinean genus the affinities of which have been the focus of some debate. It is generally thought to comprise a single species, the Long-billed Honeyeater (*Melilestes mearnsi*), but the Bougainville Honeyeater (*Stresemannia bougainvillei*) was included in *Melilestes* by Salomonsen and by Wolters. In other treatments, the latter species has been placed in *Lichmera* and in *Meliphaga*. DNA data are not available for this species and, given the misleading signals provided by superficial appearances, most authors now keep the Bougainville Honeyeater in *Stresemannia*, next to *Melilestes* in sequence. Wolters even included the Bismarck Honeyeater in *Melilestes* but, as discussed above, this is generally included in *Melidectes* or in its own monotypic genus, *Vosea*.

Until recently, three species were known to make up the genus *Melipotes*. These are the Arfak Honeyeater (*Melipotes gymnops*), the Common Smoky Honeyeater (*Melipotes fumigatus*) and the Spangled Honeyeater (*Melipotes ater*). Recently, a fourth species, the Wattled Smoky Honeyeater (*Melipotes carolae*), has been discovered in the Foja Mountains by B. M. Beehler and his colleagues. Earlier, Diamond had mentioned that he had seen the Common Smoky Honeyeater in these same mountains, but it is possible that what he actually recorded was the Wattled Smoky Honeyeater; the possibility that both species occur in the Foja Mountains has been rejected by Beehler. Members of the genus *Melipotes* are mainly berry-eaters, and it is not known if they take nectar. Apparently uniquely among honeyeaters (but see below), they lack any brush-like tip on the tongue, as observed by H. Scharnke, but the tongue does appear to have a rudimentary four-part tip. According to A. L. Rand, this tongue morphology is presumably an adaptation to the largely frugivorous diet. Species of *Melipotes* possess brightly coloured facial wattles, and it is this feature that has generally led to their being allied with the genus *Melidectes*. Most systematic treatments place the two genera next to each other, but the DNA data reveal no close affinities between them; they are nested within quite separate assemblages. Clearly, facial wattles have arisen and been lost several times within the evolution of the honeyeaters. Beehler and colleagues constructed a phylogenetic tree based on morphological characters. According to their analysis, the Common Smoky and Wattled Smoky Honeyeaters are sister-species and they, in turn, are associated with the Arfak Honeyeater. The Spangled Honeyeater is the basal member of the genus.

MacGregor's Honeyeater, from New Guinea, was classified as a bird-of-paradise from the time of its original description, in 1896, although Iredale had suggested that it be removed from that family because it was different from other birds-of-paradise. A sequencing study of mitochondrial DNA by J. Cracraft and J. Feinstein produced very strong evidence that "MacGregor's Bird-of-paradise", as it was until then known, was in fact a honeyeater, most closely related to the New Guinean genus *Melipotes*. Although an early limited cranial study by Bock suggested that it was closest to the cnemophiline birds-of-paradise, the reanalysis of skull and skeletal characters by Cracraft and Feinstein provided better support for honeyeater affinities for MacGregor's Honeyeater. Ironically, DNA-sequencing studies indicate also that cnemophilines are not birds-of-paradise but, instead, represent an early corvid lineage with as yet indeterminate close affinities. Closer examination reveals several features common to MacGregor's Honeyeater and the genus *Melipotes*. They are largely frugivorous honeyeaters that lack the brush-like tip of the tongue, they are similar in bill shape, and they lay eggs that are pinkish with brown spotting, the spots more abundant at the larger end. Both groups possess dark grey or black plumage and coloured facial skin. The yellow facial skin of MacGregor's Honeyeater is a fully developed wattle that is anchored behind the eye. In the Common Smoky, Arfak and Spangled Honeyeaters, the yellow facial skin surrounds the eye, but only beneath it is developed as a wattle; it can also flush red when an individual is excited. The Wattled Smoky Honeyeater has red-orange facial skin, with a wattle that hangs down from each side of the face. In this respect, the fleshy wattle is more akin to that found in MacGregor's Honeyeater than to those of the other members of *Melipotes*. Furthermore, Beehler and colleagues observed some mottling of the facial colour of the Wattled Smoky Honeyeater, although not the change from unflushed to flushed observed for other species of *Melipotes*.

The third and final group in assemblage 3 comprises two genera and five species of Australian chat. These are the White-fronted (*Epthianura albifrons*), Orange (*Epthianura aurifrons*), Yellow (*Epthianura crocea*) and Crimson Chats (*Epthianura tricolor*) and the Gibberbird (*Ashbyia lovensis*), all terrestrial insectivores adapted to arid Australia. Most are gregarious and sexually dichromatic, with differing breeding and non-breeding plumages. They have traditionally been aligned with the Australasian thornbills in Acanthizidae and with the Australo-Papuan fairy-wrens of the family Maluridae, and they are sometimes, as in the current treatment, placed in their own family, Epthianuridae.

The ten species in the genus *Melidectes* are fairly large birds with a long, usually stout bill and coloured facial skin.

The **Yellow-browed Honeyeater** is one of the nine genus members that are endemic to montane New Guinea. This species has an extensive area of bare pale green skin around the eye, as well as a white gape wattle. Unusually among meliphagids, it hybridizes readily with the congeneric Belford's Honeyeater (*M. belfordi*) where their populations overlap. In the past, several hybrid populations were thought to be distinct subspecies.

[*Melidectes rufocrissalis* rufocrissalis, Ubaigubi, EC New Guinea. Photo: William S. Peckover]

The four species in the genus *Manorina* are endemic to Australia. The most morphologically distinctive and genetically distinct is the **Bell Miner** of east and south-east Australia. The smallest member of *Manorina*, this species has a fairly long, square-ended tail, and a short, stout, slightly decurved bill. While its three congeners are largely grey in plumage and have a striking head pattern, the Bell Miner is mostly olive-green and has a comparatively subdued head pattern, comprising a black forehead and malar, a broad yellow loreal patch, and a small area of red-orange skin behind the eye.

An examination of tongue morphology by S. A. Parker revealed that Australian chats possess a brush-tipped tongue, although this is less developed in the White-fronted Chat. The Gibberbird has a quadrid tongue without brush-tipping, presumably a secondary simplification. The tongue morphology was strongly suggestive of honeyeater affinities. Parker noted also that the eggs of the Australian chats bear strong similarity to those of some honeyeater genera. On the basis of plumage patterns, the Australian chats, excluding the Gibberbird, have been segregated into three subgenera, which Wolters elevated to genera: *Epthianura* for the White-fronted Chat, *Parepthianura* for the Crimson Chat, and *Aurepthianura* for the Orange and Yellow Chats. The extensive DNA-sequence data of Driskell and Christidis, however, completely contradict this arrangement and identify, instead, two species pairs, one consisting of the Crimson and Yellow Chats and the other the Orange and White-fronted Chats.

The genus *Anthochaera* contains five large, slender, heavily streaked honeyeaters with a fairly long, graduated tail and decurved bill. Two members of the genus have wattles of bare skin whereas the other three, including the **Western Wattlebird**, do not. The congeners are further differentiated by the presence or absence of scaly feathering on the cheeks and by the nature of their territorial calls. Meliphagids have a long, brush-tipped tongue, which helps them gather nectar from flowers. Birds are also capable of thrusting the tongue forwards, a further adaptation for nectarivory.

Assemblage 4. The fourth honeyeater assemblage comprises five genera and 40 species, 31 of these being included in a single genus, *Myzomela*, which is distributed from Wallacea eastwards through New Guinea, Australia and into the Pacific. Two monotypic genera, *Sugomel* and *Gliciphila*, are confined to Australia, another monotypic genus, *Glycichaera*, is shared between northern Australia and New Guinea, and the remaining genus, *Ptiloprora*, has six species restricted to New Guinea. As discussed above, the Black Honeyeater, *Sugomel*, has generally been included as one of three species in *Certhionyx*, but recently the three have been shown to constitute three separate genera. The DNA-sequence data of Driskell and Christidis link the Black Honeyeater strongly with *Myzomela*, but the levels of genetic differentiation support separate generic treatments. The finding of a sister relationship between the Black Honeyeater and *Myzomela* is not surprising, as the two are similar in overall shape, having a short squat body with a long decurved bill. According to Schodde and Mason there are apparent differences in tongue furcation between the two genera, but this feature has so far received only cursory investigation.

Koopman divided *Myzomela* into three groups: a small group comprising dull-plumaged species, a larger one consisting of brightly plumaged species, and a third with just one species, the Red-collared *Myzomela* (*Myzomela rosenbergii*). The dull-plumaged "eques-obscura group" contains the Drab *Myzomela* (*Myzomela blasii*), White-chinned *Myzomela* (*Myzomela albigula*), Red-throated *Myzomela* (*Myzomela eques*), Ashy *Myzomela* (*Myzomela cineracea*) and Dusky *Myzomela*

(*Myzomela obscura*). In these species, both sexes have predominantly brownish-grey plumage, with little, if any, metallic red, and the red, if present, is limited to the throat. The species are either sexually monomorphic or only slightly dimorphic. This group is confined to New Guinea, Australia and parts of the Lesser Sundas. The Ashy *Myzomela*, confined to the Bismarck Archipelago, has sometimes been treated as a subspecies of the Red-throated *Myzomela* of New Guinea and the West Papuan Islands, but in appearance it is most similar to the widespread Dusky *Myzomela*, which ranges from the Moluccas east to New Guinea and northern Australia. Although the Drab *Myzomela*, found in the southern Moluccas, and the White-chinned *Myzomela*, living in the Louisiade Archipelago, off south-eastern New Guinea,

are treated as sister-species by many authorities, their widely separate distributional ranges suggest that their relative affinities to the Dusky Myzomela should be investigated. Indeed, W. Rothschild and E. J. O. Hartert regarded the two as conspecific with the Dusky Myzomela. Conversely, Gadow recognized the Moluccan forms of the Dusky Myzomela as constituting a separate species, "*M. simplex*", known as the "Moluccan Myzomela". Another species that was included with the "*eques-obscura* group" by Wolters is the Red Myzomela (*Myzomela cruentata*) from New Guinea, but its overall red or red-tinted male plumage and dullish female plumage make its inclusion in this group somewhat anomalous. Koopman aligned it with the sexually dimorphic "*jugularis-cardinalis* group", but it is probably best treated as a separate, unique lineage within *Myzomela*. Similarly, the Red-collared Myzomela from New Guinea is of indeterminate affinities and was treated as a separate lineage within *Myzomela* by Koopman, Wolters and others. The DNA-sequencing data of Driskell and Christidis aligns it more closely with the monomorphic "*eques-obscura* group" than with the dimorphic "*jugularis-cardinalis* group"; in the DNA study, the monomorphic group was represented by the Dusky Myzomela and the dimorphic group by the Cardinal Myzomela (*Myzomela cardinalis*), the Scarlet Myzomela (*Myzomela sanguinolenta*) and the Red-headed Myzomela (*Myzomela erythrocephala*).

The brightly plumaged "*jugularis-cardinalis* group" is the largest in terms of species and is the most widely distributed. In this group the sexes are distinctly dimorphic. The females are neutral olive-grey and have traces of red on the forehead and throat, whereas the males commonly have large patches of metallic red on the head, rump and breast. The taxonomic circumscription of the Black Myzomela (*Myzomela nigrata*) has proven to be contentious. Its current distribution is in New Guinea and the West Papuan Islands. Koopman included the Ebony Myzomela (*Myzomela pammelaena*) from the Bismarck Archipelago and the Sooty Myzomela (*Myzomela tristrami*) from the eastern Solomon Islands within the Black Myzomela complex. Most other authors, including Salomonsen and Wolters, followed I. C. J. Galbraith and E. H. Galbraith in treating the Sooty Myzomela as a separate species. These authors aligned it more closely with the Scarlet-naped Myzomela (*Myzomela lafargei*) complex. Similarly, although most now treat the Ebony Myzomela as a full species, there is far less consensus on whether it is more closely linked to the Black Myzomela or to the Scarlet-naped Myzomela complex. Little information has been gathered on the affinities of

either the New Ireland Myzomela (*Myzomela pulchella*) or, in New Guinea, the Scarlet-bibbed Myzomela (*Myzomela sclateri*). Similarly, the Orange-breasted Myzomela (*Myzomela jugularis*) of Fiji is another highly distinctive species that may also represent a unique lineage. The song of the Mountain Myzomela (*Myzomela adolphinae*) of New Guinea is very similar to that of the Scarlet-bibbed Myzomela, but in plumage patterns the former is most similar to the Red-headed Myzomela. It is likely, therefore, that the affinities of the Mountain Myzomela may lie with the Red-headed Myzomela complex, although Koopman placed the species next to the Black-bellied Myzomela (*Myzomela erythromelas*) of the Bismarck Archipelago.

There is debate on the taxonomic circumscription of the Red-headed Myzomela. The northern Australian and southern New Guinean populations are universally accepted as comprising the one species, but the taxonomic status of the two forms from the Lesser Sunda Islands, currently treated as full species, the Sumba Myzomela (*Myzomela dammermani*) and the Crimson-hooded Myzomela (*Myzomela kuehni*), is disputed. Koopman included both within the Red-headed Myzomela, whereas Salomonsen, Wolters, C. M. N. White and M. D. Bruce, and others retained the Crimson-hooded Myzomela as a separate species. The Sumba Myzomela is similar to the Red-headed Myzomela in its pattern of sexual dimorphism, but it differs in size and in levels of melanistic pigmentation, and it was treated as a separate species by Sibley and Monroe. The Crimson-hooded Myzomela is sexually monomorphic and differs considerably in plumage patterns from the other two; it is duller in general, and its red head extends to a bandless breast and white belly. Another species that might, according to Koopman, be linked with the Red-headed Myzomela complex is the Red-rumped Myzomela (*Myzomela vulnerata*) from Timor. In most systematic sequences it is placed between the Black-bellied Myzomela and the Red-collared Myzomela, but the latter, as discussed above, is more closely linked to the "*eques-obscura* group".

Still within the "*jugularis-cardinalis* group" of *Myzomela*, the Cardinal Myzomela complex comprises anything from one to eight species. The complex contains four broad species groups with separate distributional centres: one in the Moluccas and Lesser Sundas, the second in Australia and New Caledonia, a further one in Melanesia and Polynesia, and the fourth in Micronesia. Within Wallacea three distinct groups of subspecies are recognizable, and Bruce suggested that all three could be accepted as distinct species, a suggestion which was adopted by Sibley

The two species of Ramsayornis are small, dumpy and short-tailed honeyeaters with a relatively short, slightly decurved bill. Both species are monotypic.

The **Brown-backed Honeyeater** occurs in New Guinea and nearby islands, and in north-eastern and eastern Australia. The species is rather drab in plumage, being mostly brown above and white below, but has a narrow white subocular stripe, bordered below by a thin brown moustachial stripe. As with almost all other meliphagids, the Brown-backed Honeyeater shows sexual dimorphism: males are larger than females, although the sexes are identical in plumage.

[*Ramsayornis modestus*, Julatten, Queensland, Australia.

Photo: David Stowe]

Conopophila honeyeaters are small birds with a slightly decurved bill and short tail. Two of the three species, including the **Grey Honeyeater**, are endemic to Australia.

This species' plumage is nondescript, being brownish-grey above and white below. The only noteworthy plumage features are a thin, partial pale grey eyering, and white tips to the rectrices. In most sexually dimorphic species, one sex is larger than the other in all measurements. This, however, is not the case in the Grey Honeyeater, where males have longer tails and possibly longer wings, but females are probably heavier.

[*Conopophila whitei*, Australia.
Photo: Roland Seitre]

The two straightbills in the genus *Timeliopsis* are medium-sized birds with a short tail and a medium-length, dagger-shaped bill. Both are endemic to New Guinea, with the **Tawny Straightbill** occupying the lowlands and the **Olive Straightbill** (*T. fulvigula*) the higher altitudes. Both are unremarkable in appearance, their English names adequately describing their overall coloration. The Tawny Straightbill, however, strays from the meliphagid norm in terms of iris colour. In most honeyeaters, the iris is dark brown, black or red-brown. In the Tawny Straightbill, however, it is vibrant orange-red.

[*Timeliopsis griseigula fulviventris*, near Brown River, SE New Guinea. Photo: Brian J. Coates]

and Monroe and by Schodde and Mason. The species are defined as the Sulawesi *Myzomela* (*Myzomela chloroptera*) with four or perhaps even five subspecies, the Wakolo *Myzomela* (*Myzomela wakoloensis*), with two subspecies, and the Banda *Myzomela* (*Myzomela boiei*), also with two subspecies. The validity of the various subspecies needs to be tested, as many of the arguments on the according of species rank to the three groups revolve around how best to circumscribe the various forms such that they constitute coherent entities. Furthermore, F. E. Rheindt and R. O. Hutchinson have suggested that the Seram and Buru forms of the Wakolo *Myzomela* could represent two additional species. The Scarlet *Myzomela* of Australia and the New Caledonian *Myzomela* (*Myzomela caledonica*) are commonly treated as a single species, and were included by Salomonsen with the three Wallacean forms to make one widely distributed species. The Australian and New Caledonian group, however, represents a biogeographically coherent entity, separate from the Wallacean group, and it is unlikely that the two groups would form a monophyletic clade in relation to the Micronesian and Polynesian forms of the Cardinal *Myzomela* complex. An unresolved question is whether the Scarlet and New Caledonian *Myzomelas* are separate species. The Cardinal *Myzomela* complex is represented in Micronesia by seven subspecies that were grouped as the Micronesian *Myzomela* (*Myzomela rubratra*) by Pratt and colleagues. While the cohesiveness of this group is not questioned, debate still exists as to whether it is specifically separable from the Cardinal *Myzomela* group centred in Melanesia and Polynesia. Within the latter group, the population on the Fijian island of Rotuma is sometimes separated as a distinct species, the Rotuma *Myzomela* (*Myzomela chermesina*). The other subspecies, distributed throughout the Solomon Islands, Vanuatu, the Loyalty Islands and Samoa are all regarded as forming a monophyletic group known as the Cardinal *Myzomela*.

Currently, up to six species are recognized as representing the Scarlet-naped *Myzomela* complex, which is restricted to the Bismarck Archipelago and the Solomon Islands. As discussed above, the Ebony *Myzomela*, from Bismarck, is sometimes included within the Black *Myzomela*. The other five forms in the complex are the Scarlet-naped *Myzomela*, the Yellow-vented *Myzomela* (*Myzomela eichhorni*), the Black-headed *Myzomela* (*Myzomela melanocephala*), the Red-bellied *Myzomela* (*Myzomela malaitae*) and the Sooty *Myzomela*. Only the Yellow-vented *Myzomela* comprises marginally differentiated sub-

species. A DNA study undertaken by C. E. Smith and Filardi examined differentiation across four of these forms, and the levels of DNA divergence indicated that the Scarlet-naped, Black-headed, Yellow-vented and Red-bellied *Myzomelas* are all valid species. The first two were found to be each other's closest relatives. Interestingly, these four members of the Scarlet-naped *Myzomela* complex did not form a monophyletic assemblage with regard to the Cardinal *Myzomela*, the last-mentioned represented by its Rennell Island subspecies, *sanfordi*. E. Mayr and Diamond had suggested that the Red-bellied *Myzomela* could be more closely allied to the Cardinal *Myzomela* complex; furthermore, they indicated that the Scarlet-naped complex and the Cardinal *Myzomela* complex might in fact be very closely related and represent allopatrically centred radiations. In this respect, the DNA evidence is supportive of these suggestions.

According to the DNA data of Driskell and Christidis, the Green-backed Honeyeater from north-eastern Australia and New Guinea is part of a clade that includes the New Guinean genus *Ptiloprora* and the Tawny-crowned Honeyeater (*Gliciphila melanops*) of Australia. As discussed above, the placement of the Green-backed Honeyeater in *Timeliopsis* by Schodde and Mason is incorrect. Both genera feed primarily by gleaning foliage for insects, which is a rare specialization among honeyeaters. The possession by both groups of a moderately long, straight bill most likely reflects convergence resulting from similar feeding strategies. An association between the Green-backed Honeyeater and *Ptiloprora* had not been suggested before the DNA results, and further investigation is required.

Ptiloprora comprises up to six small to medium-sized honeyeater species with streaked plumage on the head and back, a thin curved bill and a rather long tail. The Olive-streaked Honeyeater (*Ptiloprora meekiana*) has predominantly yellowish plumage, and the Leaden Honeyeater (*Ptiloprora plumbea*) is, as its name suggests, grey, while the remaining four show varying degrees of rufous in the plumage. The Rufous-sided Honeyeater (*Ptiloprora erythroleura*), Black-backed Honeyeater (*Ptiloprora perstriata*), Rufous-backed Honeyeater (*Ptiloprora guisei*) and Mayr's Honeyeater (*Ptiloprora mayri*) form a group of very similar-looking species, and there are suggestions that the first two may hybridize where they meet in western New Guinea. Mayr's Honeyeater was treated as a subspecies of the Rufous-backed Honeyeater by Salomonsen and others, but Diamond suggested that it could also have affinities with the Black-backed Honeyeater and was best treated as a separate species. In their DNA study,

A typical honeyeater bill is strong and fairly long with some degree of decurvature.

As its English and scientific names suggest, the **Long-billed Honeyeater** is at the upper end in terms of bill length. Its bill is very long, heavy and quite strongly decurved. This New Guinea endemic is a medium-large species with drab, predominantly brown plumage. It is generally considered to be the only member of the genus, although, in the past, some authorities have added the Bougainville Honeyeater (*Stresemannia bougainvillei*) to *Melilestes*.

[*Melilestes megarhynchus megarhynchus*, Ubaigubi, EC New Guinea. Photo: William S. Peckover]

Driskell and Christidis examined only the Leaden and Rufous-backed Honeyeaters, and little could therefore be deduced on relationships within the genus.

As discussed previously, the Tawny-crowned Honeyeater has most often been included in the genus *Phylidonyris*. Boles and N. W. Longmore compared adult and juvenile plumage patterns, display-flights, maxillo-palatines and eggs of all the species traditionally included in *Phylidonyris*. They concluded that not only did the Tawny-crowned Honeyeater warrant placement in its own genus, but there was no evidence to suggest that it was closely related to *Phylidonyris*. Their conclusions are fully supported by the DNA data. The affinities of the Tawny-crowned Honeyeater are still poorly resolved. Although DNA analyses place it in a clade with the Green-backed Honeyeater and *Ptiloprora*, there was only moderate statistical support for this grouping.

Assemblage 5. The final assemblage comprises three well-supported clades. Included in this assemblage are the species-rich and wide-ranging genera *Philemon* and *Lichmera*, the primarily New Guinean *Xanthotis*, the mainly Australian *Melithreptus* and *Entomyzon*, the Australian *Cissomela*, *Grantiella*, *Plectorhyncha*, *Trichodere* and *Phylidonyris* (*sensu stricto*), and southern Polynesian *Foulehaio*.

As mentioned above, the Banded Honeyeater, in *Cissomela*, is not related to the Pied and Black Honeyeaters, with which it was formerly included in the genus *Certhionyx*. The DNA-sequence data of Driskell and Christidis suggest that it is part of a clade that includes also *Lichmera*, *Phylidonyris* and *Trichodere*. In skull and palatine configuration *Cissomela* apparently is rather different from the *Lichmera*–*Phylidonyris*–*Trichodere* group, but further detailed comparisons are needed. A close relationship among the three last-mentioned genera has been postulated on several occasions, this based on superficial morphological assessments. *Lichmera* comprises up to eleven species, with the greatest diversity centred in the Moluccas and the Lesser Sunda Islands. The genus is highly heterogeneous in plumage pattern and may, in fact, represent an agglomeration of several different genera, but data on this matter are currently lacking. From a comparison of plumage patterns and bill coloration, several species groups are recognizable. One group comprises dull-plumaged species with a black bill, namely the the Scaly-crowned Honeyeater (*Lichmera lombokia*), Olive Honeyeater (*Lichmera argentauris*), Indonesian Honeyeater (*Lichmera limbata*), Brown Honeyeater (*Lichmera indistincta*) and Dark-brown Honeyeater

(*Lichmera incana*). This widespread group has representatives in the Lesser Sundas and Moluccas, Australia and New Guinea, and New Caledonia and Vanuatu. The Indonesian Honeyeater is often treated as a subspecies of the Brown Honeyeater, and its occurrence through the western Lesser Sundas was interpreted by Schodde and Mason as being the result of secondary invasion. The level of sexual dimorphism in the Indonesian Honeyeater, however, is much more marked than that found in any of the forms of the Brown Honeyeater. The Scaly-breasted Honeyeater (*Lichmera squamata*) of the eastern Lesser Sundas and the Silver-eared Honeyeater (*Lichmera albaauricularis*) of New Guinea exhibit some similarities in breast pattern and may form a species group. The Buru (*Lichmera deningeri*) and Seram Honeyeaters (*Lichmera monticola*) form a third species group, the two being united by the presence of a pale-based bicoloured bill. Two brightly coloured species are the Yellow-eared Honeyeater (*Lichmera flavicans*) from Timor and the Black-necklaced Honeyeater (*Lichmera notabilis*) from nearby Wetar. The two have been suggested as forming a species group, but the patterns of breast-scaling on the Yellow-eared Honeyeater are more reminiscent of those occurring on the Scaly-breasted and Silver-eared Honeyeaters. The plumage patterns of the Black-necklaced Honeyeater are much more similar to patterns found in *Phylidonyris* and *Trichodere*.

There are no DNA data that could help to elucidate the systematic position of the Lesser Streaked (*Myza celebensis*) and Greater Streaked Honeyeaters (*Myza sarasinorum*), both from Sulawesi. E. Stresemann thought that these were related to *Lichmera*, whereas Salomonsen placed them more distantly, near the south-west Pacific *Gymnomyza*, without any obvious justification. The two species bear superficial plumage and morphological resemblances to both *Ptiloprora* and *Lichmera*, although these two genera are unrelated to them according to DNA data. On biogeographical grounds affinities with *Lichmera* are more likely, as this genus has its centre of diversity within Wallacea.

The genus *Phylidonyris* has been circumscribed as comprising species with a slender body and bill, but there has been much debate over whether it constitutes a natural group. The DNA-sequence data of Driskell and Christidis indicated that *Phylidonyris* as previously constituted was polyphyletic; the White-fronted Honeyeater and Tawny-crowned Honeyeater represent unrelated monotypic genera, respectively *Purnella* and *Gliciphila*. DNA-sequence data unite the Crescent Honeyeater (*Phylidonyris pyrrhopterus*), New Holland Honeyeater (*Phylidonyris novaehollandiae*) and White-cheeked Honeyeater (*Phylidonyris niger*) as a monophyletic clade, with the latter two as sister-species. This pattern of relationships is consistent with all other plumage and morphological assessments. Within the White-cheeked Honeyeater, two geographically widely separated subspecies are recognized, the nominate race in central-eastern Australia and *gouldi* in south-western Australia; the two are distinct in bill shape and plumage, and have occasionally been treated as two distinct species. This subject warrants further investigation. Two other species traditionally included in *Phylidonyris* are now placed in the genus *Glycifohia*. These are the Barred Honeyeater (*Glycifohia undulata*), from New Caledonia, and, just to the north-east, the Vanuatu Honeyeater (*Glycifohia notabilis*). As no DNA-sequence data are available on these two species, it is not possible to speculate on their genetic affinities. On the basis of similarities in ventral patterning, however, Schodde and Mason suggested links with the wide-ranging genus *Lichmera*, and on biogeographical grounds this is more likely than are links to Australian-restricted *Phylidonyris*. Boles and Longmore also questioned whether the Barred and Vanuatu Honeyeaters were closely linked to *Phylidonyris*.

The White-streaked Honeyeater (*Trichodere cockerelli*) of north-eastern Australia has often been associated with the genera *Lichmera* and *Phylidonyris*, and some authors, for example Salomonsen and Wolters, have even chosen to include it within the former. DNA-sequence data, however, support its placement in a monospecific genus and align it most closely with *Phylidonyris*.

A second well-supported clade identified by DNA-sequencing comprises the south Polynesian *Foulehaio* together with *Melithreptus* and *Entomyzon*, which are largely restricted to Aus-

The genus *Glycifohia* contains two medium-sized species, each with a long, slender and markedly decurved bill. One species is endemic to Vanuatu and the other to New Caledonia. The latter is the **Barred Honeyeater**. The species' English name is apposite, as its plumage is scalloped with black and white, creating a strongly barred effect. In common with many family members, the shape and structure of its bill broadly reflects the main component of its diet. In this case, the bill's slenderness and decurvature facilitate nectarivory, for example on Geissois and Grevillea.

[*Glycifohia undulata*, Mont Koghis, near Noumea, New Caledonia. Photo: Phil Gregory]

The four species of honeyeater grouped in the genus *Melipotés* are endemic to the mountains of New Guinea. They are medium-sized or large meliphagids with a short tail and a short, stocky bill, the culmen of which is only very slightly decurved. All *Melipotés* have a large facial wattle, which is bright yellow in the case of the **Spangled Honeyeater**, flushing red when the bird is agitated. This species is the largest of the four, being more than twice the weight of the other species. It is considered to be the basal member of the genus, with the remaining three species forming a superspecies.

tralia. An association between the last two genera has often been postulated, but there has never been any suggestion that they were related to *Foulehaio*, which has, in fact, often been included in or associated with *Meliphaga*. The Wattled Honeyeater (*Foulehaio carunculatus*) comprises three subspecies, two in Fiji and the other distributed across Fiji, Tonga and Samoa; whether any of these merits treatment as a separate species requires examination. The Kadavu Honeyeater (*Xanthotis provocator*), also from Fiji, was included in *Foulehaio* by both Salomonsen and Wolters. Given that the remaining species of *Xanthotis* occur in Australia and New Guinea, a reappraisal of the generic affinities of the Kadavu Honeyeater is warranted.

Whilst almost all meliphagids have been known for many decades, one species eluded ornithologists until as recently as November 2005. On an expedition to the Foja Mountains in north-west New Guinea, researchers discovered a new taxon in the genus *Melipotés*, formally describing it two years later as the **Wattled Smoky Honeyeater**. Remarkable as this may be, the age of meliphagid discovery in New Guinea may not be over. Intriguing observations of unidentified *Melipotés* in the Fakfak Mountains hint that further new taxa may exist, as yet undescribed by scientists.

[*Melipotés carolae*,
Foja Mts, New Guinea.

Three large aberrant-looking honeyeaters from the Pacific are often included in the genus *Gymnomyza*. These are the Giant Honeyeater (*Gymnomyza viridis*), from the mountains and lowlands of Fiji, the Mao (*Gymnomyza samoensis*), from the mountains of Samoa, and the Crow Honeyeater (*Gymnomyza aubryana*), from the mountains of New Caledonia. The first two were placed together in a genus *Amoromyza* by Wolters. The Crow Honeyeater, with its distinctive black plumage, certainly stands apart from the others in general appearance, but it is not clear whether the three comprise a natural assemblage, nor is there any better understanding of their affinities with other meliphagids. Wolters placed them next to the Wattled and Kadavu Honeyeaters, presumably as all are centred in the Pacific.

Sibley and Ahlquist, from information derived from DNA-DNA hybridization, identified a sister relationship between *Entomyzon* and *Melithreptus*, and G. M. Storr even combined the two as a single genus. The members of both genera possess a well-marked white or cream nape-band. *Melithreptus* honeyeaters possess a coloured crescent of bare skin above the eye, while *Entomyzon* has a large patch of coloured facial skin covering the whole area around the eye. Schodde and Mason focused on apparent similarities in skull and palate features, vocalizations and communal behaviour between *Entomyzon* and the miners in *Manorina*, and instead argued that *Entomyzon* formed a separate lineage in a complex that included both *Manorina* and *Melithreptus*. The DNA-sequence data of Driskell and Christidis clearly support a sister relationship between *Entomyzon* and *Melithreptus*, but not between these two and *Manorina*. In considering the levels of morphological and sequence divergence, *Entomyzon* and *Melithreptus* are most appropriately retained as separate genera.

Six or seven species make up the genus *Melithreptus*. Schodde and Mason recognized two species groups. The first includes the Black-chinned Honeyeater (*Melithreptus gularis*), Strong-billed Honeyeater (*Melithreptus validirostris*) and Brown-headed Honeyeater (*Melithreptus brevirostris*). These share several plumage features, such as a broad white nape-band, along with short, stout feet, and they feed largely by probing twigs, bark and branches. A. Keast separated the Brown-headed Honeyeater as a discrete lineage, as did Wolters. The northern Australian subspecies *laetior* of the Black-chinned Honeyeater has often been separated as a distinct species, the "Golden-backed Honeyeater". Ford noted several ecological and morphological differences that could justify such treatment, but was equivocal on the issue. The ap-

parent zones of intergradation suggested by Schodde and Mason are based on very patchy distributional material. Clearly, more work is required on this. The other group contains the White-throated (*Melithreptus albogularis*), White-naped (*Melithreptus lunatus*) and Black-headed Honeyeaters (*Melithreptus affinis*). The first two species have a white nape-band that is narrowed at the extremities behind the eye, while the Black-headed Honeyeater lacks the nape-band altogether. All three species have slender feet, and feed by gleaning from foliage and twigs. The White-naped Honeyeater, on mainland Australia, and the Black-headed Honeyeater, on Tasmania, appear to be allopecies, but the affinities of the White-throated Honeyeater are less apparent. The south-western subspecies of the White-naped Honeyeater, *chloropsis*, was treated as a full species, the "Western White-naped Honeyeater", by both Storr and R. E. Johnstone. It is readily distinguishable from the eastern race in size, in bill shape and in the colour of the bare skin around the eye, although the differences are less than those that distinguish the two subspecies of the Black-chinned Honeyeater.

The three subspecies of the Blue-faced Honeyeater (*Entomyzon cyanotis*) divide into two groups based on the colour of the facial skin and the wing patch. The race *albibennis*, in north-western Australia, has greenish facial skin and large white patches on both surfaces of the wing. The nominate race and *griseigularis*, from eastern Australia and southern New Guinea, have bluish facial skin and smaller, buffish patches largely restricted to the underside of the wing. The two morphological groups appear not to come into contact, and they were treated as separate species in the late nineteenth century. DNA data may shed further light on their taxonomic status.

According to the DNA data of Driskell and Christidis, the friarbirds in the genus *Philemon* form a group with *Xanthotis*, *Plectorhyncha* and *Grantiella*. The White-streaked Friarbird (*Melitograis gilolensis*) of the northern Moluccas was included in *Philemon*, along with the other friarbirds, by both Salomonsen and Wolters. Nevertheless, its distinctive brownish-black plumage with fine white shaft streaking and the bare skin around the eyes and on the nape set it apart from all other friarbirds and, as a consequence, many modern treatments retain it in a monotypic genus. The remaining friarbirds comprise a relatively homogeneous group of plain grey-brown, medium-sized to large honeyeaters with areas of blackish skin on the face and head.

Many of the species have a variably developed casque on the bill which can vary among subspecies, too. Mayr identified four species groups among the friarbirds. The most speciose assemblage he termed the "moluccensis group", and this coincides with the subgenus "*Philemon*". According to Schodde and Mason, this subgenus comprises eight species. The Dusky Friarbird (*Philemon fuscicapillus*) of the northern Moluccas, the Seram Friarbird (*Philemon subcorniculatus*) from Seram, and the Black-faced Friarbird (*Philemon moluccensis*) from Buru are generally regarded as allopecies; the first two have a slight protuberance at the base of the bill, the Black-faced Friarbird lacking this. Rheindt and Hutchinson treated the Tanimbar and Kai populations, formerly considered a subspecies of the Black-faced Friarbird, as a separate species, the Tanimbar Friarbird (*Philemon plumigenis*), which seems a logical step. They argued that the Tanimbar and Buru taxa are as morphologically distinct from each other as they are from the Seram Friarbird. Furthermore, in terms of biogeography, Buru is generally linked to Seram, while Tanimbar is more closely linked to Kai and the Banda Sea Islands.

The taxonomic circumscription of the Helmeted Friarbird (*Philemon buceroides*), which occurs in the Lesser Sunda Islands, New Guinea and northern Australia, is far from resolved. At issue is the question of whether the Lesser Sunda and central northern Australian races constitute one species, and the New Guinean, north-east Queensland and Torres Strait subspecies another. Both Salomonsen and Mayr recognized the "New Guinea Friarbird" as a species, "*P. novaeguineae*", although Mayr also included the New Britain Friarbird (*Philemon cockerelli*) within it; all recent treatments have retained the New Britain Friarbird as a separate species. Most, though not all, forms of the Helmeted and New Guinea Friarbirds have a well-developed casque, and the patterns of variation make it difficult to define species boundaries. Schodde and Mason argued that, if the "New Guinea Friarbird" is recognized as a species, the population of north-eastern Queensland, subspecies *yorki*, should likewise be elevated to species level, suggesting that it could even be more closely linked to the Silver-crowned Friarbird (*Philemon argenticeps*). This suggestion is contradicted by the available DNA data (see below). Parker demonstrated the existence of two forms of Helmeted Friarbird in the Northern Territory of Australia: *gordoni* on Melville Island and the coastal areas of the adjacent mainland, and the nominate race on the sandstone ridges of the Arnhem

Macgregor's Honeyeater clearly confused early taxonomists since it was described at the end of the nineteenth century as a bird-of-paradise (*Paradisaeidae*). DNA sequencing has subsequently confirmed the placement of the monotypic genus *Macgregoria* in *Meliphagidae*, while careful morphological scrutiny has revealed a close relationship with the genus *Melipotes*, which is similarly endemic to montane New Guinea. The two genera share features such as a prominent, brightly coloured facial wattle, a short bill, and dark grey or black plumage. Moreover, both genera lack the distinctive brush-tipped tongue common to almost all honeyeaters.

[*Macgregoria pulchra*, Mt Scratchley, SE New Guinea. Photo: William S. Peckover]

The most speciose meliphagid genus, *Myzomela*, also contains the smallest family members. The genus ranges widely, from Wallacea in the west, through New Guinea and Australasia to the south-west Pacific. Its 31 members include the **Red-collared *Myzomela***, the male of which is typical of *Myzomela* in having a large area of bright crimson in the plumage, a colour not exhibited by any other meliphagid genus. The female differs substantially, having scarlet only on the rump and uppertail-coverts. Such sexual dichromatism is more prevalent in *Myzomela* than any other meliphagid genus.

Land escarpment. He considered *gordoni* to represent a separate species, the "Melville Island Friarbird". Although the latter has not been accepted as a species by subsequent taxonomists, the Arnhem Land escarpment population has been separated as a subspecies under the name *ammitophilus* and is sometimes referred to as the "Sandstone Friarbird". Resolution of the taxonomy within the Helmeted Friarbird complex will require extensive sampling of populations by means of DNA-sequence analyses.

Confined to the Admiralty Islands, the White-naped Friarbird (*Philemon albitorques*) is distinctive among its congeners in that it has a whitish collar and underparts, which contrast dramatically with the brown head and upperparts. It has a small knob at the base of the bill, whereas the two other Bismarck endemics, the New Britain and New Ireland Friarbirds (*Philemon eichhorni*), lack such a knob. The Silver-crowned Friarbird is generally treated last in the taxonomic sequence, and Salomonsen did not include it in the "*moluccensis* group". This northern Australian endemic is sympatric with the Helmeted Friarbird, including the New Guinea populations; all other members of the "*moluccensis* group" are allopatric. Were it not for sympatry, Mayr would have included the Silver-crowned Friarbird within either the Helmeted Friarbird or the "New Guinea Friarbird" on the grounds of morphological resemblances. The DNA-sequence study of Driskell and Christidis examined species-level relationships of five of the friarbirds, including the Silver-crowned Friarbird, the north-east Queensland race *yorki* of the Helmeted Friarbird and the Noisy Friarbird (*Philemon corniculatus*). These three formed a clade, but the Silver-crowned and Noisy Friarbirds were identified as more closely related to each other compared with the Helmeted Friarbird. The DNA data therefore support Salomonsen in not including the Silver-crowned Friarbird within the "*moluccensis* group", and also indicate that similarities between it and the *yorki* form of the Helmeted Friarbird are convergent. Mayr and others have treated the Noisy Friarbird and the New Caledonian Friarbird (*Philemon diemenensis*) as constituting a species group in the subgenus "*Tropidorhynchus*". These two have a knobbed bill and distinct bare black skin on the head. Further analyses are needed in order to determine whether the Silver-crowned Friarbird should also be included in this group.

The third group recognized by Mayr, and corresponding to the subgenus "*Microphilemon*", comprises species with a fairly straight bill and a more fully feathered head. Three species are

generally recognized, these being the Timor Friarbird (*Philemon inornatus*), Brass's Friarbird (*Philemon brassi*), from New Guinea, and the widespread Little Friarbird (*Philemon citreogularis*), ranging from the Lesser Sundas east to New Guinea and north and east Australia. The Lesser Sunda form, however, was regarded by Sibley and Monroe as a separate species, the Grey Friarbird (*Philemon kisserensis*). Indeed, retention of the Grey Friarbird as a subspecies of the Little Friarbird is anomalous if one considers the biogeography: the islands of Kisar, Leti and Moa, where the Grey Friarbird occurs, are just north of Timor, and consequently the Grey Friarbird's affinities more plausibly lie with the Timor Friarbird than they do with the Australian-New Guinean Little Friarbird. Plumage and morphological differences are subtle, which complicates matters, but a prudent approach is to keep the Grey Friarbird as a separate species; DNA analysis could help to resolve this matter. Mayr, along with Schodde and Mason, has argued that Meyer's Friarbird (*Philemon meyeri*) represents the most divergent member of the genus, and it is placed in the subgenus "*Philemonopsis*". This New Guinean species was included in the DNA study of Driskell and Christidis. Instead of being identified as a basal lineage, it formed a clade with the Little Friarbird, the other clade comprising the Helmeted, Noisy and Silver-crowned Friarbirds. These two clades would be predicted on the basis of morphological similarity: the three species with a knobbed bill and with distinct, bare black skin on the head in one clade, and the two straight-billed, more fully feathered species in another. It is generally held that Meyer's Friarbird represents the "primitive" friarbird because of perceived links between it and the honeyeater genus *Pycnopygius*. Not only is such an argument incorrect in a phylogenetic framework, but the DNA data clearly negate any close association between *Pycnopygius* and the friarbirds. Infrageneric relationships within the friarbirds need to be reassessed.

The genus *Xanthotis* has generally been associated with *Meliphaga* and *Lichenostomus*. Indeed, Salomonsen combined all three as a single genus. As discussed previously, however, DNA studies have indicated that the three genera are unrelated. Whether the Kadavu Honeyeater is best retained in *Xanthotis*, placed in *Foulehaio* or segregated in its own genus, *Meliphactor*, is far from resolved. The protein-allozyme study of Christidis and Schodde identified a close sister-group relationship between Macleay's Honeyeater (*Xanthotis macleayanus*) and the Tawny-breasted

The eleven species of *Lichmera* honeyeater are distributed from Bali east to the south-west Pacific. They are medium-small meliphagids with a fairly long, slim, decurved bill, and all have a distinctive triangular ear-tuft, a feature that is otherwise very rare among the Meliphagidae. Otherwise, all but two *Lichmera* are nondescript in plumage, and the **Indonesian Honeyeater** is no exception. Its plumage is predominantly grey-olive, offset by a brighter yellow-olive panel on the folded wing. Some taxonomists treat this taxon as the Wallacean subspecies of Brown Honeyeater (*L. indistincta*).

[*Lichmera limbata*,
Bali, Indonesia.
Photo: Morten Strange]

Honeyeater. The Spotted Honeyeater (*Xanthotis polygrammus*), while still clearly part of the genus, was further diverged. Within the Tawny-breasted Honeyeater. Schodde and Mason recognized five principal groups, four of which intergrade where they abut in New Guinea. The five groups are: the nominate and *fusciventris*, two virescent subspecies from the West Papuan Islands and north-western New Guinea; plain dusky grey *meyeri*, *madaraszii* and *philemon*, in northern New Guinea and adjacent islands; rufescent *visi*, in far eastern New Guinea; white-faced and ventrally spotted *spilogaster*, in the Trobriand Islands, off south-east New Guinea; and bare-faced and fawn-breasted *saturator* and *filiger*, from southern New Guinea, the Aru Islands and north-eastern Australia. Whether some of these groups constitute separate species awaits further investigation.

Finally, the DNA-sequence data of Driskell and Christidis identify a well-supported sister relationship between the Striped Honeyeater (*Plectorhyncha lanceolata*) and the Painted Honeyeater. These species are morphologically disparate and, before the DNA findings, a close relationship between them had never been suspected. Schodde and Mason noted resemblances between the Striped Honeyeater and the friarbirds in tail form and in the spicate breast feathering. The Painted Honeyeater, currently in the monotypic genus *Grantiella*, was included within *Conopophila* by Salomonsen, who also, interestingly, placed the Striped Honeyeater next to this genus. Most other authors have generally aligned the Painted Honeyeater with *Phylidonyris* and *Trichodere*, a relationship refuted by the DNA evidence. Despite the lack of any obvious morphological resemblances between the Striped and Painted Honeyeaters, the nests of the two species are apparently similar in structure. Moreover, the Painted Honeyeater specializes in feeding on mistletoe (Loranthaceae), and it has been reported that the Striped Honeyeater, too, likes to feed on mistletoe.

Morphological Aspects

Honeyeaters are generalized ten-primaried passerines, but they have a specialized brush-tipped tongue and internal structural modifications to the bill adapted to a nectarivorous diet. Although they are difficult to characterize, the physical appearance of most honeyeaters readily distinguishes them. They are typically rather slim, with a slender head, a low sloping forehead and crown, a variably long and decurved bill, almost straight in some species, and moderately long legs and tail; they present a varying

horizontal to upright stance that is often somewhat watchful and almost pugnacious. Honeyeaters use a wide range of habitats and ecological niches, and, while many are adapted to feeding on nectar, others have a diet consisting largely or mainly of fruit, insects or lerp, honeydew or manna (see Food and Feeding). Consequently, they show a diversity of sizes and shapes, and vary particularly in the shape and length of the bill.

Meliphagids are typically medium-sized, most species having a total length lying within the range of about 15 cm to 25 cm, but the family's members range in size from being tiny to being quite large. The smallest species are in the genus *Myzomela*, the largest genus in terms of number of species, consisting of 31 tiny to medium-small honeyeaters distributed from Wallacea in the west eastwards to New Guinea and Australia and throughout the south-western Pacific. The smallest appears to be the Mountain *Myzomela* of montane New Guinea, only 9 cm in length and with a mean weight of 7.4 g; one of its alternative English names, "Elfin Honeyeater", is very apt. In Australia, the Scarlet *Myzomela* is about 10 cm in length and has a mean weight of 8 g, and the Black-bellied *Myzomela* of lowland New Britain is likewise only 9–10 cm long. The Black and Banded Honeyeaters, two monotypic genera of Australia, are also small, each being 12 cm in length and weighing 9.5 g. Other genera of mainly small to medium-small species include: the two *Acanthorhynchus* spinebills of south-west and east Australia, some 14–15 cm in length and weighing 10–11 g; the six *Melithreptus* species, one of which extends to southern New Guinea, ranging in length from 10.5 cm to 16.5 cm and with mean weights of 10–20 g; and the eleven *Lichmera* species, distributed from Bali and the Lesser Sunda east to the south-west Pacific.

At the opposite extreme, the largest species are the wattletbird genus *Anthochaera* of Australia, *Macgregoria* of alpine New Guinea, *Gymnomyza* of the south-western Pacific, and the widely distributed friarbirds in the genus *Philemon*. The Yellow Wattletbird of Tasmania is the longest, but not the heaviest, honeyeater, males having a total length of 44–50 cm and weighing 135–260 g, and females being slightly smaller, at 37–43 cm and 104–190 g. MacGregor's Honeyeater, until recently considered a bird-of-paradise (see Systematics), is probably the heaviest meliphagid; males are 40 cm long and weigh 242–357 g, with a mean of 266 g, while females are 35–40 cm and 190–230 g, with an average weight of 206 g. Other large species include the Red Wattletbird, with males 33–37 cm in length and 90–140 g in weight, and females 35 cm and 82–133 g, and the Crow Honey-

eater of New Caledonia, which has a total length of 35–41 cm; while weights of the latter are very poorly known, one male weighed 248 g. Of the friarbirds, the “*P. moluccensis* super-species” consists of eight large species, all 30 cm or more in length: the Dusky Friarbird, at 30 cm, the Seram Friarbird, at 35 cm, the Black-faced and Tanimbar Friarbirds, each 31–37 cm long, the New Britain Friarbird, at 33–35 cm, the New Ireland Friarbird, measuring 32 cm, the White-naped Friarbird, at 34–37 cm, and the widespread Helmeted Friarbird of tropical northern Australia, New Guinea and the Lesser Sundas, which is some 32–36 cm in length and weighs 90–177 g.

A number of other genera or species are fairly large, including the remaining two wattlebirds. The Little Wattlebird has a total length of 27–35 cm, and a mean weight of 75 g for males and of 60 g for females; Western Wattlebird males are 29–33 cm long and weigh 71 g, the corresponding details for females being 27–30 cm and 54 g. Most of the *Melidectes* honeyeaters of montane New Guinea also are large, Belford's Honeyeater, for example, being 26–29 cm in length and the males having a mean weight of 74.7 g and the females about 60 g. Similarly, the Blue-faced Honeyeater is large, with an overall length of 26–33 cm and mean weight in adult males of 112 g and in adult females of 98 g. The Australian miners in the genus *Manorina* are medium-large to large and, unlike most other honeyeaters, rather stockily built; they range in size from the Bell Miner, some 19 cm in length and 25–35 g in weight, to the Noisy Miner, about 26 cm long and weighing 70–80 g.

The genera *Lichenostomus* and *Meliphaga*, together comprising 35 species, are morphologically similar, medium-sized and classic honeyeaters. They range in length from 14.5 cm, as in the case of the Grey-headed and Yellow-tinted Honeyeaters, to 22 cm, as in the Varied and Yellow-throated Honeyeaters, with mean weights ranging from the 12.5 g of the Yellow-tinted to the 31–33.5 g of the Yellow-throated and Varied Honeyeaters, although the weights of many species are poorly known. Other genera of medium-sized species are *Phylidonyris*, *Myza*, *Pycnopygius* and *Timeliopsis*, and a number of monotypic genera, including *Purnella*, *Oreornis*, *Glyciphila* and *Trichodere*.

Sexual dimorphism in size is the norm throughout the Meliphagidae, with males larger than females in nearly all species, although, unfortunately, sufficient data are lacking for many of the species, especially from New Guinea, Wallacea and the Pacific islands. The summaries of measurements and weights published in the *Handbook of Australian, New Zealand and Antarctic Birds* reveal that, for all 70 of the Australian and New Zealand species, the males are larger than the females in at least one measure or weight; there are no species for which females were found to be significantly larger than males. A few members of the family exhibit quite marked sexual dimorphism in size, as illustrated by the medium-small Crescent Honeyeater. Males of the nominate race have a mean wing length 7.4–8.1 mm greater, a mean tail length 7.9–9.2 mm greater and a weight 1.9–3.6 g greater than the corresponding figures for the females. The San Cristobal Honeyeater also appears strongly dimorphic: average wing length, tail length and weight of adult males are 135.9 mm, 114.3 mm and 80.4 g, respectively, while the figures for adult females are 118 mm, 100.2 mm and 54.7 g.

Only in one species are the trends not so clear-cut. In the Grey Honeyeater, males have a significantly longer tail than females and they tend to have longer wings, although the difference is not significant, but females weigh more, although, again, not significantly. The sample sizes for this species, however, are not large, and these trends may not hold if more data were to become available. Dimorphism in size typically occurs with most or all measures within a species, but this is not always the case. For example, males of the Pied Honeyeater have significantly longer wings, at 86.5 mm, than those of females, which measure 83.1 mm, but tail lengths of the two do not differ significantly, despite similar sample sizes. When closely related bird species with similar diets and foraging methods are found to co-exist in the same habitat at the same altitude, they often differ in weight by a factor of about two. This difference in size allows the two species to co-exist in part because the smaller species can forage on finer twigs and foliage and so on, but also because the two

species differ in the size of food that they can catch and handle. On Bougainville, there is broad altitudinal overlap between the Scarlet-naped Myzomela, which ranges from sea-level up to 1800 m and more, and the larger Bougainville Honeyeater, which occurs from 700 m to at least 1950 m; the former, 12–13 cm in total length, weighs some 10–14 g, which was estimated to be about one-half to one-third as much as the weight of the Bougainville Honeyeater, 17–18 cm in length but of unknown weight.

There can be much variation within species, too. While such variation often delimits subspecies, intraspecific variation is sometimes clinal and follows general ecogeographical trends described by Bergmann's, Allen's or Gloger's Rules. For example, the nominate race of the Silver-crowned Friarbird exhibits clinal variation in both size and colour following Gloger's and Bergmann's Rules: birds from more humid areas appear darker than those from more arid areas, and individuals of northern populations are slightly smaller in size than those of more southern populations. Two formerly recognized subspecies of this species, incidentally, are now known to represent clinal variation within the nominate race. The Striped Honeyeater likewise shows clinal variation in size consistent with Bergmann's Rule, with northern populations smaller than those in the south. Island forms can also be larger than their conspecifics on the mainland, as typified by, for example the Tui of the Chatham Islands, individuals of which are considerably larger and heavier than those from the main islands of New Zealand. Similarly, off south-western Australia, Singing Honeyeaters from some islands off the edge of the species' mainland range, such as Rottnest Island and Garden Island, are larger, and also darker, than their mainland conspecifics.

As with most species, weights can vary, sometimes considerably, on a daily or seasonal basis or from year to year. For example, an individual Yellow Wattlebird of the nominate race weighed 170 g in September and 203 g when recaptured in the following August, whereas another individual weighed 200 g in May and 183 g when recaptured in July. In the Chatham Islands, a male Tui weighed 160 g when first captured, on 11th January, but when it was retrapped, on 3rd August, its weight had shot up to 238 g. On the New England Tableland of east Australia, both male and female Eastern Spinebills were heavier in winter than in autumn, with males about 2 g heavier than females throughout this period; weights of both sexes declined after periods when overnight temperatures dropped below –4°C and nectar supplies had prob-

As currently constituted, the genus *Phylidonyris* comprises three species endemic to Australia. At other times, up to four additional species have been ascribed to it. *Phylidonyris* are medium-sized honeyeaters with a long, robust, decurved bill. The three are strikingly patterned in black and white, and have contrasting yellow panels in the folded wings and tail, formed by bright fringes to the remiges and rectrices respectively. The **New Holland Honeyeater** differs from its congeners in its bearded appearance, which is formed by the elongated white malar feathers, throat bristles and neck plume.

[*Phylidonyris novaehollandiae canescens*, Melaleuca, Port Davey, South West Wilderness, Tasmania.

Photo: Dave Watts]

ably declined. At this site, New Holland Honeyeaters were significantly heavier in late autumn and winter than in early autumn and summer but, conversely, Yellow-faced Honeyeaters showed no significant changes in weight over the course of the year.

Morphologically, a key characteristic of the family is the specialized, long and protrusible tongue, and associated tongue musculature. The tip of the tongue is modified into a brush, which allows extraction of nectar from flowers. This brush tip of the Meliphagidae is very different from the bifid tongue tip of the nectarivorous sunbirds and hummingbirds (Trochilidae). The basal and central parts of the honeyeater tongue are curled upwards and inwards on both sides, forming a single open channel, or trough, along the upper surface of the tongue, and the tip is deeply cleft into four primary segments, although there may be two, four or eight segments, each of which is covered by many fine bristles, or filaments, that arise from the lateral edges or the tip, or both, of the segments. The bristles themselves are moderately flexible, often slightly concave and grooved, the grooves running back and converging to join the trough. Within this basic structure there is, however, much variation from species to species. For example, in the Tui, the brush at the tip of the tongue is composed of four subequal, acicular and apparently movable segments, each of which gives off finer bristles over much of the length of the segment. In comparison, the brush of the New Zealand Bellbird is deeper than that of the Tui, and the finer bristles are at the ends of the segments. The tongue of both of these species is caniculate for its whole length, deeply so in the Tui, and less so in the bellbird. In a detailed analysis of the tongues of nectar-feeding birds, D. C. Paton and B. G. Collins found that, for 36 species of honeyeater, the length of the brush tip of the tongue was correlated with both body weight and the total length of the tongue, and ranged in length from 5 mm, in the Eastern Spinebill, to 17 mm, in the Long-billed Honeyeater. They also found much variation in the number of bristles, the averages ranging from about 120 in the Red Wattlebird to 40 in the Brown Honeyeater, this number again correlated with body weight. The arrangement of bristles again varied: some genera, such as *Acanthorhynchus*, had 40–60 bristles at the tip of the tongue and up to 70 shorter bristles down each side of the tongue, whereas others, such as *Melithreptus*, *Phylidonyris* and *Lichenostomus*, had few or no bristles along the sides.

That the tongue is protrusible is also important in that it enables it to reach some otherwise inaccessible nectar sources. For

example, the tongue of the large and rather heavy-billed Red Wattlebird extends far enough beyond the tip of the bill to be able to probe and collect nectar of many tubular flowers: the mean length of the bill, to the feathering, is 23.5 mm, but the mean length of bill and extended tongue is 44 mm. During the process of feeding on nectar, the tongue is rapidly extruded and withdrawn, with mean rates of 6.3–12.4 “licks” per second recorded for a range of meliphagids, and, for the Singing and Brown Honeyeaters, mean rates of 8–10 licks per second. When the tongue is protruded, nectar and other liquids are drawn into the brush by capillary attraction and, as the tongue is withdrawn and the bill closed, the brush is pressed against the palate and liquid forced into the channel of the tongue and then into the throat. Bird-pollinated plants in Australia and New Guinea show much diversity in floral structure, size, arrangement and pattern of nectar presentation, and the brush-tipped tongue provides an advantage in that it takes nectar spread thinly over a large surface area, as found in flowers of some foodplants, such as at least some eucalypts (*Eucalyptus*) and *Banksia*. Further, honeydew, another important energy source (see Food and Feeding), can likewise be spread thinly over the surfaces of leaves and bark and in tiny fissures on these surfaces, and the brush-tipped tongue can cover this surface area and simultaneously penetrate the small cracks that hold honeydew.

While all honeyeaters have a brush-tipped tongue, a significant adaptation to a nectarivorous diet, the family has evolved a diverse array of feeding methods and strategies and use of a wide range of resources. Although most, if not all, meliphagid species probably consume at least some nectar, many have diets primarily of fruit, insects or manna, lerp and honeydew, or combinations of these (see Food and Feeding). In such species the brush tip can be reduced. For example, in the genus *Melipotes* of New Guinea, all four members of which are of medium size and have a short, almost stubby bill, and at least three of the four a largely frugivorous diet of berries, the brush tip is obsolete; the structure of the tongue of the newly described species from the Foja Mountains, the Wattled Smoky Honeyeater, has not been investigated. Interestingly, the brush tip is nearly vestigial also in the insectivorous Australian chats, currently placed in the family Epthianuridae but central to the honeyeater assemblage (see Systematics).

In general terms, the bills of honeyeaters are typically strong, moderately long to long, from roughly 11 mm to 44 mm, and

The six *Melithreptus* honeyeaters are small or moderately small species with a short, slightly decurved bill. All occur in Australia, with one species reaching southern New Guinea. All congeners have a crescent-shaped, bright-coloured patch of bare skin above the eye, and five have a pale band on the nape. The latter feature is enshrined in the English name of the **White-naped Honeyeater**. This attractive species has a black cap, predominantly olive-green upperparts, and white underparts with a grey wash. Its two subspecies differ in the colour of their bare eye-patch.

[*Melithreptus lunatus lunatus*,

Australia.
Photo: Peter Fuller]

Friarbirds of the genus *Philemon* are medium-sized or large honeyeaters that are remarkably similar in appearance, having grey-brown plumage, a deep-based, decurved bill and an extensive area of black facial skin. Most species have a protruding casque at the base of the bill and many have both a nuchal crest and a gorget of elongated breast feathers. The **Silver-crowned Friarbird**, endemic to northern Australia, possesses all three characteristics. With the relative homogeneity of the genus, infrageneric relationships and species limits are keenly debated, and at least two taxa currently treated as subspecies have claims to be elevated to the level of full species.

[*Philemon argenticeps kemp*, Mt Isa, Queensland, Australia. Photo: Drew Fulton]

varyingly decurved, with slit-like operculate nostrils, all adaptations, along with the brush-tipped tongue, to their diet and foraging behaviour. There is, however, much variation in length, depth, width and curvature of the bill. For example, the bill of *Acanthorhynchus* is long, slender and fairly gently decurved, that of *Melilestes* is long but heavy and fairly strongly decurved, while that of the friarbirds, the wattlebills and many *Melidectes* is moderately long and decurved but heavy, and the bill of the genera *Plectorhyncha*, *Timeliopsis* and *Melipotes* is fairly short and straight or almost straight and almost conical. To some extent, bill morphology, as well as other aspects of morphology, reflects the feeding habits of a species, although correlations between bill dimensions and diet are less than clear-cut, possibly in large part because of the range of foods eaten by each species. Honeyeaters range from being predominantly nectarivorous to being predominantly insectivorous, with a few species largely frugivorous, but few are wholly specialized on one or other of these diets, and many also consume other resources, such as manna, honeydew and lerp, to some degree. Thus, bills are utilized also to probe or glean for insects and other non-nectar foods, and from substrates other than flowers. Moreover, the flowers themselves that are exploited by honeyeaters vary greatly in morphology, from being, for example, open and cup-shaped to being long and tubular, while others grow in large and complex inflorescences.

Given this diversity, it is no surprise that there are no absolute relationships between bill morphology and diet. Nevertheless, general trends are evident within the family, and bill shape can be loosely consistent with diet: smaller species with a long bill that *tend* to feed more on nectar than on insects; small to medium-sized species with a short bill that *tend* to feed more on insects and other non-nectar foods; and medium-sized to larger species with a short bill that often include much fruit in the diet. In some apparently specialized nectar-feeders, the bill is proportionately long, slender and varyingly curved. In Australia, the *Acanthorhynchus* spinebills are small, with a long, slender and noticeably decurved bill. The *Myzomela* species are among the smallest honeyeaters and have bills varying from moderately decurved to strongly decurved, and all are predominantly nectarivorous. The Black, Banded and Pied Honeyeaters, all now placed in monospecific genera, are similarly small to medium-small, with a fairly long and decurved bill, and a diet predominantly of nectar.

Perhaps the longest bill, proportionately, is that of the medium-sized and aptly named Long-billed Honeyeater of New Guinea and the West Papuan and Aru Islands. This species' bill is long but also strong and heavy, and appears to be used for probing crevices, curled leaves and fruit, and gleaning from trunks and branches, foliage and rotten timber, as well as for probing flowers for nectar. The largely New Guinean *Melidectes* also have a proportionately long bill, most notably in the "*Melionyx* subgroup" of the Long-bearded, Short-bearded and Sooty Honeyeaters (see Systematics) and the Bismarck Honeyeater. The large friarbirds and wattlebills, too, possess a long bill, although the proportional length of this is not so great as in some other meliphagids. Conversely, a number of species have a noticeably short and rather straight bill. The Green-backed Honeyeater has a moderately long but straight and pointed bill and is primarily an insectivore, although it does supplement its diet with small fruits and it forages among eucalypt flowers, taking either nectar or insects.

The enigmatic and nondescript Grey Honeyeater of inland Australia has a short and only gently decurved bill, and its diet, while not well known, consists predominantly of insects, as well as some nectar and fruit. In New Guinea, the two aptly named straightbills in the genus *Timeliopsis* are medium-small or medium-sized honeyeaters, each with a moderately long, rather straight and dagger-like bill having only a slight decurve of the upper mandible; both appear to be largely insectivorous. The genus *Melithreptus*, which is almost confined to Australia, a single species extending to southern New Guinea, possesses a short, almost straight bill and a strongly insect-based diet. All four species of *Melipotes* have what is, for birds of their size, a quite short, almost stubby bill and lack a brush-like tip of the tongue, which appear to be adaptations to a largely frugivorous diet of berries. It will be interesting to find out the details of the tongue and diet of the newly described *Melipotes* of the Foja Mountains.

The long and decurved bill of most honeyeaters appears to provide advantages for the birds' mode of foraging at flowers. Honeyeaters typically perch while probing flowers for nectar, although some, particularly some smaller species, sally-hover briefly. It is usually not possible for the birds to perch directly in front of an inflorescence, in contrast to species that hover, which can often position themselves in front of an inflorescence and insert the bill. Perched honeyeaters therefore have to reach towards the flower, sometimes hanging to do so, to place the tip of the bill at the flower's opening, before it can be inserted to reach the nectar. A decurved bill is better suited to this than a straight or upturned bill, whereas a straight bill can be inserted as effectively as a decurved bill when directly in front of a flower, as during hovering. Honeyeaters also reach out to flowers, partly insert the bill, and then drag the flower towards them before inserting the bill fully. Generally, in nectarivorous species, longer bills are more effective than short bills at reaching nectar at the base of long tubular flowers.

As with other measurements and weights, in which males are larger than females, the bill of males tends also to be longer than that of the females and, where sufficient data exist, the differences are statistically significant. Such differences, however, appear to be proportional to overall body size. There is also geographical variation in bill morphology within species. Of course, bill dimensions can vary intraspecifically to the extent that they characterize subspecies. Taking as an example the Red Wattletail, the subspecies *clelandi* of Kangaroo Island is similar in size to the nominate race of coastal and subcoastal eastern mainland Australia, but the bill of *clelandi*, at least in males, is significantly longer than that of the nominate race, although the tarsus is shorter. Geographical variation can also be clinal, as described in Allen's Rule, whereby the bill and feet of a species are larger at lower latitudes than they are at higher latitudes. Not all variation in bill dimensions, however, follows these rules. Lewin's Honeyeater exhibits no clinal variation in bill length, or in any other measure, over its latitudinal range, which extends across 24.5° from north-eastern to south-eastern Australia. Further, individuals of the Eastern Spinebill from Kangaroo Island have significantly longer

bills in both sexes, and significantly shorter wings and lower body weight in males, than do those from adjacent mainland populations, contrary to what one would expect according to Allen's and Bergmann's Rules. There is a single instance within the honeyeaters in which the length of an individual's bill appears to vary seasonally. In mid-eastern Australia, the total head length of individual Eastern Spinebills was found to vary by 2–3 mm over the course of a year, being greatest in winter and shortest in summer, and it was suggested that these differences were due to changes in bill length as a result of differential rates of wear in different seasons.

All honeyeaters are primarily arboreal, and their legs are typically of moderate length but robust, and the feet and claws are strong, with scutellate, bilamini-plantar tarsi. The Australian chats, herein in the family Epthianuridae, are really meliphagids adapted for a terrestrial habit (see Systematics). In Australia, three of the *Manorina* miners, the Noisy, Yellow-throated and Black-eared Miners, commonly forage on the ground, as does the Tawny-crowned Honeyeater. Several meliphagid species in montane New Guinea appear to forage much on the ground, although all are poorly known and the proportion of time spent on the ground compared with that on other foraging sites is not known. In the Snow Mountains of Papua, there are many reports of the Orange-cheeked Honeyeater foraging on the ground in subalpine and alpine meadows, while the Short-bearded Honeyeater is thought to forage mainly in shrubs and on the ground. Whether this behaviour has manifested itself in modifications to the legs, feet or claws awaits study. Some other species also spend much time clambering on vertical trunks and branches when foraging. The behaviour of the Long-billed Honeyeater is distinctive, involving much time spent in ascending tree trunks in the manner of an Australasian treecreeper (Climacteridae). Again, it is not known whether the leg and foot structures of this species differ considerably from those of other honeyeaters.

Nearly all members of the family have some coloured bare skin on the head, particularly around the eyes or ears, around the base of the bill or on the chin, although such bare skin can be highly inconspicuous. In many cases, the area of bare skin is small, merely swollen or extended gape stripes or lines, as in many *Meliphaga* and *Lichenostomus* species, or narrow to broad orbital rings or eye-patches, as those of, for instance, *Lichenostomus* and *Lichmera*. The Pied Honeyeater has a small pale blue crescent of bare skin below the eye. All six members of

the genus *Melithreptus* have a conspicuous, semi-circular bare eye wattle on and above the upper eye. This wattle is light blue to medium blue in south-eastern populations of the Black-chinned Honeyeater and pale green to straw-yellow in northern populations, light blue to pale green in the Strong-billed Honeyeater, cream to very pale greenish-white or bluish-white in the Black-headed and White-throated Honeyeaters, and orange-red in eastern populations of the White-naped Honeyeater but pale greenish-white or white in the latter's western populations; in the Brown-headed Honeyeater, it is developed into a complete, broad, creamy orbital wattle. In contrast, many genera display large and colourful patches of bare facial skin. These are perhaps most developed in MacGregor's Honeyeater, which sports a large, hemicircular yellow fleshy wattle around the eye that covers much of the side of the head. The Blue-faced Honeyeater, as could be expected from its name, has an extensive area of iridescent blue skin around the eye and over much of the side of the head; in juveniles and immatures, however, the facial skin is yellow, the adult colour gradually developing over the first twelve or more months. All four members of the closely related genus *Melipotes* exhibit a large bare patch of yellow, orange or red skin surrounding the eye, the lower edges of which are variously developed into wattles, which can change colour when the bird is stimulated. For example, the facial skin of the Common Smoky Honeyeater is normally bright yellow, but when the bird is stimulated, as when fighting, or even when hanging upside-down while foraging, the facial skin becomes brilliant red; this coloration fades rapidly when the stimulus is removed, diminishing first from around eye. Probably all four species are able to change the wattle colour in this way.

All of the *Melidectes* species have some bare facial skin. That of the Long-bearded, Short-bearded and Sooty Honeyeaters, the "*Melionyx* subgroup", is a small but conspicuous area of pale skin behind and below the eye, some having a second, smaller and red postocular patch. In the remaining *Melidectes* species, the area of bare skin around the eye is much larger, and variously pale blue, green or yellow, or combinations of these. For example, the Yellow-browed Honeyeater has a large area of pale greenish-yellow skin around and behind the eye, a large pale yellow gape wattle and a small pinkish-red throat wattle, and the Ornate Honeyeater has a large patch of pale yellow skin around and behind the eye, combined with a small pinkish gape wattle and an orange-red throat wattle or bare malar area. In Australia, the Regent Honeyeater, in the genus *Anthochaera*, also has a large patch of normally dirty yellow, warty bare skin covering the lores and broadly around the eyes. Two of its congeners, the Red and Yellow Wattlebirds, have pendulous wattles, red and yellow respectively, hanging from the side of the head. At its most extreme, though least colourful, the area of bare black or blackish skin of many species of friarbird extends over almost the entire head.

Many species of friarbird have, in addition, a knob, or casque, at the base of the bill. This is developed to a varying degree, from large and prominent in the Noisy and Helmeted Friarbirds to little more than a subtle raised swelling in others, such as the Dusky Friarbird. Some others, such as the Little, New Britain and New Ireland Friarbirds, have no casque. Young friarbirds, both juveniles and young immatures, can also lack the knob of the adults.

For the most part, the eyes, bill, legs and feet of the honeyeaters are fairly drab. In most cases the bill is blackish-brown to dark grey or black, and the irides are dark brown, red-brown or black. The colours of the legs and feet vary, but are generally dull, being pale to dark grey, blue-grey, pinkish-brown or yellow-brown, grey-brown or black. There are, however, many exceptions to these norms. A number of species have a brightly coloured bill. On Taveuni and Vanua Levu, in Fiji, the nominate race of the Giant Honeyeater has a bright yellow bill. In Australia, all of the miners have a bright yellow bill combined with a small patch of bare yellow or red skin behind the eye, and the Painted Honeyeater has a bright coral-red bill. In New Guinea, the Yellow-browed Honeyeater's bill is very pale greyish or greyish-yellow, and that of the Ornate Honeyeater is pale blue-grey. A number of meliphagids have a bicoloured bill. That of the Crow Honeyeater is largely black to grey-black, with a yellowish to orange base of the lower mandible and gape, and the Bridled

The genus *Xanthotis* comprises four species, which further divide into a two sister taxa, a more divergent species and a species whose generic status is less clear. The last of these is the *Kadavu Honeyeater*, which many authors have placed in *Foulehaio* alongside the *Wattled Honeyeater* (*F. carunculatus*), some with *Ptiloprora*, and yet others in its own monotypic genus, *Meliphacator*. Wherever its generic home, the *Kadavu Honeyeater* is a subtly attractive creature, its grey plumage suffused with pale streaks and offset by a broad yellow surround to the eye.

[*Xanthotis provocator*, Fiji.]

Photo: Roland Seitre]

The **Striped Honeyeater** is the only member of its genus and is endemic to mainland Australia.

Plectorhyncha is one of four meliphagid genera to have heavily streaked plumage, the others being *Anthochaera*, *Phylidonyris* and *Ptiloprora*. DNA-sequencing has revealed the closest relative of this medium-large, long-tailed honeyeater to be the Painted Honeyeater (*Grantiella picta*), another monotypic genus endemic to Australia. The Striped Honeyeater is a good example of Bergmann's Rule, which states that populations of a species closer to the Equator are smaller than those at higher latitudes.

[*Plectorhyncha lanceolata*, Round Hill, New South Wales, Australia.

Photo: Graeme Chapman]

Honeyeater has a yellow base on its otherwise black bill. The Spiny-cheeked Honeyeater has a bright pink bill with a black tip.

There are few examples of seasonal changes in bare parts, though they are seen within the genus *Lichenostomus* in Australia. In the Fuscous Honeyeater, the bare parts change between the breeding season and the non-breeding season, although the plumage does not. The breeding adults have the bill, nares and gape all black, but in non-breeding adults the bill and tomia are black distally and orange-yellow or yellow on the basal half, the nares are orange-yellow or yellow, and the gape is yellow to pale yellow; the orbital ring, too, changes colour, from black when breeding to yellow when not breeding. During the transitional stages, the intensity of yellow of the orbital ring, bill and gape varies, and it appears to change from non-breeding to breeding in winter and from breeding to non-breeding in mid- to late summer. Similarly, breeding White-plumed Honeyeaters have the bill, cere and gape entirely black, but non-breeding adults have an orange-yellow or orange-brown base on both mandibles or just the lower mandible, and the gape is yellow. In Victoria, most White-plumed Honeyeaters caught in the period from late summer to early winter have non-breeding bare parts, whereas most of those captured in spring have breeding bare parts, with transition from non-breeding to breeding apparently in winter to early spring and transition to non-breeding in summer. As a further example, adult Yellow-plumed Honeyeaters have a black bill, gape and orbital ring when breeding, whereas non-breeding adults have a pale yellow to yellow-orange base on the otherwise black bill and a yellow or orange-yellow gape and orbital ring. Slight differences in bare-part coloration in at least some individuals have been reported for the Yellow-tufted and Purple-gaped Honeyeaters; in the case of the latter, the purple gape and fleshy continuation of the gape may sometimes become more intensely purple in the breeding season. It is possible that more detailed studies, particularly of non-Australian species, will reveal further examples of seasonal changes in bare parts, both among *Lichenostomus* species and in other genera.

In most honeyeaters, the iris is dark brown to red-brown or blackish. Some species, however, have the irides bright and contrasting. Those of the two spinebills are bright red, and those of the Tawny Straightbill and Long-billed Honeyeater are bright orange-red. Several species of *Ptiloprora*, but not the Olive-streaked and Leaden Honeyeaters, have green irides, whereas those of the Blue-faced Honeyeater are cream-coloured and those of the New Holland Honeyeater are white. Green-backed Honeyeaters have silvery-white to blue-cream eyes, and the Spiny-cheeked Honeyeater and a number of *Lichenostomus* and *Meliphaga* species, including, for example, the Mangrove, Bridled and some Lewin's Honeyeaters, have blue or blue-grey irides. The large and bright orange to orange-red iris of the Long-billed Honeyeater combines with a plain and "open" face to give a rather strongly staring appearance.

A few meliphagids have brightly coloured legs. In Fiji, whereas the legs of the Viti Levu subspecies *brunneirostris* of the Giant Honeyeater are olive-brown, those of the nominate race on Taveuni and Vanua Levu are bright yellow, as also are the legs of the Orange-cheeked Honeyeater of central montane New Guinea and the Bell Miner of south-eastern Australia. The remaining three Australian miners also have fairly strongly brownish-yellow legs, as does the Yellow Honeyeater. Unlike the diversity of colouring and patterning exhibited by the bare skin on the head and neck and, to a lesser extent, by the bill and irides, however, the legs and feet of the Meliphagidae in general are fairly dull. The function of these characters has not been studied, but many or all are no doubt involved in communication.

Plumages of honeyeaters are not wildly colourful, and the ground colours are typically sombre, mostly grey, green or olive-green to olive-brown and black, or combinations of these. Nevertheless, many of the species combine these rather subdued colours to produce subtly elaborate and attractive plumages, particularly in concert with the patches of bare skin, described above, and also with varyingly bright yellowish or yellowish-olive markings on the head, neck, wing or tail. The exception to this general picture is the genus *Myzomela*, many members of which, uniquely among the Meliphagidae, have brilliant glossy red, crimson or

scarlet in the plumage. Wing markings in particular are found widely throughout the family, often as distinct olive-toned to yellow outer edges or fringes, or a more diffuse wash in these areas, on the primaries or secondaries, or both, although such margins are usually absent or only fine on the outermost or outer two primaries, even in well-marked species. These markings often contrast strongly with the rest of the plumage of the upperparts and can combine to form large and conspicuous panels on the folded wings, and they are a prominent feature of many genera, including *Phylidonyris*, *Grantiella*, *Conopophila* with the exception of the Grey Honeyeater, *Purnella*, *Trichodere* and *Manorina*, and also of the larger species in *Melidectes*. For example, an alternative name for the New Holland Honeyeater is the "Yellow-winged Honeyeater", and in this species the broad golden-yellow outer edges of the remiges combine to form a bright panel on the folded wing, contrasting boldly with the otherwise black-and-white plumage; this species' congeners, the White-cheeked and Crescent Honeyeaters, display similarly strong and contrasting yellow panels in their wings. In the case of the Regent Honeyeater, the upper surface of the folded wing is black, with pale yellow scaling on the wing-coverts and three bold yellow panels, one on the greater primary coverts, one on the secondaries and one on the outer primaries. Unusually, in the largely black MacGregor's Honeyeater, the edges of the primaries, and the resulting wingpanel, are chestnut, but are bold and conspicuous against the black of the rest of the wing, both when the bird is perched and when it is in flight. Many other species have the edging and fringing well marked, but the colours of these margins and the rest of the feathering do not differ nearly so greatly, and the plumage lacks the obviously contrasting panels. Such a pattern is widespread, for example in the genera *Lichenostomus* and *Meliphaga*, many species of which have the dorsal plumage varyingly olive-green to olive-brown and the margins of the remiges contrasting only slightly or not at all, so that the folded wing and the dorsum appear generally olive. The edges of the remiges of the Blue-faced Honeyeater are the same in colour as the dorsum and most of the upperwing-coverts, so that the entire upperparts of the bird, including the folded wing, appear almost uniformly olive-green. In the Long-billed Honeyeater, the upperparts are largely dark brown to dark olive-brown, but with fine, faint buff-olive outer edges of the remiges, most obviously on the secondaries, which contrast only slightly with the rest and do not form a panel. Typically, those species with bright panels on the wings also have

Most species of honeyeater are noisy and active. Many are also at least seasonally gregarious, moving around their environment in small family groups. Miners (*Manorina*) are particularly sociable and flock all year round. The **Yellow-throated Miner** is usually seen in small gatherings of 5–10 birds, but neighbouring groups may join forces to create flocks of up to 50 or even 100 individuals, particularly outside the breeding period. Miners also engage in “corroborees”, where members of a tightly packed group flutter their wings and call agitatedly. Such displays may promote bonding and deter predators.

similarly strong edgings on the rectrices, although they are often not so neatly delimited as are the margins of the remiges and are, in any case, normally far less conspicuous. Again, the New Holland Honeyeater is something of an exception in that its tail is edged with bright yellow that matches the yellow of the upperwing.

Little plumage ornamentation, as opposed to simple coloration, is evident in the Meliphagidae, and what is to be found is not elaborate. Possibly the most distinctive ornamentation is seen in the adult Tui, which is largely glossy black to black-brown with a strong dark blue, green-violet or even golden iridescence and with a unique and conspicuous pair of white ball-like tufts on each side of the throat, which often appear as a single larger tuft; the Tui also has a white, lacy hindneck-collar that extends to the sides of the neck and the upper mantle. A few species have elongated feathers on the chin, throat or breast. For example, both the Long-bearded and the Short-bearded Honeyeaters have a well-developed “beard” consisting of elongated white feathers along the sides of the throat. The New Holland Honeyeater is strongly pied and also has a bearded appearance, with a broad white malar plume formed by wispy and moderately long feathers, a prominent white neck-plume that arises below and behind the ear-coverts and fans on to the sides of the neck, and elongated white hair-like bristles over the black lower throat.

Many of the friarbirds in the genus *Philemon* have long, lanceolate feathers on the throat and upper breast that form a distinctive, somewhat layered and often streaked gorget, in some cases combined with nuchal tufts of slightly elongated and erect feathers, these often standing out against the bare skin. The Helmeted Friarbird, for instance, has a short tuft of upcurled feathering on the upper hindneck, and the Silver-crowned Friarbird has a similar short and upcurled tuft on the hindneck and sides of neck, these tufts in both cases having a distinctly combed appearance. The much smaller White-streaked Honeyeater also has a gorget of lanceolate feathers on the chin, throat and upper breast. The Spiny-cheeked Honeyeater has a bold white cheekstripe that continues as a stripe down the side of neck; it is formed by feathers with thick shafts but reduced barbs, giving a spiny appearance. Perhaps the most common forms of ornamentation in the family are simple neck plumes and ear-tufts. Neck plumes usually consist of slightly elongated and differently coloured plumes

running across the upper sides of the neck, behind the ear-coverts; in several species they appear bicoloured, although the second colour is often not part of the elongated plume but merely a coloured band of plumage next to it. Such neck plumes are characteristic of *Lichenostomus*, and are prominent in the Yellow-plumed, Grey-fronted, Fuscous, Yellow-tinted and White-plumed Honeyeaters. They are perhaps best developed in the Yellow-plumed Honeyeater, on which a long, bright yellow plume extends from the side of the throat backwards around the rear edge of the ear-coverts and ends in a pointed tuft near the nape; at the rear of the ear-coverts, which are greyish-olive, is a diffuse black band bordering the plume.

Ear-tufts are formed by elongated feathers of the ear-coverts, usually the rear coverts, that protrude slightly to strongly beyond the surrounding plumage. As with neck plumes, they are characteristic of the genus *Lichenostomus*, and they are perhaps best developed in the Yellow-tufted Honeyeater, the elongated bright yellow rear ear-coverts of which form a distinct pointed tuft contrasting boldly with the species’ black facial mask. Ear-tufts are a prominent feature also of the Purple-gaped, Grey-headed and Black-throated Honeyeaters. The genus *Meliphaga* is similarly characterized by the possession of white to pale yellow ear-tufts. In contrast to those of *Lichenostomus*, however, the tufts are rounded, not pointed, and typically not raised, appearing as simple patches of colour, although it would appear that all of these species can erect these tufts to some extent. Ear-tufts are present on a few other meliphagids in other genera, notably in all eleven *Lichmera* species, as well as the Spotted Honeyeater and to some extent its three congeners in *Xanthotis*, and the White-streaked Honeyeater in the monotypic *Trichodere*. At least some of these species are able to raise the ear-tufts and make them more prominent, as demonstrated by, for example, the Eungella Honeyeater.

None of the honeyeaters is truly crested, although the subspecies *cassidix* of the Yellow-tufted Honeyeater, sometimes known as the “Helmeted Honeyeater”, has elongated and erect yellow feathers on the forehead forming a distinctive frontal crest, usually more than 4 mm long. All species can probably raise the feathers of the forehead and crown to some extent, giving an impression of a steeper forehead and slightly raised crown, but they do not appear crested. Such behaviour is usually only brief, for instance when alarmed or threatened or in agonistic situations.

Friarbirds (*Philemon*) are among the most sociable members of the Meliphagidae and frequently occur in small groups or larger loose flocks. The **Noisy**

Friarbird is typical in this respect, often foraging in congregations of up to 30 birds, sometimes more in fruiting or flowering trees.

Groups of friarbirds and other honeyeaters also investigate non-food resources such as pools of water, and often drink communally. Groups of Noisy Friarbirds can live up to the species' English name, being highly vocal, and at high volume, when gathering in large numbers.

Beyond this plumage ornamentation and the elaborate bare parts, meliphagids are fairly subdued in appearance, but they can nevertheless combine the features of the plumage in attractive fashion. One example is provided by the largely black-and-white *Phylidonyris* species with their yellow wingpanels and tail sides, and another is seen in the beauty of the chestnut, black and grey of the two spinebills. A few species are essentially monochromatic, or largely so, in black, brown, olive or, in the case of *Myzomela* alone, red. All three species of *Gymnomyza* of the Pacific islands are monochromatic, ranging from wholly drab olive to sooty black or olive-black or glossy black. MacGregor's Honeyeater is uniformly black, apart from its striking chestnut wingpanels and bare parts, and the Long-bearded, Short-bearded and Sooty Honeyeaters in *Melidectes* are largely sooty black or blackish-brown. A group of *Myzomela* honeyeaters of New Guinea and its associated islands, the Bismarck Archipelago and the Solomon Islands presents an entirely glossy black or duller sooty-black appearance, in some cases with paler axillaries and underwings. These are the Ebony, Ashy, Sooty and Black Myzomelas.

Members of a few genera, such as *Anthochaera*, *Phylidonyris* and *Ptiloprora*, are heavily streaked, and the Striped Honeyeater, in the monotypic *Plectorhyncha*, is diagnostically and coarsely streaked black and white on the top and sides of the head and neck, and otherwise mostly brownish-grey above, with bold dark streaking on the "saddle", and white with diffuse, fine dark streaking below. Many members of the family, especially some *Xanthotis* and *Melidectes*, are scaly below, whereas others are much more subtly scaled paler, as seen in some of the "*Melionyx* subgroup" of *Melidectes*. All six *Melithreptus*, which are small to medium-small, have a black or brown head and neck, and in all except the Black-headed Honeyeater this is combined with a white nape-collar and bare semi-circular wattles over the eye. Interestingly, the much larger Blue-faced Honeyeater in the monotypic genus *Entomyzon*, which has been shown to be close to *Melithreptus* (see Systematics), combines a dark head and neck with a white nape-collar and a large, bright blue bare facial patch. The Yellow-throated Honeyeater has a large patch of yellow on the chin and throat. One genus that stands apart from all the others in the family is *Myzomela*, most of which have glossy or iridescent red plumage, typically combined with black, brown or

olive, although the Red *Myzomela* is entirely bright red. Although often tiny, the myzomelas are among the most spectacular and beautiful of the Meliphagidae. Some are entirely black, such as the Black *Myzomela*, while others are drab brown or olive, such as the Dusky and Drab *Myzomelas*, but most have varying amounts of red, scarlet or crimson in the plumage. Although variation is extensive, such red is often found as a hood, or down the centre of the upperside of the body, often including the centre of the mantle and back and extending to the rump and uppertail-coverts, or sometimes restricted to the rump and uppertail-coverts, or on the chin and throat. For example, adult male Cardinal *Myzomelas* appear mostly black, with a deep red or scarlet hood and central upperbody, the latter strikingly conspicuous in flight, whereas the adult male Red-collared *Myzomela* is glossy jet-black with a complete and broad, brilliant scarlet collar covering all of the hindneck, the side of the neck, and the throat and upper breast, continuous with the scarlet of the mantle, back, rump and uppertail-coverts.

Whereas the sexes differ significantly in size, there is usually no difference between them in plumage or bare parts. Unlike most other honeyeaters, however, the myzomelas do show marked sexual dimorphism in plumage. Of the 31 species in the genus *Myzomela* as recognized in the present treatment, as many as 25, about 80%, exhibit some sexual dimorphism, although in ten of these the differences are considered slight. In the rest, the sexes differ strikingly in plumage, with the males often brilliantly coloured and the females duller and less strongly marked. The adult males of the Cardinal and Red-collared *Myzomelas*, as described above, are essentially red and black. The adult female of the former, however, is largely dull olive-brown above, with a smaller and duller red hood, and usually with scattered small patches of red on the central upperbody, while the female Red-collared *Myzomela* is very different from the male, being grey-brown above with a reddish wash on the ear-coverts, hindneck, side of the neck and mantle and back, and red on the rump and uppertail-coverts, and pale brown to buff below, with a red crescent-shaped patch on the breast. Marked sexual dimorphism is evident in a few other species. The Black and Pied Honeyeaters, in the respective monotypic genera *Sugomel* and *Certhionyx*, exhibit significant variation between males and females, the adult males of both being strongly pied and the females much duller,

predominantly brown and white. Likewise, the sexes of the Western Spinebill differ markedly from each other, with females much duller than males and lacking the latter's distinctive markings. In a number of other meliphagids, the females are like duller or more washed-out versions of the male or lack some brighter signal markings. For example, female Eastern Spinebills are much like males, from which they are distinguished only by having a duller, dark grey cap that contrasts with the black mask, and the female Rufous-throated Honeyeater differs from the male only in its paler and less uniform throat patch. The adult female Crescent Honeyeater is like a duller, washed-out version of the male, with paler and browner upperparts, duller yellow panels in the wing and tail, a narrow and buff supercilium, rather than a bold and white one, and a duller olive-brown, not black, crescent on the side of the breast; in addition, it lacks the male's prominent white markings on the outer tail feathers. Females of the Painted Honeyeater, the Regent Honeyeater and the New Zealand Bellbird are similar to but duller than the respective males. In a few cases, such as in the nominate race of the Brown Honeyeater, the sexes differ only subtly, and in some, such as the Red Wattlebird, the differences are very slight and distinguishable only in the hand.

Many sexually dimorphic species of *Myzomela* appear to show a distinctly biased sex ratio, with males frequently seen much more often than females and, if such a plumage exists, much more often than female-like immatures. While many anecdotal reports of such a bias exist in the literature, there are also some hard data to support it. In a ringing study of the Scarlet *Myzomela* in south-eastern Queensland, in eastern Australia, the sex ratio of 482 individuals caught in mist-nets was found to be skewed in favour of males by a factor of 1.5:1, neither sex appearing to be more susceptible to trapping. Similarly, an examination of 162 museum specimens revealed the ratio of males to females to be as high as 9.9:1, although the magnitude of that ratio is no doubt at least partly a result of a collecting bias, since males are much more conspicuous than females both in appearance and in behaviour. Comparable biases in the sex ratios in collections are found for most *Myzomela* honeyeaters. For the Orange-breasted *Myzomela*, for example, Mayr reported a ratio of males to females of 4.7:1 in the large series which he had, and similar biases in the other *Myzomela* species are reported.

The moult cycles and strategies of the Meliphagidae are fairly simple. So far as is known, adults of all except a couple of species undergo a single complete post-breeding, or pre-basic, moult

annually, usually after the end of breeding. The primaries are moulted outwards, or ascendantly, typically starting at the innermost primary, and the rectrices are moulted from the central feathers outwards and usually symmetrically. The secondaries are replaced in an inward sequence, typically starting at the outermost, although the tertials are often replaced in irregular sequence. The timing and sequences of moult are reasonably well known for many species occurring in Australia and New Zealand, detailed analyses having been undertaken for the *Handbook of Australian, New Zealand and Antarctic Birds*. For other parts of the family's range, however, these details are very poorly known, with published data typically limited to comments on moult for small numbers of specimens that may have been collected. These few data certainly reveal no obvious patterns in the timing of moult on a regional scale, and much work needs to be done on the timing of moult in relation to breeding and seasonal climate, which itself requires detailed observations in order to ascertain the temporal limits of the breeding season of the species in question. All of this awaits further study.

Only two meliphagid species are known to undergo two moults annually, performing both a complete post-breeding moult and a partial pre-breeding, or pre-alternate, moult. As a point of interest, a partial pre-breeding moult is undertaken also by two of the Australian chats in the family Ephianuridae, which is now considered to be part of the Meliphagidae (see Systematics). In each annual cycle, adult Banded Honeyeaters perform a partial pre-breeding moult, involving the feathers of the body only, and a complete post-breeding moult, these producing alternating breeding and non-breeding plumages, the latter differing from the breeding plumage in the varyingly brown mantle, back and scapulars, which are wholly black in breeding plumage, although some other parts of the plumage also are replaced. With this tropical species, the timing of the post-breeding moult appears to be broadly seasonal, occurring mainly in the late dry season during July–October, but it seems not to be at all synchronized within the population; for example, some individuals start to shed the primaries in June and others not until September. Signs of breeding plumage are evident in December–January, and complete breeding plumage is acquired by February. The only other species thought to perform a partial pre-breeding moult annually, though in this case with no seasonal change in appearance, is the Black-chinned Honeyeater. Its subspecies *laetior*, sometimes treated as a separate species under the name of “Golden-backed Honeyeater”, seems to moult the body plum-

Honeyeaters tend to be active to the point of being boisterous. Aggressive behaviour is very common, particularly when there is a mate or food resource to defend. Such interactions may escalate into full-blown fights, during which opponents grapple using the feet and/or the bill. Feet are used to trap the opponent's legs or to strike at the body. When attacking with the bill, the target is the opponent's bill. These **White-plumed Honeyeaters** may be squabbling over access to a small pool of water. Such disputes are a normal part of life for a species that is generally gregarious, and may even be colonial.

[*Lichenostomus penicillatus penicillatus*, Leopold, Victoria, Australia.

Bathing is as essential a part of the meliphagid daily routine as it is for all birds. Aside from its role in feather and body care, purposes that require light moistening and complete soaking respectively, bathing may also assist body cooling in hot climates. A good bathing spot should have an adequate and reliable supply of water, be sufficiently secluded so as to not attract the attention of predators, and have a good access point such as a low-lying branch. These **Fuscous Honeyeaters** have found such a location, and the adult (left) is standing in the water, using its wings and tail to flick water over its body. It is accompanied by a juvenile (right), which can be aged by its swollen yellow gape and less distinct yellow neck plume.

Australia.

Photo: Raoul Slater]

age in winter–spring, and there is a possibility that some individuals of the nominate race also may do so. Whether such cryptic moults exist for other species beyond Australia is not yet known. In temperate Australia and New Zealand, moult usually occurs in the austral spring and summer. In tropical northern Australia, it appears that, at least in some species, the primaries are replaced during the dry season. One would expect the timing of moult in lowland New Guinea and the tropical Pacific to reflect that in tropical Australia. The timing in montane New Guinea is not properly known. For MacGregor's Honeyeater, unspecified moult was recorded in July–November for eleven of 35 specimens and in February for one, during the breeding season of this high-altitude species.

The moults of a number of species from temperate Australia have been studied in detail. For example, in southern Australia, New Holland Honeyeaters replace their primaries in spring–summer, from early October to late April, the average duration of this moult of the primaries being just over 100 days. In one study, the timing of the primary moult differed slightly between sexes, females starting on average about two weeks later than males, and the timing differed also between two study sites. Individuals would have 1–8 primaries growing simultaneously in both wings. New Holland Honeyeaters begin the moult of the secondaries and tail towards the end of the primary moult, and finish it slightly after the replacement of the primaries is complete. With Noisy Miners, the duration of the moult of the primaries was about 128 days for individuals, and up to 174 days for the entire local population. Two medium-small honeyeaters from arid inland Australia were found to moult over some 100–140 days.

Juvenile plumage develops during the nestling period and, so far as is known, all young meliphagids leave the nest in full or almost full juvenile plumage. The extent of the subsequent post-juvenile, or first pre-basic, moult varies. Most species undergo a partial post-juvenile moult, often into an essentially adult-like first immature, or first basic, plumage, and do not acquire full adult plumage until the first complete moult, when the individual is one year old. For some species, however, the post-juvenile moult can be either partial or complete, usually resulting in adult plumage if complete, the extent of this moult being related to the hatching date of the young. Among New Holland Honeyeaters, individuals that hatched in the spring underwent a partial post-juvenile moult during the summer–autumn period, when 2–6 months old, whereas those that hatched in autumn had a complete post-juvenile moult in the following spring, when they were 4–7 months old; no juveniles started moult between April and mid-September. Partial post-juvenile moults involve the replacement of all or most of the body plumage, but usually all juvenile remiges and rectrices and a varying number of wing-coverts are retained. For example, the post-juvenile moult of the Bell Miner involves the replacing of all or most body feathers, from none to a few rectrices and tertials, all or some marginal and median wing-coverts, none to a few greater secondary coverts, and none to a few inner secondaries; the young usually retain the alula, most outer secondaries, some rectrices and the primaries, although, rarely, even the primaries can be moulted, possibly by individuals that hatch early in the season. These retained juvenile feathers are kept through the first year of life, and can often be distinguished from adult feathering as they are softer and wear more rapidly than the equivalent tracts of adults. This can be particularly noticeable in species that spend a lot of time thrashing through the understorey vegetation while foraging and chasing conspecifics and other birds; the tip of the juvenile tail, in particular, can become a rather ragged mess.

Some relevant details of the juvenile plumage are generally visible only when the individual is captured. Compared with the adult, the longest feather of the juvenile's alula can be broader and is often more rounded at the tip, and the tips of the outer primaries are more rounded, but the rectrices are narrower and more pointed at the tip than those of the adult. In addition, the rectrices, and sometimes other feather tracts, can exhibit growth-bars, narrow bands of contrasting diffraction that run roughly perpendicular to the shaft and which vary with rates of growth and other factors, or fault-bars, narrow translucent bands caused by faulty formation of barbules and occurring only occasionally.

Both growth-bars and fault-bars are usually most obvious on the rectrices, and can be indicative of juvenile plumage.

Interspecific hybrids are apparently rare in Meliphagidae, but they have been widely reported in the genus *Melidectes*, between Belford's Honeyeater and the Yellow-browed Honeyeater. The former occurs generally at higher altitudes than those preferred by the Yellow-browed Honeyeater, but the two species hybridize freely where they come into contact; hybrid "swarms" contain individuals very like Belford's Honeyeater, others close to Yellow-browed, and a complete range of intermediates. At higher altitudes, above about 2400 m, hybrid populations gradually merge with typical individuals of Belford's Honeyeater. Hybrids have a paler bill than that of "pure" Belford's Honeyeaters and display a varying range of other Yellow-browed Honeyeater characters. While some interbreeding probably occurs naturally in undisturbed habitats in a narrow altitudinal band where the two species overlap, it has been suggested that large-scale hybridization is a result of extensive habitat disturbance, caused initially by native agriculture and, in more recent times, possibly by other human activities. Such habitat disturbance brings the two species into contact over broader areas and permits extensive and accelerated hybridization to take place. In north-eastern Australia, limited hybridization between the Varied and Mangrove Honeyeaters apparently occurs in a narrow zone between Cardwell and Townsville, in east Queensland, where the two overlap in range.

Apparent artificially induced hybridization has been reported between two mallee-dwelling miners, where human modifications of the mallee habitat of the endangered Black-eared Miner has resulted in extensive interbreeding with the far commoner Yellow-throated Miner. Another, recent example of hybridization is found on San Cristobal, in the south-eastern Solomon Islands. The Cardinal Myzomela is widespread in the south-western Pacific Ocean, including some of the south-easternmost Solomons, whereas the Sooty Myzomela is confined to San Cristobal. The latter species occupies the whole of the island and nearly all habitats, whereas the Cardinal Myzomela, thought to be a recent invader from small islands of the south-east Solomons, is restricted to the northern coast. The Cardinal Myzomela is predominantly scarlet and the Sooty Myzomela is black, but early specimens of the Sooty Myzomela, from 1908, have patches of red in the plumage, suggesting hybridization with Cardinal Myzomelas. The frequency of such hybrids in collections de-

Meliphagids use a variety of waterbodies for the purpose of bathing. Natural sources such as springs, streams and rock pools are commonly utilized, and honeyeaters are not hesitant about abluting in artificial constructions. Species that tolerate human presence may make use of garden birdbaths, as is the case with this **Little Wattlebird**. Honeyeaters usually employ one of two bathing methods: they may stand in the water and use their wings to flick water over themselves; or they may hover over the water and plunge-bathe—the bird drops into the water, submerging partly or fully, before flying to a perch in order to preen.

[*Anthochaera chrysoptera chrysoptera*, Pomona, Queensland, Australia.
Photo: Raoul Slater]

creases from that time, suggesting that the rate of interbreeding may have been declining over time. The decrease in levels of hybridization may be due to the fact that contemporary populations of Cardinal Myzomelas are sufficiently established that individuals easily find conspecific mates, whereas early colonists experienced greater difficulty in doing so.

While not a characteristic of the honeyeaters themselves, one of the more interesting aspects of the family is the widespread visual and vocal mimicry of members of the friarbird genus *Philemon* by orioles of the genus *Oriolus*. This was first observed by A. R. Wallace on the islands of Seram and Buru. Species of friarbird within the "*P. moluccensis* superspecies", which are among the largest of all meliphagids, are variously mimicked by orioles of the "*O. boursiensis* superspecies" on islands of Wallacea, in the West Papuan Islands, and in New Guinea and northern Australia. The co-existing friarbirds and orioles are as follows: the Seram Friarbird and the Grey-collared Oriole (*Oriolus forsteri*) on Seram; the Dusky Friarbird and the Dusky-brown Oriole (*Oriolus phaeochromas*) on Halmahera; the Black-faced Friarbird of the nominate race and the nominate race of the Black-eared Oriole (*Oriolus boursiensis*) on Buru; the subspecies *plumigenis* of the Black-faced Friarbird and the race *decipiens* of the Black-eared Oriole on Tanimbar; the nominate race of the Helmeted Friarbird and the subspecies *finschi* of the Olive-brown Oriole (*Oriolus melanotis*) on Wetar; the nominate race of the Helmeted Friarbird and the nominate race of the Olive-brown Oriole on Timor; the Helmeted Friarbird subspecies *jobiensis* and *novaeaguinae* and the Brown Oriole in New Guinea; and the Helmeted Friarbird races *gordoni*, *ammitophilus* and *yorki* and the Green (*Oriolus flavocinctus*) and Olive-backed Orioles (*Oriolus sagittatus*) in Australia. In most of these pairs or groups, the species are similar in plumage, postures, movements and flight, and in at least some cases also in vocalizations, and confusion in the field, even by experts, is common. Within the first four of these pairs, the friarbird and the oriole are very similar to each other; the representatives of pairs on Wetar, on Timor and in New Guinea are quite similar in female plumages, but the males are considered, respectively, somewhat similar, dissimilar and quite similar; and the friarbirds and orioles of Australia are not alike. Moreover, in New Guinea, the Streak-headed Honeyeater is quite

similar to the Brown Oriole and the Helmeted Friarbird. For example, the Helmeted Friarbird in New Guinea is mimicked vocally and visually by the Brown Oriole, and to a lesser extent by the Streak-headed Honeyeater, and the three species forage and vocalize together; it is possible that interspecific duetting occurs. Helmeted Friarbirds and Brown Orioles have been reported also as nesting in the same tree. A number of reasons have been put forward for this mimicry. It seems, however, that the oriole mimics largely escape attack by the larger and pugnacious species that are their models, and which would otherwise drive them off from foraging sites. Earlier, Wallace had suggested that the mimicry, and the close association of the two species, may have helped the orioles to avoid predation.

Habitat

The Meliphagidae are predominantly Australasian, or Australo-Papuan, and the greatest number of genera and species are found in Australia and New Guinea, the largest landmasses within the range of the family and the centre of its origin, evolution and diversification. Meliphagidae is the largest family of birds in Australia, with 69 species, approached in diversity only by the cockatoos and parrots (Psittaciformes) and, among the passerines, the thornbills and allies. It is also the largest family, with 73 species, in New Guinea and its associated islands, excluding the Bismarck and Louisiade Archipelagos and the Solomon Islands; only the parrots (Psittacidae) and the pigeons and doves (Columbidae) come close in numbers of species in New Guinea. Australia and New Guinea share only 15 species. In total, 127 of the 175 species of honeyeater, some 73%, are found in Australia and New Guinea, although not all are restricted to these regions, some species occurring also in Wallacea or the south-western Pacific.

From Australia and New Guinea, the family has spread west throughout Wallacea, to the north and north-east through the Bismarck Archipelago to Micronesia, as far as the Northern Mariana Islands, and to the east through the island groups of the south-western Pacific Ocean to Samoa, Tonga and New Zealand. The origin of species on the various outlying islands, however, varies considerably. In Vanuatu, for example, the three species of

meliphagid, the Dark-brown Honeyeater, Vanuatu Honeyeater and Cardinal Myzomela, are thought to have originated in Australia and to have arrived via New Caledonia, rather than having spread east from New Guinea through the Melanesian islands. Only a single species, the Indonesian Honeyeater, has crossed Wallace's Line, and then only just, with a tiny footprint in the Oriental Region on the island of Bali. Similarly, only a single species, the Micronesian Myzomela, occurs in the far north of the family's distribution, in Micronesia. Three species, the Cardinal Myzomela, the Wattled Honeyeater and the Mao, extend to the easternmost limit of the family in Samoa, although the Wattled Honeyeater is the only meliphagid found in Tonga.

Myzomela is by far the largest and most geographically widespread genus in the family. With 31 species, it extends from Sulawesi in the west, eastwards throughout New Guinea, northern and eastern Australia, and the Micronesian and Melanesian islands to as far as Fiji and Samoa. The genus includes a number of "supertramp" species, the Scarlet-bibbed Myzomela being a good example: a species of high dispersal ability, reproductive potential and ecological amplitude but low competitive ability, confined to small species-poor islands where population turnover is high and competitors few, and to recently defaunated volcanoes which it can recolonize ahead of competitors. Two other geographically widespread genera are *Lichmera* and *Philemon*, with 11 and 15 species respectively. Both are found in Australia and New Guinea and have radiated in Wallacea, *Lichmera* extending to Bali, the westernmost extent of the family, and both have representatives in the south-western Pacific. The closely related *Meliphaga*, with 15 species, and *Lichenostomus*, with 20, are two of the most speciose genera and occur in Australia and New Guinea, with a single representative of *Meliphaga*, the Streak-breasted Honeyeater, confined to Wallacea. *Meliphaga* is, however, predominantly Papuan, with nine species restricted to New Guinea, four to Australia and one species shared between the two, whereas *Lichenostomus* is found predominantly in Australia, to which 17 of its members are restricted, two others being confined to New Guinea and one present in both regions. Other, smaller genera with representatives in both Australia and New Guinea are *Ramsayornis*, *Conopophila*, *Glychichaera*, *Melithrepus*, *Entomyzon* and *Xanthotis*.

The radiation of the honeyeaters has resulted also in a number of small or monotypic and endemic genera. Thus, Sulawesi has the genus *Myza*, with two species, and monotypic *Melitograis* is

confined to the northern Moluccas. New Zealand has two endemic species of honeyeater, in the monotypic genera *Prosthemadera* and *Anthornis*, and elsewhere in the south-western Pacific six genera are confined to various islands or island groups. These six are *Guadalcanaria*, *Meliarchus*, *Stresemannia*, *Glycifolia*, *Foulehaio* and *Gymnomyza*.

Finally, New Guinea holds eight endemic genera, three of them monotypic, and Australia has 13 endemic genera, of which nine are monotypic. One of the eight New Guinean genera, *Melidectes*, contains ten species, one of which reaches the Bismarck Archipelago.

As could be expected with such a large and widespread family, representatives are found in all, or nearly all, habitats within its distributional range, and it would in many ways be easier to list those habitats where honeyeaters do not occur. The habitats used by the Meliphagidae, however, vary greatly over the range of the family, and they largely reflect availability of niches. The ecological niches found in Australia are very different from those found in New Guinea or in the huge numbers of islands of Wallacea or the south-western Pacific. Meliphagids occupy virtually all wooded habitats in Australia and New Guinea. In Australia, data from the *Atlas of Australian Birds*, from 1998 to 2003, indicate that at least one species of honeyeater has been recorded from each 1-degree block in Australia. The greatest diversity is in eastern and south-eastern Australia, from Cape York, in north Queensland, south to Victoria and west to south-eastern South Australia, with high diversity also in the Kimberley and Top End of northern Australia and in south-western Australia. In east and south-east Australia, most 1-degree blocks have more than 19 honeyeater species and more than 30 species have been recorded in many of them. While the relatively small number of species, fewer than ten per block, in much of central Australia in part reflects the scarcity of observers there, it also reflects the known distribution of these honeyeater species. Within the broad habitat types recognized in Australia, the honeyeaters are present in all except five. These five are: pure grasslands, such as the Mitchell grass (*Astrelba*) habitat of the Barkly Tableland and the arid-land *Triodia* spinifex hummock grasslands; semi-succulent chenopod shrublands; alpine herbland and meadowland; buttongrass (*Gymnoschoenus*) sedgeland, found in west Tasmania; bare stony gibber plains; and unvegetated marine and aquatic habitats, such as beaches and intertidal zones. Even so, honeyeaters can be found at the ecotone between these and other habitats, such as where acacia (*Acacia*) or eucalypt wood-

As well as bathing in terrestrial water sources, meliphagids readily take showers. This **Brown Honeyeater** is rain-bathing, deliberately exposing its feathers to falling raindrops while perched. Given that the coverage afforded by intermittent rain is less than that of a static water body, the honeyeater may have to contort its body into unusual positions in order to moisten all areas. Many species have also been recorded foliage-bathing, particularly after rain. Here the bird flies into wet foliage and uses its body to shake the vegetation so that water droplets fall onto its feathers.

lands about chenopod shrublands or spinifex grassland, and they occur also where scattered trees or shrubs are distributed through such habitats. Further, the Australian chats, here separated in the family Ephianuridae but now considered meliphagids (see Systematics), do occupy the grassland and chenopod-shrubland niche: for example, the Gibberbird inhabits undulating gibber plains sparsely vegetated with tussock grasses or low chenopod shrubs, the White-fronted and Orange Chats are often found in low chenopod shrublands, and several species of chat are occasionally found in grasslands with patches of chenopods.

Australia presents little altitudinal relief. The highest points on the mainland are along the Great Divide, which stretches from the far north-east southwards along the eastern seaboard to Victoria, where it swings west into mid-central Victoria. The Southern Highlands of the south-east are the highest points on the Australian mainland, and the only extensive alpine habitats, with widespread snow cover in the winter months, this usually melting in spring but with small snowdrifts persisting until late summer or through the year in small high and protected sites. Mount Kosciuszko, at 2228 m, is the highest point anywhere in Australia or Tasmania; elsewhere in the Southern Highlands are extensive ranges and peaks of over 2000 m, but even much of these highlands are between 1500 m and 2000 m. North of the Southern Highlands, high tablelands, above 1000 m, are found along the Great Divide, such as at Barrington Tops and the New England Tableland in the central-east, and the Atherton Tableland in the north-east, where Mount Bartle Frere is Queensland's highest peak, at 1622 m. The Central Plateau of Tasmania is also high and cold, with extensive alpine and subalpine habitats; the highest peak is Mount Ossa, rising to 1617 m.

As in Australia, honeyeaters are found throughout New Guinea and in nearly all habitats, although, unfortunately, there is no quantitative analysis of the number of species per unit area. An atlasing project for New Guinea would be a valuable, if ambitious, project for the future. The habitat exceptions listed above for Australia are relevant also to New Guinea, although, at high altitude in New Guinea, honeyeaters make some use of alpine grasslands. Unlike Australia, however, New Guinea is dominated by the high cordillera of the Central Range, which extends in an unbroken and complex series of ranges from the isthmus of the Vogelkop, in the north-west, to Milne Bay, at the tip of the south-eastern peninsula. The Snow Mountains in the west and

the mountains of the south-east also have peaks of more than 4000 m, and high, flat valleys are dispersed through the central cordillera. The highest peak is Puncak Jaya, known earlier as Mount Carstensz or Carstensz Pyramid or Massif, in the west of the island, which, at 5030 m, is well over twice as high as Australia's tallest peak; Mount Wilhelm, in the Eastern Highlands, rising to 4509 m, is the highest in eastern New Guinea, and also twice as high as Australia's Mount Kosciuszko. In addition, there are a number of outlying ranges, notable among these being the Tamrau and Arfak Mountains of the Vogelkop and the Kumawa and Fakfak Mountains of the Bomberai Peninsula, and, to the north of the Central Range, the Wandammen, Van Rees, Foja and Cyclops Mountains, the North Coastal Range, which includes the Bewani, Torricelli and Prince Alexander Mountains, and, in the north-east, the Adelbert Ranges and the mountains of the Huon Peninsula. The Central Range is surrounded by extensive lowland regions, such as the broad humid floodplains of the Rouffaer-Ikenburg-Mamberamo Rivers in the north-west and the Sepik River in the north-east, and the Eilanden-Digul Rivers and Fly River in the south. There are four large lowland areas of low rainfall: the Trans-Fly region, the area around Port Moresby, the northern coast of the south-eastern peninsula, and the upper Markham-Ramu Valley.

Many of the islands of Wallacea and the south-western Pacific Ocean are mountainous, with only small areas of coastal lowlands. For example, Sulawesi, the largest island in Wallacea, rises rapidly from the coast through a narrow belt of hills to the high dissected central ranges, with most of the land area above 500 m and about 20% above 2000 m; the highest peak, at 3440 m, is in south-central Sulawesi. Seram, in the Moluccas, likewise has a largely narrow area of coastal lowlands that rises to a central peak. Similarly, in the Pacific, the Fijian island of Viti Levu is dominated by a central mountain chain, the peaks of which are above 1300 m, with broken highlands and steep escarpments surrounded by coastal lowlands. Conversely, many islands are lower and lack high mountain ranges. In Wallacea, for example, the Tanimbar Islands, in the eastern Lesser Sundas, are a group of some 60 low islands, of which Yamdena is the largest and consists of a low hilly plain reaching maximum elevations of 100–200 m. While it is not possible to characterize in a simple way all the islands of Wallacea and the south-western Pacific, the vegetation of these regions exhibits many similarities to that of Australia and New Guinea, particularly large swathes of lowland and montane rainforest and secondary forest, mangroves and, less widely, lowland monsoon forests, including semi-evergreen and mixed deciduous monsoon forest, as well as eucalypt savanna woodlands and *Melaleuca leucadendra* woodlands. The distribution of these vegetation types varies greatly from one island to another, reflecting differences in rainfall, geology and soils.

Rainforest is the dominant vegetation over much of the range of the Meliphagidae, the exception being the large areas of Australia dominated by open sclerophyllous habitats. Much of New Guinea is covered with rainforest, as are many of the islands of Wallacea and of the south-western Pacific Ocean. The rainforests of New Guinea are extensive and continuous, varying in structure, floristics and species diversity with altitude, from the closed humid forests of the lowlands to the stunted forests that grow to the tree-line of the highest ranges. Most ornithological studies have divided the rainforests of New Guinea into several broad classes which merge into one another and the altitudinal limits of which vary from site to site. Lowland rainforests are tall, structurally complex and highly floristically diverse, with a canopy to 40 m and more, and they merge into the hill forests, which are often as diverse as the lowland forests. From 750 m to 1500 m, the hill forests give way to the montane forests, which at their lower altitudes, the lower montane forest, have high densities of epiphytes and are typically heavily moss-laden but are less diverse than the lower forests; above about 2700 m, the upper montane forests are less tall, far less floristically diverse and heavily moss-covered and extend to the tree-line at 3700–4200 m.

Forest edge and secondary growth are complex but varying forest habitats. They are formed as a result of natural events such as treefalls and cyclones, or as a result of human activities, in-

Avian bathing activity tends to vary in relation to certain environmental factors. Sunshine is known to stimulate bathing, whereas overcast skies and falling temperatures appear to suppress it. The most likely reason for this relationship is that birds need to dry out after bathing. Warmth and sun help them do so more efficiently which, in turn, reduces bathing's incursion into foraging time or parental responsibilities. This **Red Wattlebird** is sunbathing to dry itself. Stretching its neck and drooping its wing increases the surface area of feathers exposed to the air, thereby expediting the drying process.

[*Anthochaera carunculata* woodwardi, Two People's Bay, Western Australia, Australia. Photo: Don Hadden]

It is essential for birds to keep their flight-feathers in excellent condition. This **Yellow-throated Miner** is deftly passing individual primary feathers through its bill with a nibbling action. In doing so, the bird may be restoring the structure of barbs and barbules, removing dust and other foreign particles, or massaging new uropygial preening oil into the feather structure.

cluding road-building, logging, and clearing for agricultural production, such as plantations, crops and gardens, or they grow naturally, such as along waterways. Such habitats are typically successional, depending on the effects of any ongoing disturbance. The secondary growth ranges from dense shrubby or woodland regrowth to tall forest.

Given the extent of rainforest in New Guinea, it is little surprise to find that many species are primarily rainforest-dwellers. The two species of *Timeliopsis*, endemic in New Guinea, are both forest inhabitants: the Olive Straightbill is found mainly in mid-montane forest and forest edge between about 1100 m and 2450 m, whereas the Tawny Straightbill lives mainly in lowland and foothill primary rainforest, but also in forest edge and tall secondary growth, from sea-level to 800 m. The Long-billed Honeyeater is another forest species, found mainly in forest and secondary growth in lowlands, foothills and lower mountains to 1500 m, and the genera *Ptiloprora*, with six species, and *Melipotes*, with four, are also primarily denizens of montane forest. *Melidectes* consists of ten species, many of which are forest-dwellers but several of which occur in forest-edge habitats. Three of them, the Sooty, Long-bearded and Short-bearded Honeyeaters, are all high-altitude species, living above 3000 m in high montane and subalpine forest, woodland and shrubland; the closely related Bismarck Honeyeater of New Britain, the only *Melidectes* not confined to the main islands of New Guinea, is similarly restricted to primary montane forest, though at lower altitudes than those at which the preceding three species are found. The remaining members of the genus occur throughout New Guinea in forest and forest edge, although the Yellow-browed Honeyeater appears to show some preference for forest edge, secondary growth and other disturbed habitats. MacGregor's Honeyeater is a high-altitude and specialized meliphagid found mainly at 3200–3500 m, but sometimes down to 2700 m and as high as 4000 m. It is largely confined to subalpine woodland and forest, including patches within alpine grassland, dominated by two gymnosperm trees, the podocarp *Dacrycarpus compactus*, which is an important foodplant, and the conifer *Libocedrus papuanus*; its overall range is apparently limited by the distribution of *Dacrycarpus*. The Orange-cheeked Honeyeater is another high-altitude species, inhabiting subalpine forest and shrubland bordering alpine grassland.

There are also many species that are primarily forest-dwellers although such preferences are not universal within the genus, as

illustrated by various species of *Myzomela*. The Red-throated *Myzomela* is found in lowland and hill forest, mainly to about 500 m; the Red *Myzomela* lives principally in montane rainforest at 600–1500 m; and the Red-collared *Myzomela* occurs primarily in montane forest and forest edge and subalpine shrubland, mainly from 1500 m to 4000 m. Many of the *Meliphaga* species, too, are forest species, found in lowland, hill and lower montane forests.

Many of the larger islands of Wallacea, such as Sulawesi and Halmahera, and of the south-western Pacific, such as Vanuatu, Fiji and Samoa, are similar to New Guinea in their rainforest communities, with humid forest varying continuously from diverse lowland forests through hill forests to montane forests, although, in Wallacea, only Sulawesi and Lombok have elevations high enough to support alpine grasslands similar to those of the highest peaks of New Guinea. In Wallacea, several species of honeyeater are characteristic of montane rainforest; these include, on Sulawesi, the two species of *Myza*, namely the Lesser Streaked and Greater Streaked Honeyeaters, and, in the Moluccas, the Seram and Buru Honeyeaters and the Dusky Friarbird. Others are lowland or hill-forest species, such as the White-streaked Friarbird, which inhabits lowland and lower montane forest, although this species is characteristic also of forest edge or secondary growth. Many other Wallacean meliphagids inhabit rainforest, as well as exploiting a varying range of other habitats. For example, the Black-faced Friarbird occupies all wooded habitats, including primary forest, and the Streak-breasted Honeyeater inhabits primary and secondary rainforest and monsoon forest, degraded forest, scrub, semi-cultivated areas, gardens and, occasionally, mangroves.

Likewise, many species of the islands of the south-western Pacific are characteristic of rainforest. The three *Gymnomyza* honeyeaters all appear to require large, continuous areas of mature forest. Thus, the Giant Honeyeater lives mainly in mature primary hill, montane and stunted mossy rainforest, and less often at forest edge or in degraded forest; the globally threatened Mao is found mainly in foothill and montane forests, with its greatest densities at high altitude in the least disturbed forest; and the globally threatened Crow Honeyeater is largely restricted to dense, humid, primary rainforest, although it is recorded also in dry forest. Three monotypic Pacific genera are also primarily rainforest species: the Guadalcanal Honeyeater of the Solomon Islands is confined to montane forest, particularly high moss for-

est, the San Cristobal Honeyeater is found mainly in primary forest and less often in tall secondary forest and forest edge, and the Bougainville Honeyeater is restricted to montane forest.

In Australia, rainforest is confined to the north and east of the country. In eastern Australia, rainforest is discontinuously distributed on and east of the Great Divide, which extends from north-easternmost Queensland south to Victoria, essentially running parallel with the eastern coast. Monsoon rainforest is also present in isolated patches scattered across the northern tropics. Extensive stands of tropical rainforest are confined to the eastern Cape York Peninsula and the wet tropics of north-eastern Australia, and it is here that a number of honeyeaters shared with the rainforests of New Guinea occur: both the Graceful Honeyeater and the Tawny-breasted Honeyeater are mainly confined to lowland tropical rainforest in Australia and New Guinea, although they occupy other habitats, too, in both countries. Several members of the family, however, are endemic in north-eastern Australia, predominantly in or adjacent to rainforest, examples being the Bridled, Yellow-spotted and Macleay's Honeyeaters. Field studies revealed that the meliphagid community of upland rainforest and regrowth rainforest 20–30 years old in the wet tropics of north-eastern Australia consisted of seven species, namely Lewin's, Graceful, Macleay's, Yellow-faced and Bridled Honeyeaters, the Dusky Myzomela and the Eastern Spinebill, although several of these were recorded only rarely. Surprisingly, the community of one lowland rainforest site consisted of only four honeyeaters: these were the Dusky Myzomela and Macleay's, Graceful and Yellow-spotted Honeyeaters. Extending south from north-eastern Australia, there are other areas of tropical rainforest, for example in the Clarke Range, inland from Mackay. The Eungella Honeyeater is restricted to the higher-altitude rainforests of the Clarke Range. In south-eastern Queensland and north-eastern New South Wales lie the remnants of once extensive subtropical rainforest. While no honeyeaters are confined to this area, species such as Lewin's Honeyeater are abundant in these habitats. Farther south again, cool temperate rainforest dominated by southern beech (*Nothofagus*) is scattered along the Great Divide to Victoria and in Tasmania, in extensive stands in some places. These temperate rainforests are not major habitats for honeyeaters but, again, such meliphagids as Lewin's Honeyeater can be commonly found in them.

Scattered across northern Australia, from the Kimberley in the north-west to Cape York Peninsula in the east, are patches of tropical monsoon rainforest. These patches are typically small, and found in coastal areas, in sites protected from fire by their topography, and with fairly high levels of moisture throughout the year. They are also typically surrounded by large expanses of open savanna-like *Eucalyptus* woodlands and forests. Few honeyeaters are confined to these habitats, but they are used by a diversity of honeyeaters, especially when fruits or flowers are available. Species more often encountered in such habitats include the White-lined, Kimberley, White-gaped, Bar-breasted, Brown-backed and Rufous-banded Honeyeaters and the Dusky and Red-headed Myzomelas. In a detailed study of the monsoon rainforests of Kakadu National Park, in the Northern Territory, 13 species of honeyeater were recorded in patches of such forest, four of them only rarely so. None of these was restricted to monsoon rainforest or even considered a specialist of these habitats, although six were more abundant in monsoon rainforest than in other habitats. The use of different classes of these monsoon rainforests also varied. For example, the Rufous-banded Honeyeater was more abundant in subcoastal patches, whereas Dusky Myzomelas were more numerous in sandstone spring rainforest patches and White-lined Honeyeaters most common in sandstone spring and escarpment rainforest patches. Conversely, the Brown Honeyeater was widely distributed and used all types of patch equally. Further, the White-lined Honeyeater was significantly more abundant in patches larger than 2 ha in size than in small ones.

Whereas rainforest is a restricted habitat in Australia, in relation to overall land area, but is dominant in New Guinea, the reverse is true of sclerophyll forests and woodlands. These are the dominant vegetation of much of Australia, but in New Guinea, while still covering some extensive areas, they are confined to several discrete low-rainfall, lowland areas. Savanna woodland is estimated to comprise some 7% of New Guinea's vegetation. The islands of Wallacea and the south-western Pacific Ocean lack large areas of woodland or savanna, although such habitats do exist on some of the larger islands and are utilized by honeyeaters. The open forests and woodlands of Australia and New Guinea are dominated by one group of trees, the eucalypts. They have conventionally been placed within a single genus, *Eucalyptus*, but more recently have been split into nine separate subgenera or genera, which may have ecological significance to birds; while this "split" has yet to be widely accepted in its entirety, recognition of the genus *Corymbia* for the bloodwood eucalypts seems to have gained general acceptance. These eucalypt-dominated, sclerophyllous forests and woodlands are found through much of Australia except in the drier semi-arid and arid zones, and even there riparian eucalypt forests or woodlands traverse the otherwise non-eucalypt vegetation associations that surround them. Most species of *Lichenostomus* and *Meliphreptus* inhabit eucalypt forests and woodlands, as does a range of other species in diverse genera.

The eucalypt savanna woodlands of northern Australia are the tropical representatives of the open forests and woodlands of temperate, semi-arid and arid zones of that country. The Rufous-banded Honeyeater of northern Australia and New Guinea is commonly found in open, grassy, tropical eucalypt woodlands, such as those dominated by silver box (*Eucalyptus pruinosa*) with an open ground layer of spear-grass (*Stipa*), or woodland dominated by Darwin woollybutt (*Eucalyptus miniata*) and Darwin stringybark (*Eucalyptus tetradonta*) with a grassy ground cover of *Themeda* and *Sorghum* or spinifex (*Triodia*). The Banded Honeyeater, confined to the northern Australian tropics from the Kimberley eastwards to northern Queensland, is found mainly in open eucalypt forests and woodlands, usually with a tall grassy understorey of species such as *Sorghum*, *Heteropogon*, *Alloteropsis* and *Themeda* or a ground cover of spinifex. The tropical lowland eucalypt savanna of the Trans-Fly region of New Guinea is the other significant habitat shared with northern Australia, and this is again reflected in the fact that this habitat holds a few species that are present in both countries. Other large areas of lower rainfall and savanna woodland and forest are found around Port Moresby, on the northern coast of the south-eastern

With the large number of genera in Meliphagidae, it is hardly surprising that there is considerable variation in vocalizations. Even a single species may have a wide-ranging repertoire. The Banded Honeyeater gives a buzzing call almost constantly. On occasion, it may switch to a high-pitched double whistle or to a single loud whistle, which is sometimes given as a series. Its song is relatively melodious within the context of the family. It is short, clear and tinkling, and may be given while the songster is perched or in song flight. Pairs also engage in antiphonal duets.

[*Cissomela pectoralis*, Gibb River Road, Kimberley, Western Australia, Australia.
Photo: Don Hadden]

peninsula and in the upper Markham–Ramu Valley. The White-throated, Brown, Brown-backed and Rufous-banded Honeyeaters are a few of the species shared between northern Australia and New Guinea that utilize these habitats.

Riparian sclerophyll forests and woodlands provide a further distinctive habitat, one preferred by a number of species. For example, in north-eastern Australia, the Yellow Honeyeater is found primarily in open riparian *Eucalyptus* forests and woodlands surrounding a variety of wetlands, although it occurs also in riparian associations dominated by paperbarks (*Melaleuca*) and *Lophostemon*, including those with a dense understorey of palms. Also in the northern Australian tropics, the Rufous-banded Honeyeater inhabits mostly open, riparian paperbark forests surrounding wetlands, as well as mangroves, and the Brown-backed Honeyeater is found mainly in riparian paperbark thickets or woodlands around ephemeral wetlands, as well as in adjacent forest or open woodland dominated by eucalypts or paperbarks, typically along watercourses. Such habitats are, of course, used also by other honeyeaters at times, even if not as their main habitats.

The bird assemblages of the riparian vegetation of the Northern Territory have been the subject of detailed study, providing an indication of the relationships between honeyeaters and riparian and non-riparian vegetation. The relatively permanent waters of the large rivers that dissect the northern tropics support narrow bands of vegetation surrounded by very different open savanna forests and woodlands. This riparian vegetation is floristically diverse and characterized by *Melaleuca*, *Lophostemon*, *Eucalyptus*, the bamboo *Bambusa arnhemica* and the palm-like *Pandanus*. During investigation of the avifauna of the riparian vegetation and the surrounding savanna, a number of honeyeater species, including the Dusky Myzomela and the Bar-breasted, Rufous-banded, White-throated, Yellow-tinted and White-gaped Honeyeaters, were recorded in riparian vegetation significantly more often than they were in non-riparian vegetation; conversely, several, including the Banded Honeyeater, Yellow-throated Miner and the Silver-crowned Friarbird, were in non-riparian vegetation significantly more often. A number of species exhibited no significant preference for either, as demonstrated by the Brown, Rufous-throated, Black-chinned and Blue-faced Honeyeaters and the Little Friarbird. The riparian zones, however, also varied, and different species used different classes of riparian vegetation. For example, White-throated Honeyeaters, Dusky Myzomelas and

White-gaped Honeyeaters were in riparian vegetation in relatively high-rainfall areas, with abundant *Melaleuca* and bamboo, close to the river source and with flood heights well above the sampled area, whereas Rufous-banded Honeyeaters were found in riparian zones with a low canopy, around wide rivers and lagoons, that rarely flooded high into the vegetation and were the most northerly and highest-rainfall sites. Throughout arid and semi-arid Australia, sparse riparian woodlands or forests, typically dominated by *Eucalyptus*, such as the widespread river red gum (*Eucalyptus camaldulensis*), black box (*Eucalyptus largiflorens*) or coolabah (*Eucalyptus microtheca*), are surrounded by much drier and sparser vegetation, including grasslands, acacia shrublands or savanna woodlands. Some widespread meliphagids extend into such riparian habitats in the drier parts of their range. The wide-ranging White-plumed Honeyeater, for example, is seen predominantly in open, riparian river red gum forests and woodlands, but occurs also in a wider range of open forests and woodlands. In inland northern Australia, the Grey-fronted Honeyeater is found in low riparian growth, often beneath taller riverine vegetation. South of the tropics, the subhumid savanna woodlands and forests give way to open, dry eucalypt forests and woodlands and, in eastern and south-western Australia, tall wet sclerophyll forests, also dominated by eucalypts.

The tallest open forests in Australia, the wet sclerophyll forests of eastern and south-eastern parts, including Tasmania, and a small area of south-western Australia, develop on moist rich soils, and are dominated by tall eucalypts such as mountain ash (*Eucalyptus regnans*) and alpine ash (*Eucalyptus delegatensis*) in eastern Australia, and karri (*Eucalyptus diversicolor*) in the south-west. They are generally within 200 km of the coast. The understorey varies with rainfall, and with fire history, from rainforest or rainforest elements, including tree-ferns, in moist sites to small trees such as acacias and sapling overstorey trees, mainly eucalypts, and low sclerophyllous shrubs in drier sites. Many members of the Meliphagidae use wet sclerophyll forests, mainly the canopy level and especially when eucalypts are in flower, although there appear to be no species restricted to such habitats. The Strong-billed Honeyeater of Tasmania is found predominantly in mature wet sclerophyll forests dominated by mountain ash or alpine ash, including old regrowth forest, but it is common also in dry sclerophyll forests and sometimes in cool temperate rainforest. Other species of *Melithreptus*, such as the White-naped

Studies have been carried out on the vocal repertoires of several species of meliphagid from Australia and New Zealand, including the **Noisy Miner**.

This species is indeed noisy and has twelve different vocalizations, in addition to a song. Its calls can be quite different in tone and nature, varying from strident and whistling to scolding and chuckling. While many birds have an alarm call that signals the approach of a predator, the Noisy Miner uses different vocalizations to communicate whether the threat is aerial or terrestrial.

Honeyeater, are often found in wet sclerophyll, as are a number of species in other genera, including the Yellow-throated Honeyeater of Tasmania and the Bell Miner and Yellow-faced Honeyeater of eastern Australia. The Scarlet Myzomela is another species that also regularly uses wet sclerophyll forest, especially when it is in flower.

Dry, open eucalypt-dominated forests and woodlands are widely distributed in temperate, semi-arid and arid zones of Australia and are the habitat of a wide range of honeyeater species, including the Near-threatened Painted Honeyeater and the Endangered Regent Honeyeater. Many species of the dominant meliphagid genera are found in such habitats, including, as examples, the White-eared and Fuscous Honeyeaters, in *Lichenostomus*, the Brown-headed, White-naped and White-throated Honeyeaters, in *Melithreptus*, the Little, Western and Red Wattlebirds, in *Anthochaera*, the Yellow-throated and Noisy Miners, in *Manorina*, and the Noisy and Little Friarbirds, in *Philemon*. These wooded habitats, however, vary greatly, from tall, dry forests with a grassy or varyingly dense understorey of tall shrubs or small trees and saplings, to the widespread open grassy woodlands of the temperate inland plains, and to coastal woodlands with a dense understorey of shrubs, including heath, and alpine woodlands with a grassy or shrubby understorey. For example, on the New England Tableland of northern New South Wales, in open eucalypt forest with an understorey primarily of *Banksia* species and a ground layer of grasses and ferns, seven meliphagid species were recorded commonly: the Eastern Spinebill, the New Holland and White-cheeked Honeyeaters, the Red Wattlebird, and Lewin's, Yellow-faced and White-naped Honeyeaters. Species recorded less commonly were the Scarlet Myzomela, the White-eared and Brown-headed Honeyeaters, the Noisy Friarbird and the Regent Honeyeater. Thus, twelve species were recorded in the study area, although the composition of the honeyeater community varied over the year. A similar community, of ten species, was recorded in open forest near Sydney, in south-eastern Australia, where the Eastern Spinebill, Little and Red Wattlebirds, New Holland, White-cheeked, White-eared, Tawny-crowned, Yellow-faced and Lewin's Honeyeaters and Noisy Friarbird exploited the same habitat. In a study of tall open forest in south-western Australia, the honeyeater community consisted of Red Wattlebirds, White-naped, Brown and New Holland Honeyeaters

and Western Spinebills. Also in south-western Australia, but in semi-arid eucalypt woodland about 8 m tall with an understorey consisting largely of *Eremophila*, *Melaleuca*, *Dodonea*, *Acacia* and *Santalum*, the bird species most often seen consisted of nine species of honeyeater, although not all were in the area at the same time, with 5–8 species recorded per month, and only four were recorded in all months. Here, Yellow-throated Miners, Red Wattlebirds and White-eared and Brown-headed Honeyeaters were observed throughout the year; the other species recorded were the Singing, Yellow-plumed, Spiny-cheeked, White-fronted and Brown Honeyeaters. As can be seen, the honeyeater assemblage here is similar in generic and species composition to the communities of eastern Australia.

Parts of semi-arid or arid southern Australia are vegetated with a unique structural form of low eucalypt woodland, shrubland or, in places, heathland, the habitat being known as mallee. Mallee eucalypts are characterized by the fact that they possess multiple and often narrow stems that grow from a subterranean rhizome, and are typically less than 10 m tall, and mallee is the vegetation association consisting of such eucalypts. Unfortunately, much mallee habitat in Australia has been destroyed, degraded or fragmented, particularly for agricultural development, and many mallee specialists are threatened. What is perhaps Australia's most critically endangered species, the Black-eared Miner (see Status and Conservation), is a mallee specialist restricted to long-unburnt and mature mallee woodland in temperate semi-arid south-eastern Australia. A number of other honeyeaters are confined, or virtually confined, to mallee, examples being the Purple-gaped Honeyeater, found mainly in mallee heathland, shrubland and woodland, and the Yellow-plumed Honeyeater, living primarily in tall mallee woodlands with a sparse understorey of shrubs and ground cover of chenopods. Many other species use mallee as part of a wider range of habitats. Examples include the Grey-fronted Honeyeater, which occurs chiefly in mallee in the south of its range, though occupying a wider range of habitats elsewhere, and the White-eared Honeyeater, which is a common inhabitant of mallee but is found also in many other eucalypt forests and woodlands. The White-fronted Honeyeater is found mainly in mallee woodland, shrubland or heathland, but it is present also in one of the other major sclerophyllous habitats of inland Australia, *Acacia* shrubland.

A range of other dry sclerophyllous forests and woodlands is exploited by honeyeaters. Perhaps the most important among these are the *Acacia* woodlands and shrublands that replace eucalypt communities in much of the drier parts of Australia. It is estimated that approximately 60% of the Australian continent receives less than 500 mm of rain annually, and these regions are vegetated predominantly with shrubland or low woodland, or grassland. A large proportion of these semi-arid and arid habitats are dominated by acacias, often mulga (*Acacia aneura*) and closely related species, and are frequently used by honeyeaters of inland Australia. These mulga lands extend throughout western Queensland and New South Wales, South Australia, the Northern Territory and Western Australia, and they occupy some 20% of the land area of Australia. Such communities can hold a diversity of honeyeaters; one area of flowering mulga in south-west Queensland, for example, had Spiny-cheeked, Singing, White-fronted, Black and Pied Honeyeaters and Yellow-throated Miners. Other more restricted habitats of Australia include forests or woodlands dominated by casuarina (*Casuarinaceae*) or cypress pine (*Callitris*), or by combinations of the two, which are utilized by a variety of species, such as the Yellow-plumed Honeyeater, even though no meliphagid species appear to be confined to, or even to prefer, such habitats. For example, the bird assemblage of remnant buloke (*Allocasuarina luehmannii*) woodland in south-eastern Australia included Singing, White-eared, Spiny-cheeked and White-fronted Honeyeaters. On islands, coastal strand forest or littoral woodland or forest can also be dominated by casuarinas; in the Moluccas, the Olive Honeyeater frequents coastal casuarinas, as well as coconut palms (*Cocos nucifera*) and scrub.

In New Caledonia, niaouli (*Melaleuca leucadendra*) savanna woodland is a fire-maintained habitat, found mainly on plains where indigenous forest has been burnt. It is used by Barred

Belford's Honeyeater is a characteristic contributor to the sounds commonly heard in the montane forests of New Guinea. This species often leads the dawn chorus, starting to vocalize well before daylight arrives, and it continues its renditions throughout the day. Even rain showers do not seem to deter it from communicating its presence. The species' varied vocalizations tend to be loud but rather unmusical. Calls range from rasping or cackling to staccato and gurgling. Belford's Honeyeater also gives a whistling alarm call, which alerts conspecifics to potential danger.

Friarbirds (*Philemon*) have a loud and harsh repertoire that suits their pugnacious nature. Not surprisingly for a species with ten races distributed from the Lesser Sundas through New Guinea to Australia, the characteristics and timing of **Helmeted Friarbird** vocalizations differ geographically. In New Guinea, the species calls all day and even at night. In Australia, however, it tends to call in the early morning or after rain. Some subspecies give antiphonal duets and others duet in unison, while yet others do not duet. The species is also mimicked vocally, as well as visually, by two species of oriole (*Oriolus*).

Honeyeaters, Dark-brown Honeyeaters and New Caledonian Myzomelas, among a wider range of habitats exploited by all species. The globally threatened Crow Honeyeater, while preferentially inhabiting dense, humid primary rainforest, has been recorded in dry forest, which may refer to niaouli savanna or to the highly threatened sclerophyll forest, which currently covers less than 3% of New Caledonia's land area.

Heathlands are widely scattered throughout Australia, in discrete areas and varying zones. They are present in coastal and subcoastal areas of eastern, southern and south-western Australia, on the ranges of the Great Divide of eastern Australia, above the tree-line in alpine areas of south-eastern mainland Australia and Tasmania, and on deep sandy soils in the mallee of eastern and southern Australia. The floristic diversity of heathlands is generally high, and they typically contain an abundance of nectar-producing plants, especially species of the Proteaceae, Myrtaceae and Epacridaceae, notably the genera *Banksia*, *Hakea*, *Grevillea*, *Kunzea*, *Darwinia*, *Lambertia*, *Verticordia*, *Styphelia*, *Epacris* and, in Western Australia, *Dryandra*. A number of meliphagids are characteristic of heathland, the Tawny-crowned Honeyeater being a good example of a species found in dense heathland throughout its range, but other species already mentioned as occupying other habitats, such as the New Holland and White-cheeked Honeyeaters and the Eastern Spinebill, are frequently found also in heath. The diversity and density of honeyeaters in this habitat can be high. In heathland communities around Sydney, up to ten species co-occur, including the New Holland, White-cheeked, Tawny-crowned, White-eared, Yellow-tufted and Yellow-faced Honeyeaters, the Eastern Spinebill, the Little Wattlebird and the Noisy Friarbird, although the presence and abundance of species would vary over a year; further, several of these species, such as the White-eared and Yellow-tufted Honeyeaters, use heathland only where it abuts woodland or where eucalypts are scattered through heath.

Tropical heathlands, of limited extent, are found in parts of northern Australia, and are dominated by such plant species as *Grevillea pteridifolia* and species of *Austromyrtus*, *Calytrix*, *Acacia* and *Triodia*. On islands of Arnhem Land in the Northern Territory, meliphagids recorded as using these tropical heaths include the Brown and White-throated Honeyeaters, the Silver-crowned Friarbird and the Red-headed and Dusky Myzomelas. In Wallacea,

the Seram Honeyeater inhabits both montane forest and high-altitude heath.

In New Caledonia, maquis, or "maquis miniers", is a unique, heath-like sclerophyllous, evergreen shrubland growing to 2 m tall and found mainly on ultrabasic soils, in places with a scattered emergent layer of *Araucaria* or *Agathis*. It is one of a range of habitats utilized by Barred Honeyeaters and Dark-brown Honeyeaters, and the rare Crow Honeyeater, while inhabiting primarily dense, humid, primary rainforest, has been observed also in isolated stands of stunted forest within maquis.

Large areas of mangrove forest and woodland exist in Australia and New Guinea, and on many islands of Wallacea and the south-west Pacific. In New Guinea, mangroves are found in disjunct parts of the northern coast, such as the eastern side of Cenderawasih Bay and the mouths of the Sepik and Ramu Rivers, and in long deep stretches on the southern coast of the island, especially at the mouths of the Purari, Kikori, Fly, Northwest and Otakwa Rivers, Bintuni Bay, and the southern Vogelkop. Indeed, the southern coast of eastern New Guinea has the highest diversity of mangroves in the world. Such habitats can often cover extensive areas, and exhibit a definite zonation of structure and floristics from seaward to landward edges of the mangals. A number of species are considered mangrove specialists. In New Guinea, the Red-headed Myzomela is virtually confined to extensive mangrove thickets, woodlands and forests, although, in Australia, it is often seen also in fringing vegetation on the landward edge of mangrove associations, such as stands of paperbarks. The Varied Honeyeater of coastal New Guinea and north-eastern Australia is commonly found in mangrove associations, but it, too, occurs also in other coastal vegetation adjacent to mangroves and it is often seen in the sea-front vegetation of towns and cities and is occasionally found in other associations. In mid-eastern Australia, the Mangrove Honeyeater is largely restricted to coastal and riverine mangrove woodlands; as with the Varied Honeyeater and Red-headed Myzomela, however, it is occasionally encountered in coastal scrub or woodland bordering mangroves, and it will visit flowering trees and shrubs in gardens and parks within towns with mangroves nearby. Both Singing and Brown Honeyeaters regularly exploit mangroves in parts of their ranges.

As well as such specialists, a number of species use mangroves regularly but are not confined to them. For example, the

The New Zealand Bellbird is a renowned songster. While its basic call note is simple, resembling a bell tolling, the song's use, form, length and variation are complex. The species' "dawn song" comprises up to six clear bell-like notes and is repeated for long periods throughout the day. In full song, the New Zealand Bellbird intersperses the bell-like notes with harsh, jarring calls. Both male and female sing, and pairs may duet, sometimes counter-singing against neighbouring rivals.

[*Anthornis melanura melanura*, Pounaw, Tiritiri Matangi Island, Hauraki Gulf, NW North Island, New Zealand. Photo: Don Hadden]

Rufous-banded Honeyeater of northern Australia and New Guinea is commonly found in mangroves, as well as in paperbark forests, and the Brown Honeyeater, a habitat generalist, is often seen in mangroves. Many other meliphagids occasionally enter mangroves, especially when these trees are flowering and nectar is abundant, and even species not normally associated with lowlands are attracted to them. For example, the Vanuatu Honeyeater is predominantly a montane species, but it is sometimes found in the lowlands and one was trapped in mangroves.

In a detailed study of the use of mangroves by birds in Darwin Harbour, in northern Australia, R. Noske recorded a total of 50 bird species, seven of these honeyeaters, as using the mangrove forest, which consisted of several distinct zones that varied with distance from the tidal creek running through the forest. Red-headed Myzomelas and Brown Honeyeaters were two of the most common species in these mangroves, having mean densities per hectare of, respectively, 5.5 and 2.3 individuals. Both were found throughout the mangal zones, from the zone of stilt-rooted mangrove (*Rhizophora stylosa*) beside the tidal channels of the creek, through the zone dominated by the rib-fruited mangrove (*Bruguiera exaristata*) and the wide zone of *Ceriops tagal*, which was divided into inner and outer zones by bare sandy saltflats, with the outer zone of taller mangroves; both were recorded also in a narrow zone of *Lumnitzera racemosa* fringed by paperbarks that lay farthest from the creek. Both meliphagids were observed and trapped significantly more often in the *Bruguiera* zone than in the other zones, although the use of different zones varied much over the course of the year. The five other members of the family using the mangroves were the Silver-crowned, Helmeted and Little Friarbirds, the Dusky Myzomela and, rarely, the Rufous-banded Honeyeater. In Darwin Harbour, Red-headed Myzomelas and Brown Honeyeaters exhibited significant seasonal variation in densities in the mangrove forests. For example, the density of Red-headed Myzomelas reached a peak in July–November, which coincided with breeding and the dispersal of young, and density was significantly lower in March–April than in other bimonthly periods except January–February. The Brown Honeyeater showed a similar, though less marked, pattern.

Throughout the range of the family, many species have adapted to exploit modified landscapes and habitats, especially where abundant sources of nectar are available. Honeyeaters are found in cities, towns and villages, in orchards, agro-gardens and cane fields, and in plantations of coconut palms. Throughout inland

Australia, they can be found around isolated homesteads, mine sites and other buildings where water and food may be available, and in New Zealand the Tui is a common inhabitant of urban gardens. In Australia, although honeyeaters are found in all cities and towns and around other human settlements, in many urban areas it is often the larger species that tend to dominate the honeyeater communities. Along the eastern coast, for example, species such as the Noisy Miner, the Little and Red Wattlebirds and the Blue-faced Honeyeater are common and widespread in most cities and towns. Nevertheless, a range of other meliphagids has adapted well to urban areas, among them the White-plumed Honeyeater, which is a common urban bird of Sydney, Melbourne and Adelaide, and New Holland Honeyeaters are common in many cities and towns of south-eastern and southern Australia wherever nectar-producing shrubs and trees are abundant.

The increasing use of native plants in gardens and parks of urban areas has probably done much to increase the numbers of honeyeaters, and other native birds, although it may not always have promoted improvements in species diversity. In studies of birds inhabiting urban areas of Sydney, the Noisy Miner is commonly found to be one of the dominant and common species, along with a range of other medium-sized and smaller species, including Eastern Spinebills, Red and Little Wattlebirds and New Holland Honeyeaters. Eastern Spinebills were found to be more common in gardens consisting mainly of native plants and in gardens with greater tree cover, and were negatively associated with greater extent of lawn and the presence of Noisy Miners. New Holland Honeyeaters, however, showed no associations with garden habitat variables but were negatively associated with Noisy Miners. Noisy Miners were negatively associated with all small bird species, honeyeater or not, but showed no association with habitat variables. Otherwise, a great many species occur at the fringes of cities and towns, or are found in large remnants of a diverse range of native vegetation in parks, gardens or reserves. In all the major capital cities of Australia, for example, the main botanical gardens provide a diversity of habitats and plant and food resources for a wide range of honeyeaters and other birds.

On many islands within the family's range, meliphagids frequently exploit plantations or groves of coconut palms whenever they are in flower, which can be for all or most of the year. Throughout its wide range in the south-western Pacific, the Cardinal Myzomela is commonly observed to forage on flowering coconut palms, as is the Silver-eared Honeyeater in Vanuatu, where the coconut flowers are present all year. The latter species

is common also in suburban gardens, often utilizing flowers of such plants as hibiscus, ornamental ginger, bananas and lantana. Other species appear to be more abundant in modified habitats. In Fiji, the Orange-breasted Myzomela is more common in disturbed habitats than in mature forest and is common in suburban gardens. While some island species are forest specialists, especially on the larger islands, many are found across a broad range of habitats. For example, the Wattled Honeyeater is present on many islands of western Polynesia, but with considerable and little-understood variation in its distribution and abundance in different habitats on different islands; overall it occupies a wide range of habitats, from montane forest and secondary growth to mangroves, but it is abundant in suburban gardens and large plantations of coconut palms. As has been seen, many species use forest edge or secondary growth, habitats that are increasing in extent at an unfortunate rate in some of the world's rainforest areas. The use of such areas may, however, be dependent on the persistence of unmodified habitat nearby, and without this the survival of such species could be in jeopardy. Further, in Australia, few habitats have not been modified, and this is particularly true of the woodlands and forests, which have long been altered, and continue to be, by clearing, thinning and grazing (see Status and Conservation).

In New Guinea and the islands of Wallacea and the south-west Pacific, elevation is one of the more important ecological sorting mechanisms, and a major influence on the adaptive radiations and speciation of birds. Diamond and others consider altitude to be the most important such mechanism in the New Guinea avifauna as a whole. In New Guinea and on other species-rich, mountainous islands, many bird species are known to be segregated along elevational gradients, and there are examples of pairs and triplets, and occasional quartets, of congeneric species that replace each other with altitude, with the transition abrupt and not coincident with change in vegetation. There are numerous instances of altitudinal segregation of closely related species, and this obviously affects the habitats that a species occupies. As described by Norman and her colleagues, in line with the work and suggestions of Diamond, spatial sorting mechanisms can be used as a means of explaining the distributions of the species of *Meliphaga*. Combining information from geographical, altitudinal and vertical distributions, Norman and co-workers found that nearly all *Meliphaga* species could be partitioned on these parameters alone. In all cases, closely related species occupy discrete distributions and replace each other geographically or altitudinally, thereby minimizing competition between ecologically similar forms. Conversely, species that co-occur tend to be phylogenetically distant and co-exist by segregating vertically within the habitat, as is the case with, for example, the Puff-backed, Mimic and Yellow-gaped Honeyeaters. Exceptions are provided by the Scrub, Graceful and Elegant Honeyeaters, which minimize overlap with other species through horizontal segregation, habitat differentiation or restricted altitudinal range, or combinations of these; for example, the Scrub Honeyeater is restricted to forest edge and rarely ventures into the forest interior, thus avoiding contact with Puff-backed, Mimic and Yellow-gaped Honeyeaters in the lowlands, and with Spot-breasted, Forest and Hill-forest Honeyeaters in the highlands. Other examples include the lowland Rufous-backed Honeyeater and the upland Black-backed Honeyeater. Where these two species are sympatric they have a mutually exclusive altitudinal range; thus, where the two occur together, in the Central Range in eastern New Guinea, the Black-backed Honeyeater is found from 2700 m to 3650 m and its congener from 1500 m to 2700 m, their altitudinal ranges mutually exclusive; but in western New Guinea, where the Black-backed occurs alone, it is found from about 1500 m to 3650 m, and in the Huon Peninsula, where the Rufous-backed Honeyeater occurs alone, it ranges from 1500 m to at least 3200 m. Within the Meliphagidae, other examples of altitudinal segregation in New Guinea include the pair of endemic *Lichenostomus* species, the Obscure and Black-throated Honeyeaters, the former primarily a lowland-foothill species and the latter a montane species. In Sulawesi, the two species of *Myza*, the Lesser Streaked and Greater Streaked Honeyeaters, replace

each other altitudinally. The latter is an upper montane species found throughout all except the south of the island, occurring at 1700–2800 m over much of its range, but not going below 2200 m in southern-central Sulawesi and 2000 m in south-eastern Sulawesi, where its range overlaps with that of its congener; the Lesser Streaked Honeyeater is montane, occurring from 900 m, though mainly from 1500 m, to 1800 m in north and north-central Sulawesi, to 2200 m in southern-central Sulawesi, to 2000 m in south-east Sulawesi and, in the absence of the Greater Streaked Honeyeater in southern Sulawesi, to 2500 m.

Populations of the Red Myzomela in New Britain and New Ireland provide a further interesting example of altitudinal segregation. The Red Myzomela is found in the lowlands of four islands of the Bismarck Archipelago, namely New Hanover, Tabar, Djaul and New Ireland, but on New Britain it is excluded from the lowlands and confined to elevations above 900 m by the presence of another small *Myzomela*, the New Britain endemic Black-bellied Myzomela. The converse is true on New Ireland, where the endemic New Ireland Myzomela occupies the mountains, with the Red Myzomela restricted to lowlands and hills up to about 900 m, and mainly below the range of the New Ireland Myzomela.

Competitive interactions with unrelated species can influence altitudinal distributions and use of habitat. In the Moluccas of Wallacea, the New Guinea region and northern Melanesia, the niche of small nectarivorous and insect-gleaning specialists on flowers is normally filled by *Myzomela* honeyeaters in forested habitats and by the Olive-backed Sunbird (*Cinnyris jugularis*) or Black Sunbird (*Leptocoma sericea*) in open habitats, the myzomelas and sunbirds often interacting aggressively when they meet. In the absence of sunbirds, however, Cardinal Myzomelas in Vanuatu, Samoa, the eastern Solomons and the Santa Cruz Group, Micronesian Myzomelas in Micronesia and Orange-breasted Myzomelas in Fiji are common in open habitats as well as forested ones, and the converse applies on some islands where *Myzomela* does not occur but sunbirds do. The Scarlet-bibbed Myzomela is confined to small species-poor islands of the Bismarck Archipelago and Karkar Island, off north-eastern New Guinea, and is not recorded on the nearby large islands of the Bismarcks or New Guinea. On most of these islands, it occurs at all altitudes from sea-level to mountain summits. In contrast, on Karkar, it is largely confined to altitudes above 1000–1200 m owing to competition with the two aforementioned species of sunbird, which occupy the lowlands, although it was also suggested that they use the mountains because the nectar and insect

Although most meliphagids sing while perched, some engage in song flights as a means of mate attraction or territory defence. This is particularly true in the more open habitats of Australia and New Zealand as opposed to the closed-canopy forest of New Guinea. The **Pied Honeyeater** of Australia sings both when perched and in display flight. It also sometimes accompanies its perched song with a wing-fluttering display. The song is a plaintive piping, often repeated. Singing peaks shortly after birds arrive at a breeding site, and largely ceases once breeding has commenced.

[*Certhionyx variegatus*, Carnarvon, Western Australia, Australia.

Photo: Graeme Chapman]

All meliphagids probably consume nectar. The **Eastern Spinebill** certainly spends much time feeding at flowers—roughly three-quarters of its day, judging from two ecological studies. This species uses a wide variety of flowers, with its chosen genera depending on habitat and location. In Tasmania's temperate rainforests, nectar sources are few, so it feeds mainly on leatherwood (*Eucryphia lucida*) and Tasmanian laurel (*Anopterus glandulosa*). In the New South Wales rainforests, mistletoes (*Amyema*) are a favourite, as are proteaceous shrubs such as *Banksia* in the highlands of that state.

[*Acanthorhynchus tenuirostris cairnsensis*, Atherton Tableland, N Queensland, Australia. Photo: Marie Read]

resources are exploited by few bird species at high elevations on Karkar. Interestingly, in the western Torres Strait, the Dusky Myzomela is found only on islands where the Brown Honeyeater is absent.

Other forms of spatial segregation are also apparent among New Guinean honeyeaters, and these obviously influence habitat choice. In montane regions, there is frequently a change in sex ratio and age structure with altitude. In the case of the Long-billed Honeyeater at Karimui, for example, females predominate at lower altitudes and males at higher altitudes. The Rufous-backed Honeyeater at Karimui provides a more detailed example of the influence of altitude on population structure. At lower elevations within its altitudinal range, from 1340 m to 1900 m, only females and a few immature males were netted, and no songs were heard; from 1900 m, near the elevation at which its preferred habitat with heavy moss covering began, songs were heard often and the sex ratio suddenly approached unity, and the testes of all except one male were enlarged; singing and an equal sex ratio continued to the upper limit of the species' range here, at 2490 m, but above about 2150 m the proportion of male Rufous-backed Honeyeaters with enlarged testes decreased to about 50%, indicating an increase in the numbers of immature males towards the top of the altitudinal range. Such changes have been observed for other species of honeyeater, including the Red-collared Myzomela and the Common Smoky Honeyeater.

Within Australia, there are a number of species that occupy a wide latitudinal range, and the habitats used by such species can vary over that range. For example, Lewin's Honeyeater is found along almost the entire east coast. In the far north of its range, the subspecies *amphochlora* of the McIlwraith Ranges, in the eastern Cape York Peninsula, is largely confined to upland rainforest; a little to the south, the subspecies *mab* is likewise largely confined to upland tropical rainforest in the northern portion of its range. Farther south, however, *mab* and the nominate race, while still occurring widely in a variety of rainforest types, occupy an increasing range of habitats, including wet and dry eucalypt forests and woodland, littoral woodland dominated by *Banksia*, brigalow-softwood scrub, heathland, edges of mangroves and paperbark thickets, and are widely found in parks and gardens of urban areas. In the far south, the nominate race is largely restricted to temperate rainforest dominated by lilly pilly (*Acmena smithii*),

and to wet sclerophyll forest, with some records in other forest associations.

General Habits

Honeyeaters are a highly conspicuous and characteristic element of the avifauna of Australia, New Guinea and the islands of Wallacea and the south-western Pacific. They are diurnal, and overwhelmingly arboreal. Only the Australian chats are primarily terrestrial, but they are currently treated as constituting a separate family, the Epthianuridae. Most honeyeaters are also bold, conspicuous and noisy. As well as comprising a major component of the dawn chorus, honeyeaters tend to vocalize much throughout the day (see Voice), often singing or calling from conspicuous perches or in song flights. A few species, however, are shy and wary. The Mao of Samoa is wary and inconspicuous, and is heard more often than it is seen, as is the Crow Honeyeater.

Most meliphagids are typically seen singly or in twos, which are often probably paired individuals, or in small family parties. Many sedentary species remain in permanent all-purpose territories throughout the year, although others can be dispersed in loose colonies, and the co-operatively breeding miners and Yellow-tufted Honeyeaters maintain large and stable colonies throughout the year. Other species maintain breeding territories only during the breeding season, the area defended varying from an all-purpose territory to a smaller nesting territory. While many species of honeyeater will defend food resources, during both the breeding and the non-breeding periods, they may also congregate in numbers at abundant resources, such as in flowering trees or, occasionally, to exploit insect resources, such as swarms of ants (Formicidae) or termites (Isoptera). Honeyeaters often associate with other nectarivores, such as lorikeets (Psittacidae), when foraging at sources of abundant nectar. Such congregations can often involve much intraspecific and interspecific agonistic behaviour, as birds attempt to defend part or all of the resource (see Food and Feeding).

Some species are regularly seen in flocks or groups throughout the year, this being characteristic of the miners, whereas others may associate or move about in loose flocks during non-breeding periods. Many of the large friarbirds and the tiny

Nectarivory is not always straightforward for meliphagids. Short-billed species such as the **White-gaped Honeyeater** of north Australia may have problems with flowers that have a long anther. This honeyeater has two options. It can insert its bill deep into the flower to reach the nectar source or can move to the flowers of a more accessible species. The White-gaped Honeyeater typically forages in dense vegetation, particularly on trunks and branches, but readily emerges into the open when visiting flowering trees or shrubs. This species regularly forages singly, in pairs or in small groups.

[*Lichenostomus unicolor*, Darwin, Northern Territory, Australia.

Photo: Peter Fuller]

myzomelas are commonly seen in loose flocks. In Australia, migratory Yellow-faced and White-naped Honeyeaters may gather into large flocks, although flocks are more usually fairly small. During both the autumn–winter northern passage and the winter–spring return to south-eastern Australia, Yellow-faced Honeyeaters are seen mainly in flocks, typically of up to about 100 individuals, occasionally more and exceptionally as many as 1000, although the average size of flocks in the Australian Capital Territory on northern passage was of 23.3 individuals, and the average flock size in Brisbane during southern passage was of 35 birds. These migratory flocks of Yellow-faced Honeyeaters are loose units that merge with other flocks, and individuals or small groups leave or join them. Yellow-faced Honeyeaters often migrate in mixed flocks with White-naped Honeyeaters, which themselves form flocks of hundreds, and sometimes even thousands, of individuals on northward migration, but are usually in smaller and more dispersed flocks on southern passage. In Australia, many species of honeyeater are occasional members of mixed-species foraging flocks, and others are more regularly in such flocks. For example, the Rufous-banded Honeyeater is often found in mixed flocks, particularly with its congener the Rufous-throated Honeyeater. In north-east Australia, B. Sage reported on mixed-species foraging flocks of honeyeaters at two sites. At one site, the flock consisted of 40–45 honeyeaters of six species, in six genera, with Banded Honeyeaters the most numerous, with about 25 individuals, and other species including Yellow-tinted, Brown, Black-chinned and Rufous-throated Honeyeaters and the Little Friarbird. The flock moved rapidly through the woodland, appearing to feed mainly on invertebrates.

In New Guinea, both species of *Timeliopsis* straightbill occur in mixed flocks. Tawny Straightbills are often in foraging flocks in which either the Rusty Pitohui (*Pitohui ferrugineus*) alone or Rusty Pitohuis and New Guinea Babblers (*Pomatostomus isidorei*) are nuclear species, other common flock-members including New Guinea Cuckoo-shrikes (*Coracina melas*), Spangled Drongos (*Dicrurus bracteatus*) and Sooty Thicket-fantail (*Rhipidura threnothorax*); such flocks had an average of 1.8 straightbills. When these straightbills forage with New Guinea Babblers, they are an integral part of the flock and behave more like a babbler than like a honeyeater. On Sulawesi, both species of the endemic genus *Myza* occasionally join or forage at the edge of mixed-

species flocks of Sulawesi Leaf-warblers (*Phylloscopus sarasinorum*), Citrine Canary-flycatchers (*Culicicapa helianthea*), whistlers (*Pachycephala*), white-eyes of the genera *Zosterops* and *Lophozosterops*, and fantails. New Zealand Bellbirds, too, are often found in mixed feeding flocks, and on Little Barrier Island, off the North Island, female bellbirds often associate with mixed-species feeding flocks of insectivores, which are often dominated by Whiteheads (*Mohoua albigilla*). Bellbirds often associate also with Tuis and Stitchbirds when foraging.

Most species respond to playback of their vocalizations, and often respond well to human imitation of their calls, or to “squeaking” or “pishing” sounds that somewhat resemble scolding alarm calls. On Karkar Island, off New Guinea, for example, the Scarlet-bibbed Myzomela always responded to squeaking and pishing, and at sites above 1350 m six or so individuals of this species invariably approached, followed, and flew from perch to perch around observers.

With a few notable exceptions, the displays of honeyeaters have not been methodically studied and described. K. Immelmann discussed the social and breeding behaviour of several Australian honeyeaters, but his study was of short duration and contains many generalizations. Nevertheless, the repertoire of displays of many species appears to be fairly simple. One exception is that of the colonially and co-operatively breeding miners, which exhibit a complex array of agonistic, submissive and sexual behaviour, as could be expected in their complex social systems. For example, in his examination of displays of the Noisy Miner, D. D. Dow described three flight displays, eleven postural displays and three “facial displays”, two of which involve the open bill and, in one case, the tongue, and “eye displays”, which involve a change in apparent size of the yellow facial patch behind the eye. Many of these displays indicate threat, dominance or submissiveness. New Holland Honeyeaters, which can similarly show complex social interactions in both breeding and non-breeding seasons, also have a wide range of displays, including threat and submissive postures.

Song flights are a conspicuous aspect of the behaviour of a diverse range of meliphagid genera and species, including, among others, some *Lichenostomus*, such as the Grey-fronted Honeyeater, *Phylidonyris*, and six species in monotypic genera, namely the Tawny-crowned Honeyeater, the Spiny-cheeked Honeyeater,

the Black Honeyeater, the Pied Honeyeater, the Striped Honeyeater, and the Painted Honeyeater. The song flights of the three *Phylidonyris* species, particularly those of the White-cheeked and New Holland Honeyeaters of eastern and southern Australia, are among the better known. During the breeding season, male White-cheeked Honeyeaters fly high above their nest-sites, giving full flight song near the apex of the flight, and then descend rapidly, with wings held closed, before spreading the wings when close to the ground and gliding to the top of a shrub or tree; the bird may also give a few chirps and whistles as it ascends. These song flights are thought more likely to be sexual advertising displays than to be territorial displays. The frequency of song flights varies both with the stage of breeding and individually; in north-east New South Wales in May, the birds performed 37 song flights per hour, and the rate did not alter significantly with time of day. Tawny-crowned Honeyeaters, in the genus *Gliciphila* but formerly placed in *Phylidonyris* (see Systematics), perform similar aerial displays during the breeding season, when they fly almost vertically while calling strongly and then, when 10–30 m above the ground, descend in a swift glide, at first steep and then flattening out, before alighting on a prominent perch; the descent has been described also as slow and spiralling, unlike that of *Phylidonyris*, the song flight of which the Tawny-crowned Honeyeater's otherwise resembles.

Song flights seem to be less common in New Guinea than in Australia and New Zealand. This difference appears to be real, and is possibly related to the densely forested habitats that predominate in New Guinea, although it is possible that it may, rather, reflect the number of observers and the range of studies conducted there. Nevertheless, the Streak-headed Honeyeater is known to have a song flight in which the bird rises above the forest canopy and descends, singing throughout, to a prominent exposed perch, behaviour which was noted as unusual in the region. This species, however, is known to sing in flight and from high exposed perches.

Corroborees are a complex type of social behaviour, seen best in the miners and in the *Phylidonyris* and some *Lichenostomus* honeyeaters. The word "corroboree" is taken from the Aboriginal term for a festive gathering or ceremonial dance. In corroborees, up to twelve or more birds gather in a tight group, with much calling and wing-fluttering. The possible functions of this behaviour include defence against predators and conspecific

intruders, or it may even represent a show of togetherness by members of a group. Among New Holland Honeyeaters, corroborees are usually initiated by a submissive individual in the presence of a more dominant one, and these are typically joined by others, all usually males; the birds perch closely together, repeatedly giving a special call while fluttering their wings and tail, and adopting a bowing posture, with the breast lowered, the tail raised and the head and bill tilted upwards. As display intensifies, all of the birds move closer until the heads and bodies are oriented towards one another, and more birds may join the group. The corroboree is usually of brief duration, some 5–10 seconds, and it may continue between two individuals while others move away; alternatively, the focus may shift among individuals, or the display may lead to subgroups forming, in which some of the group orient and display towards one bird while others direct their attentions towards another. Among Noisy Miners, corroborees appear to function in greeting and in rallying to maintain aggression against interspecific intruders and predators. They last for up to 30 seconds, and are performed whenever several miners meet, usually involving 5–10 individuals, but from as few as two to 40 or more. Once a corroboree starts, others join in, all birds focusing on an individual by directing the head towards it, and in larger corroborees, of 10–25 or more birds, there can be several focal individuals. The focus of attention often changes, especially in larger groups. These ceremonies occur almost anywhere, from the ground to the canopy, and prominent places, such as large exposed branches and dead trees, are used repeatedly; they are often performed at empty nests. Corroborees are performed also by Tuis, when groups of 5–7 individuals, typically males, sometimes accompanied by their mates, gather on branches 1–2 m from the ground at the intersection of several territories. Typically, two or three Tuis face each other while perched less than a metre apart, and sing vigorously, while others watch in silence; such corroborees can last for up to 10 minutes, during which time those Tuis not singing leave. Corroborees by this species are seen only at the start of breeding, and are thought to function in the maintenance of territories.

Honeyeaters are noted for being highly aggressive and pugnacious, both when breeding and when defending food resources in the non-breeding period. Aggressive interactions between individuals, whether of the same species or of different species, are often, however, fairly simple. The most commonly observed ago-

It is thought that many nectar-rich species of flower are bright red so as to attract birds and other potential pollinators. It is certainly true that honeyeaters often visit red flowers, but many in both Australia and New Guinea feed at flowers that are white, cream-coloured or yellow. An example is the bottlebrush (*Callistemon*) tree at which this **Yellow-tinted Honeyeater** is feeding. Dexterity is a common behavioural characteristic among the Meliphagidae, but this species edges towards the acrobatic when foraging, often hanging upside-down when clinging to inflorescences.

[*Lichenostomus flavescens flavescens*, Derby, Western Australia, Australia.
Photo: Don Hadden]

The diminutive members of the genus *Myzomela* are primarily nectarivorous, even in the New Guinea rainforests where such a practice is comparatively rare among meliphagids.

The **Dusky *Myzomela*** prefers to forage in the forest canopy but also descends to lower levels where it readily probes flowers for nectar. There is some evidence that this species may vary its foraging height through the seasons, birds in north-east Queensland feeding lower in the dry season. The species visits a wide range of flowers, feeding actively and acrobatically, even hanging upside-down, if necessary.

Dawn Frith]

nistic interactions, both within and between species, are simple displacements, in which the attacking bird lands on or near a perch vacated by the bird attacked, or chases, whereby the attacked bird is pursued beyond the point at which it takes off. These interactions are common in defence of food resources, but they are also part of broader territorial behaviour at the start of and during the breeding season. In coastal eastern Australia, the White-eared Honeyeater defends permanent territories throughout the year, but, at the onset of breeding, males determinedly chase other species of honeyeater, and any conspecifics that may intrude on a territory – a rare event – at much higher rates than they do at other times of the year. The territorial male can be perched and alert, and then, suddenly, fly 100 m and more in order to displace or chase, for example, a Yellow-faced Honeyeater, ignoring other individuals of the same species much closer. This increased rate of almost indiscriminate attack was found to be a good indicator that pairs had started or were about to start nest-building for the first clutch of the year. On arrival in an area and before breeding, male Black Honeyeaters often chase one another in rapid flights, one behind the other, until territories are established, after which intruders on territories continue to be chased.

Rarely, aggressive interactions escalate to fights, both within and between species. Using the bill or feet, or both, the individual grapples with an opponent and wrestles it from a perch or impedes its movement, and at least sometimes these fights result in physical injuries. Fights with the bill usually involve the grabbing of an opponent's bill, although the honeyeater may also peck at its legs and feet or breast. When fighting with the feet, the attacker grasps at its adversary's breast or other parts of the plumage, or tries to grapple with its opponent's legs or feet. A combatant will sometimes try to place a foot over that of its opponent, clamping it to the perch. When fighting on perches, the birds sometimes fall to the ground, locked together by their feet or bills.

Bill-pointing, or variations of it, is a type of behaviour common to many species of honeyeater. In territorial interactions, usually at territory boundaries, White-eared Honeyeaters often chase one another. It was observed that, on alighting in a tree, they would sometimes face each other, often on a vertical or downward-sloping branch, one bird facing down and the other up, each reaching out and pointing the closed bill at the other, the bills occasionally coming into mutual contact. The pointing display of Noisy Miners is similar, the miner, with the plumage of the

head, neck and underbody sleeked, stretching its neck out and pointing the closed bill at a target individual; at high intensity, the wings are held tight against the body and bill-snaps may be given. With Noisy Miners the angle of the body varies with the substrate, but is most often horizontal.

While aggression is typically associated with defence of breeding territories or food resources, the reasons for observed aggressive behaviour are on some occasions enigmatic. For example, on Seram, in mid-August, a Seram Friarbird was seen to attack a pair of Moluccan Red Lories (*Eos bornea*) which was inspecting a nesting hole. On three occasions, while one lory was inside the hollow and the other perched just outside, a friarbird that had been calling from a neighbouring tree persistently swooped at the lory, which ducked its head with each swoop. On the third occasion, the swooping was even more vigorous and the friarbird struck the lory on several occasions. The lory was pushed along the branch away from the hole, and it uttered alarm calls before flying off, followed by the second bird, which had been inside the hole. On the following day the lories were again at the hole, and a Seram Friarbird was heard to be calling some distance away. It was suggested that the attacks were possibly some form of territorial defence, but the lories were not feeding and could not have posed any competitive threat to the friarbirds. In this instance, the latter's aggression appears rather indiscriminate.

Activity budgets of honeyeaters for behaviour other than foraging have not been well described, but some general summaries can be presented. Studies near Sydney, in south-eastern Australia, in the autumn and winter months, revealed that Little Wattlebirds spent only 8.5% of their time in foraging but 81% in perching, while vocalizing accounted for 2.5% of their time and preening 1.5%, the remaining 6.5% being taken up by flight. The respective figures for New Holland Honeyeaters were 10.5%, 76%, 1%, 1.5% and 11%. In contrast, the time spent in foraging by these two species in Victoria was very different: Little Wattlebirds devoted 42% of their time to foraging for nectar, and New Holland Honeyeaters spent 45–93% of their time in foraging for nectar. During an irruption of Painted Honeyeaters in northern New South Wales, during October and December, this species spent 43% of its total time in foraging, 31% in resting, 10% in flying, 8% in preening, 5% in vocalizing and 3% in involvement in aggression. These gross differences in time spent in various activities may be related to the food resources being utilized and to the season, but

Unlike hummingbirds (*Trochilidae*), honeyeaters tend not to hover when feeding at flowers. Indeed, only three genera do so, namely *Acanthorhynchus*, *Myzomela* and a single member of *Lichmera*. These birds are probably able to do so because they are sufficiently small that hovering provides an energetically cost-effective means of accessing nectar sources at the edge of a plant. The **Scarlet Myzomela** usually probes for nectar from a perched position, but may sally-hover to gain access to inconveniently located flowers. Being small, this species is often chased away from flowers by larger family members.

much further study is needed. It has been found that Eastern Spinebills, when nectar is abundant, devote more time to perching and less time to probing inflorescences and moving around.

It is likely that all meliphagids bathe, although there are no published observations for many of the species. Members of this family have been seen to bathe in streams, rock pools, springs, farm dams, watering troughs for stock, and birdbaths in gardens. In shallow depths they will sit or stand in the water, flapping the wings and splashing water over themselves. In deeper water they plunge-bathe, typically flying out over the surface, often hovering briefly for up to a few seconds, before dropping to the water and partly submerging, though some species submerge fully, before flying back to a perch and preening. Typically, the honeyeater enters the water only once on each sally from a perch. Often, the procedure is repeated several times. White-plumed Honeyeaters have been seen to drop from an overhanging branch into the water, often submerging completely, before flying back to the branch, shaking themselves and preening. Noisy Miners bathe by diving head first into the water and flapping the wings, thereafter flying to a perch in order to preen. With the colonial miners, bathing is performed communally, as are most other activities.

Foliage-bathing is reported for many species. Red Wattlebirds will fly into wet foliage of trees, where they flap and flop about among the leaves, shaking the body, ruffling the feathers and ducking the head for several minutes as though bathing in standing water, before flying out to a branch and preening or flying off. Similar behaviour by a Rufous-banded Honeyeater has been observed in New Guinea, the bird fluttering against leaves wet from a recent shower or through clumps of wet foliage, frequently ducking the forepart of the body and raising and fluttering the wings as if bathing in a pool. Noisy Miners and New Holland Honeyeaters also bathe in dew-laden or rain-soaked foliage, bathing often being triggered by a shower of rain. Members of miner colonies appear to be stimulated to bathe by observing the leaf-bathing of others, until large assemblages become involved in the activity. Similarly, a female Scarlet Myzomela was seen to bathe among leaves of French beans in a recently watered vegetable garden, calling as she did, before flying off to preen. While foliage-bathing is typically done in wet foliage, a Red Wattlebird once appeared to bathe in the dry foliage of a flowering *Pittosporum*, behaving much as described for bathing in wet foliage. Other sources of water are sometimes used for the purpose of bathing. A wide range of species, including the Red Wattlebird

and the Yellow-tinted and Painted Honeyeaters, has been observed while bathing under garden sprinklers, and Guadalcanal Honeyeaters have twice been seen to bathe in a puddle on a large dead branch.

After bathing, whether in free water or in foliage, birds will typically fly to a nearby perch, where they shake the plumage and preen. Among colonial species, the colony-members will preen at the same time as other members are bathing. Furthermore, Painted Honeyeaters feeding on mistletoes sporadically stretch the wings out and up and preen, apparently to remove from their plumage sticky material left by the berries. Allopreening appears not to be common among the Meliphagidae, although it has been reported for several species of *Melithreptus* and, outside Australia, for MacGregor's Honeyeater and the Crow Honeyeater, contrary to claims by Immelmann that mutual preening does not occur in the family. Nevertheless, for a number of well-studied species, including the colonial and co-operatively breeding Noisy and Bell Miners, allopreening has not been seen to occur, at least not among adults.

Dust-bathing is seen occasionally, especially during hot weather. Noisy Miners, for example, dust-bathe in dry soil or fine litter. Sun-bathing has been reported for a few members of the family at various times, the honeyeater typically lying on or leaning to one side on the ground, with one wing outstretched and raised and the plumage fluffed up, although sunning is performed also on perches. Once, two adult Spiny-cheeked Honeyeaters and two young were watched as they sun-bathed, each one leaning over sideways with one wing raised. Seven individuals of the colonial Yellow-tufted Honeyeater were seen while sun-bathing together in a group on the ground, pushing one another aside. Although meliphagids normally sun-bathe with one wing held outstretched, New Holland Honeyeaters sometimes sun themselves with both wings extended, in spread-eagle fashion.

Anting has been recorded for a number of these species. Noisy Miners indulge in this activity at least occasionally, rubbing ants through the feathers of the upperwings, breast and flanks. Similarly, Lewin's Honeyeaters have been observed while anting, once picking up ants with the bill and holding them under the wing briefly, before eating them.

So far as is known, all members of the family are diurnal, and roost at night in trees or taller shrubs. The roosting behaviour of the Meliphagidae is not well known, but there are relevant observations for a few species. Regent Honeyeaters in Australia

Honeyeaters are often important pollinators of plants whose flower morphology coincides with the birds' bill structure. The Tui of New Zealand has a stocky, slightly decurved bill, and therefore prefers to extract nectar from fairly short flowers with little curvature. The Tui feeds regularly on nectar from flax bush (*Phormium*), as here, and from *Metrosideros*, a genus closely related to the eucalypts (*Eucalyptus*) that are so important for many Australian meliphagids. There are sexual differences in the Tui diet at particular seasons, even where the sexes feed together. In spring and autumn, the dominant males feed more extensively on nectar than do the females.

Photo: Neil Fitzgerald]

roost in densely foliated trees, saplings and shrubs, and non-breeding individuals often roosted communally in large flocks of 30 or so, although they appeared not to huddle together. In May, in eastern New South Wales, some 100–150 Regent Honeyeaters arrived at roosting sites in the Howes Valley in groups of 6–15 individuals 40–50 minutes before sunset; they would then fly off and feed elsewhere before eventually gathering into several large flocks, which finally settled after sunset, the birds roosting together in single trees or splitting up and roosting in several trees or a small stand of saplings, between 2 m and 22 m above the ground. By late May, and later in the year, in August and October, they roosted in smaller groups and often far apart from each other. Regent Honeyeaters are also one of the first species to cease activity and go to roost in the evening and one of the last species to leave the roost in the morning; in the Howes Valley, they arrived in the period from 11 minutes before sunset to 18 minutes after it, and in the morning they left the roost 15–29 minutes before sunrise, taking 4–8 minutes to leave the site. Detailed observations of this species elsewhere in eastern Australia produced findings similar to these. White-plumed Honeyeaters are active and vocal at dusk, and fly back and forth between several trees, occasionally perching, but not foraging, before flying off again, finally going to roost almost at nightfall. Family groups or fledglings are known to roost together, and breeding females often roost on the nest at night during the breeding season. After fledging, family groups of co-operatively breeding Brown-headed Honeyeaters have been seen to roost on thin twigs in foliage, usually near the top of eucalypt crowns, side by side and touching each other, but facing in different directions. The birds arrived at roosts quickly, but sometimes the group disbanded and moved off to a nearby tree or branch, before reassembling at a roost. Adults took up outer positions after the juveniles had settled. In New Zealand, newly fledged Tuks have been seen to roost together in a tree, although the siblings later roosted apart.

There are also many anecdotal reports for a number of species indicating that these tend to roost in shrubs or trees. For example, Red Wattlebirds have been observed at roost in trees along a stream, and at another site, when returning to roost in the evening, the birds always followed one another from tree to tree, using the same route. Similarly, Little Friarbirds have been seen to roost in flocks in small trees. During an irruption of Tawny-crowned Honeyeaters in forest near Manjimup, in Western Australia, most of these birds roosted in karri (*Eucalyptus*

diversicolor) regrowth saplings at night. Resident New Holland Honeyeaters foraged away from a gulley during the day, but returned there in the afternoon and roosted there at night. In American Samoa, groups of Cardinal Myzomelas have been seen to fly above the forest canopy at dusk as they moved from foraging sites in mangroves or agro-forests to presumed roosting sites in native rainforest. Similarly, in north-western Australia, a flock of 500 Little Friarbirds was recorded flying from inland roosting sites towards mangroves in the mornings and returning in the evenings.

Honeyeaters are typically active early in the morning, and many species are conspicuous and early contributors to the dawn chorus throughout their range (see Voice). While there has been some examination of morning calling, however, there have been few studies of waking and departure from roosts, or of resting during the day (see activity budgets, above). Some species, such as the Brown Honeyeater, have been observed while basking in the sun in early mornings and late afternoons during the winter months. Most members of the family appear to rest during the day in shady foliage of shrubs and trees. Brown Honeyeaters, for instance, rest during the hottest part of the day beneath dense foliage, and at 41°C the birds often pant with the mouth held open and can become slightly hyperthermic. Occasionally, honeyeaters rest elsewhere. On a day with temperatures of about 46°C in north-western Victoria, nine species of passerine, including Purple-gaped, White-plumed, Spiny-cheeked and Yellow-plumed Honeyeaters, were found to be sheltering in thick accumulations of bark, branches and other macro-litter around the bases of mallee eucalypts.

Meliphagids have been seen to drink from creeks, streams, water seepages, waterholes, various water sources on farmland and dripping taps, and they sometimes visit water in small flocks or congregate at water sources. For example, eight Striped Honeyeaters drank together at a farm dam, and gatherings of up to 50–60 Eungella Honeyeaters have been seen to use puddles for both bathing and drinking. In arid parts of Australia, Spiny-cheeked Honeyeaters drank mainly in the early hours of the morning and in the afternoon, with numbers drinking in the afternoon much lower than those during the morning peak, and few individuals came to drink at other times of the day. At a water tank at Wiluna, in Western Australia, as many as 1500–2000 visits by Spiny-cheeked Honeyeaters were counted during the first two hours of the day.

Voice

The vocalizations of the honeyeaters are incredibly varied, as could be expected with such a large and diverse family. The few generalizations that can be made are that many species have loud, strong and clear vocalizations and, more subjectively, that vocalizations of only a small proportion would be called musical or melodious, although some are. There appear to be few commonalities among genera, although the qualities of some calls within the repertoires of species can be similar, such as the scolding alarm calls of the *Lichenostomus* and *Meliphaga* honeyeaters, which are shared also by other species. Vocalizations range from the loud, harsh and guttural coughs, croaks and squawks of the *Anthochaera* wattlebirds, and the slightly more melodic but still loud and explosive rollicking vocalizations of the friarbirds, to the clear, rising and falling, tinkling bell-like songs of the Scarlet Myzomela, and similar songs of other *Myzomela*, the simple, ethereal and plaintive flute-like whistled songs of the Tawny-crowned Honeyeater, and the plaintive, mournful or piercing drawn-out piping song of the Pied Honeyeater.

A number of meliphagids have ringing or bell-like calls or songs, such as the soft but penetrating, ringing, swelling and slurred syllables of the song of the Regent Honeyeater. The main call of the Bell Miner is a musical bell-like "tink", which is uttered almost incessantly throughout the day by members of the colony. The sound from the whole colony, with individual calls not all of the same tone, ring beautifully through the forest, and Bell Miner colonies produce one of the better-known sounds of the Australian bush. On Viti Levu, in Fiji, the characteristic loud, ringing "keekow" or "kee-yow" calls of Giant Honeyeaters, usually run together in series or repeated monotonously, combine to create a loud yodelling cacophony that reverberates through the forest and can be heard from over 1 km away. Other species have more complex repertoires, with a range of rich and varied songs, such as the Black-chinned Honeyeater and Spiny-cheeked Honeyeater of Australia, and the two endemic New Zealand honeyeaters, the Tui and the New Zealand Bellbird, are classed among the world's best songsters on the grounds of the pureness of tone and the complexity of their vocalizations. The New Zealand Bellbird, as its name implies, has a complex and varying song, the notes like the tolling of a distant bell. Its dawn song

consists of pure bell-like notes, occasionally interspersed with quieter notes, repeated monotonously for up to 40 minutes, and the full song includes bell-like notes as well as "chunks", "clonks", harsh "jars", and quiet notes. The songs of Tuks are loud, rich, complex and highly varied, and include rich, liquid warbling notes, deep bell-like "bongs", chimes, cries, sighs, gurgles, whistles, coughs and wheezes.

Others have much simpler vocalizations and repertoires. Lewin's Honeyeater is a commonly heard species of eastern Australia, with a simple repertoire. The main adult call, the "Rattle", is chatter or rattle consisting of rapidly repeated staccato notes or syllables, like the sound made by a machine-gun. The only other calls which this species is known to make are a repeated, loud and harsh scolding "schwep" in alarm, typical of *Meliphaga* and *Lichenostomus*, and, very occasionally, a slow, single-note "toc" or "chot", repeated rather slowly and monotonously at regular intervals, like a slow version of the rattle call. Similarly, the Tawny-crowned Honeyeater appears to have a fairly simple repertoire, consisting of a whistled song, a mournful call, and one or two alarm or distress calls.

There have been few detailed studies of the vocalizations of the honeyeaters, and much of our knowledge of individual species comes from a diverse range of anecdotal reports. Most of those studies that have been conducted have been in Australia and New Zealand, although Diamond and others have reported on the duetting of a variety of New Guinea and Pacific Ocean species. The vocal, as well as visual, mimicry of friarbirds by orioles has also been widely described; this is discussed in more detail at the end of this section. Unfortunately, the distinction between songs and calls in the Meliphagidae has not been examined, and there is little uniformity in application of the terms to the various genera and species in the family. Definitions used, if considered at all, vary and, more often than not, the term "song" is used on the basis of the melodiousness of a vocalization, harsher and simpler vocalizations being labelled "calls" and the more musical and pleasant sounds labelled as "songs". Alternatively, the term "song" is used for one or several of the more complex vocalizations within the repertoire of a species, or the most common vocalization is thus labelled. This is far from satisfactory, but it is not a problem confined to the Meliphagidae.

Within Australia and New Zealand, a few species have been well studied, and their repertoire described in detail. These include two sibling species of *Lichenostomus*, the Yellow-throated Honeyeater of Tasmania and the White-eared Honeyeater of eastern and southern mainland Australia, the two forming a superspecies, and another *Lichenostomus*, the White-plumed Honeyeater, as well as two of the four miners, the Bell and Noisy Miners, and the New Holland Honeyeater. M. A. Jurisevic and K. J. Sanderson also conducted a detailed study of the vocal repertoire of six species of honeyeater from South Australia, namely the Red and Little Wattlebirds, the Noisy Miner, and the White-plumed, New Holland and Crescent Honeyeaters. Separately, they also examined the alarm vocalizations of these and other species. In New Zealand, the vocalizations of both the Tui and the New Zealand Bellbird, while not the subject of detailed contemporary studies, are nevertheless well known. The *Handbook of Australian, New Zealand and Antarctic Birds* presented detailed summaries of vocalizations of all the Australian and New Zealand meliphagids, and wherever possible included sonagrams of at least some vocalizations. The White-eared Honeyeater was found to have a repertoire of eight fairly loud and distinctive calls, although several of these were used only infrequently. The most commonly used calls were the "Chew call" and the "Two-note call", both of which are loud and appear to be utilized in the same circumstances; "Clock calls", "One-note calls" and "Scolding" also were used often, but less so than were chew and two-note calls; and the "Rapid Clock", "Trill" and "Chip" calls were used only infrequently. Most of these calls consisted of a varying number of repeats of a single distinctive syllable, both chew and two-note calls, for example, consisting of syllables repeated up to six times. Similarly, the Yellow-throated Honeyeater was found to have eight calls. At least some of these vocalizations sound very similar to those of the White-eared Honeyeater of the mainland, and comparisons of sonagrams show that the main calls of

Plants use nectar to attract pollinators. Honeyeaters, however, do not always reciprocate. Whereas the Brown Honeyeater is morphologically suited to feed on the tubular flowers of Eucalyptus stoatei and thus acts as a pollinator, it is not deterred by less conveniently shaped flowers. In such instances, honeyeaters may engage in nectar thievery, piercing the base of the flower to extract the nectar. As the birds do not brush against the stamen or stigma, they do not contribute to the pollination process.

[*Lichmera indistincta* indistincta, Katherine, Northern Territory, Australia.
Photo: Roland Seitre]

In terms of diet, members of the genus *Xanthotis* are generalists. **Macleay's Honeyeater** is primarily insectivorous, but will also take fruit and nectar, for instance from native bottlebrush (*Callistemon*) trees. The species forages at all levels of its forest habitat, but is most frequently encountered in the canopy. Whilst usually an active yet unobtrusive feeder, Macleay's Honeyeater can become rather noisy when feeding among dead leaves, a niche that it regularly exploits. The species usually feeds alone or in pairs, but sometimes forms groups of up to 30 individuals.

[*Xanthotis macleayanus*,
Atherton Tableland,
N Queensland, Australia.

the two are similar in structure and composition. Sonagrams of two-note calls of White-eared Honeyeaters and "Breeding Songs" of Yellow-throated Honeyeaters are very similar in appearance, both consisting of two-note syllables and both given during the breeding season. White-plumed Honeyeaters were found to have a repertoire of two calls, including the chip call and three types of "Alarm Call", and three types of song, one of which varies between sites and has two or three variants at any one site. The New Holland Honeyeater has a repertoire of seven main calls, dominated by simple, single-note calls.

Bell Miners have been the subject of several detailed studies, and have a considerably more complex range of calls. A total of 18 adult vocalizations and four juvenile calls has been distinguished, all of which could contain harmonics. Many of these calls, however, have a range of variants; for example, the chip call had five distinguishable variants, making the overall repertoire considerably larger. Noisy Miners, too, have a varied repertoire of loud and penetrating calls, whistles and scolding calls; one study recognized twelve separate vocalizations, and other work identified a further two. In addition, Noisy Miners perform a complex dawn song, which may, incidentally, be given also at dusk. This is composed of, or at least includes, a variety of individual vocalizations and possibly other clear whistled notes; it is delivered by single individuals but more usually is given communally, when it often involves antiphonal singing.

Much work has been done also on the alarm vocalizations of honeyeaters, and other birds, in Australia. Jurisevic and Sanderson examined the alarm vocalizations of twelve species of honeyeater, along with a range of other species. They recorded two basic types of alarm call: the first involved harsh and nasal, broad-frequency (1–10 kHz) calls, of several types, including chattering calls, which allow for interspecific and intraspecific communication, easy location and long-distance transmission; and the second narrow-frequency (1–5 kHz) whistled and tonal calls, the whistles usually descending, emitted as rapidly repeated staccato notes. The White-plumed and Yellow-plumed Honeyeaters and the Noisy and Bell Miners had several types of broad-band call. Some congeneric species had very similar alarm calls: the White-plumed, Yellow-plumed and Singing Honeyeaters, in *Lichenostomus*; the Noisy, Yellow-throated and Bell Miners, in *Manorina*; and the New Holland and Crescent Honeyeaters, in

Phylidonyris. Other species that gave broad-band calls were Lewin's Honeyeater, the Red and Little Wattlebirds and the Noisy Friarbird. The broad-band calls were given in response to avian and other threats which were on the ground or perched, or during mobbing, but they were not recorded as a response to birds of prey or other large birds in flight, unless the meliphagids were mobbing these. Seven species of honeyeater gave narrow-frequency calls. These were the White-plumed and Yellow-plumed Honeyeaters, the Red Wattlebird, the Noisy and Bell Miners, and the New Holland and Crescent Honeyeaters. These species emitted narrow-band calls in response to flying threats or potential threats, such as birds of prey or other large birds, and apparently also when surprised by a potential threat, whether in flight or on the ground. Some narrow-band calls appeared also to provide warnings to other species. For example, the whistled alarm calls of New Holland Honeyeaters would cause European Goldfinches (*Carduelis carduelis*) and White-plumed Honeyeaters, the former an introduced species, to fly for cover, and Crimson (*Platycercus elegans*) and Eastern Rosellas (*Platycercus eximius*) would do the same in response to the tonal alarms of Noisy Miners.

Nearly all information on the possible functions of the various vocalizations of honeyeaters are the result of observational studies, supplemented with many claims in anecdotal reports, the latter usually with little evidence. The main vocalizations, however, appear to function in the defence of a range of territories, associated with aggressive behaviour, ranging from the short-term defence of resources, such as individual flowering plants or even parts of the crowns of flowering trees, to the defence of large and permanent territories or the colonial defence of large areas by species such as the miners. They are sometimes associated also with courtship behaviour. Similarly, song flights, which are performed by a number of species (see General Habits), appear to function in territorial defence, as well as being implicated in courtship behaviour.

The "Tink call" of the Bell Miner, as well as being a contact call among members of the colony, and possibly an alarm call, appears to function as an interspecific territorial call, deterring other species from entering miner colonies. When the sound of a Bell Miner colony was played at sites without Bell Miners, but where colonies of the latter were nearby, other bird species reduced their calling, which was consistent with the silent behav-

The only member of its genus, the **Wattled Honeyeater** is primarily nectarivorous, feeding on a variety of flowering trees, shrubs and palms.

Its target blooms differ wildly in size: those of the nutmeg *Myristica inutulis* are very small, in contrast to the large and splendid flowers of the coral tree (*Erythrina variegata*). The Wattled Honeyeater has also learnt to make use of non-native plants such as banana (*Musa*), coconut palms (*Cocos nucifera*) and, as here, torch ginger (*Etlingera elatior*), a plant native to South-east Asia and the Greater Sundas but now widely cultivated in Fiji.

[*Foulehaio carunculatus*,
Fiji.
Photo: Tim Laman]

four of birds of other species that attempted to intrude into Bell Miner colonies. These intruding birds, however, did not leave the site, which indicated that the eviction of other species from miner colonies probably requires additional stimulus, such as chasing or other aggressive behaviour. Probably all meliphagid species give alarm or distress calls, the function of which is self-explanatory. At least some species appear to have separate alarm calls for aerial and terrestrial predators. For instance, in response to aerial predators Bell Miners give the "Eek" call and Noisy Miners the "Aerial Predator Alarm", whereas ground predators elicit from these respective species the "Mmm call" and the "Chur call". Alarm calls often draw other honeyeaters towards the caller, which may then lead to mobbing of the predator or corroborees (see General Habits), or both. The "Wheek call" of Bell Miners is often given after an alarm, and may attract birds to a mobbing event, but they utter a separate call, the "Waw", when actually mobbing a bird. Whereas nestlings and fledged juveniles tend to give distress calls when handled, adult honeyeaters are typically silent in the hand.

Other vocalizations are commonly considered to be contact calls, between members of a pair or among colony members, and many species, especially migratory ones, such as the White-naped and Yellow-faced Honeyeaters, have characteristic flight calls. The colonial Bell Miner commonly gives the wheek call at dusk, individuals often uttering it continuously while flying to a roosting site, and this call is thought possibly to assist in co-ordinating roosting.

At least some species have specific calls associated with communication with nestlings or fledglings. As an example, the "Mew call" of Bell Miners is given mainly by the adults when with young. With this species, the mew elicits a begging response from the young, and this has been confirmed by call playback, but it is used also to induce another adult to leave the young when the caller is approaching, to signal to other birds that the caller is

leaving the young, to encourage nestlings to leave the nest, and to lead fledglings away from danger. Nestlings and recently fledged juveniles usually have specific begging calls, typically simple whistles or piping notes. Nestling Bell Miners have a begging call, the "Sceet call", that is different from that of fledged juveniles.

For most species, there appears to be little or no difference in vocalizations between the sexes, although, as with many other aspects of meliphagid biology and ecology, relevant observations and, especially, interpretation of anecdotal reports are hampered by the lack of conspicuous differences in morphology between the sexes. Nevertheless, some species do have sex-specific vocalizations. Of the 18 adult vocalizations of Bell Miners, six were given only by females, mainly during the courtship period and not in the non-breeding period or when attending nestlings; one or, possibly, two were given only by males. Further, while the New Zealand Bellbird's song varies greatly, the song of the female is distinguishable from three types of song given only by males. Even with vocalizations given by both sexes, there may be differences in pitch between the two. Again, the bellbird provides a good example of this: on Three Kings Islands, north of the North Island, both male and female have the same harsh call note, but that of the female is a little higher-pitched. Among species for which there are no apparent differences between the sexes in the sounds uttered, it appears that in some cases there are differences in the frequency of use of different sounds, or in the circumstances of their use. Although there are few quantitative data, males of at least some species, examples being the Scarlet Myzomela and the Black Honeyeater, appear to vocalize more than do the females, but such observations are, of course, more easily made for plumage-dimorphic species, such as many myzomelas. On the other hand, female New Holland Honeyeaters were found to be usually more vocal than were the males, especially during the early stages of breeding, although song flights, which are conspicuous, are performed only by males.

Most members of the family show diurnal and seasonal variation in rates of vocalizing, although some appear to exhibit little variation in this respect. The Bell Miner, for example, appears to call throughout the day, though there may be quiet periods in colonies, and calling seems not to vary seasonally. A few species, such as the Tui, not uncommonly sing on moonlit nights. Keast has conducted several studies examining diurnal rates of singing, with most data from the Hawkesbury River in New South Wales, in south-eastern Australia, and some comparisons with data from the Northern Territory, in northern Australia. Several species of honeyeater were major contributors to the dawn chorus, and included the Little Wattlebird and Yellow-faced Honeyeater on the Hawkesbury River, and the White-gaped and White-throated Honeyeaters in the Northern Territory. The rates of singing of these species in spring, however, varied much through the day, the Little Wattlebird and the White-gaped Honeyeater calling much less after sunrise, whereas the Yellow-faced and White-throated Honeyeaters continued to call intermittently throughout the day. On the Hawkesbury River, in October, Little Wattlebirds began vocalizing 28–23 minutes before sunrise and continued to sing until about five minutes after sunrise, with a peak of singing during the 20 minutes preceding sunrise. Thereafter, only sporadic and brief bursts of song were heard from wattlebirds during the rest of day, but with a resurgence before sunset. In comparison, at the same site and time, Yellow-faced Honeyeaters began their dawn song within a few minutes of the first calls of the dawn chorus, 35–20 minutes before sunrise, and stopped singing suddenly, 14–8 minutes before sunrise; thereafter, they uttered daytime song throughout the day but at low rates, with slightly higher rates in the first hour or so of daylight and again towards sunset.

In a separate study, in north-east New South Wales, in May, Little Wattlebirds apparently defending feeding territories were found to call throughout the day, with highest rates of calling in the morning and lower rates at midday and in the afternoon. This recorded decline in vocal activity from the morning to the afternoon was possibly related either to re-establishment of feeding territories in the early hours or to a decline in the standing crop of nectar during the day.

The Blue-faced Honeyeater, a large, distinctive meliphagid placed alone in its genus, has a very varied diet. The species probes for nectar at flowers, particularly those in the genera *Eucalyptus*, *Melaleuca* and *Grevillea*. Usually foraging in small groups, it also preys on arthropods and small lizards, and feeds on fruit from both indigenous and exotic plants. This individual is using its strong legs and powerful claws to hang dexterously from a non-native banana (*Musa*) inflorescence. It may be seeking nectar or, alternatively, insects lurking within the flower. In addition to gleaning and sallying, the Blue-faced Honeyeater also flutter-chases through foliage, pouncing on any arthropod that it disturbs.

[*Entomyzon cyanotis* cyanotis, Beerwah, Queensland, Australia.
Photo: Graeme Chapman]

Some meliphagids, particularly in Australia, are believed to be at least partially nomadic. The movements in the non-breeding season of some subspecies of the **Noisy Friarbird** are complex, but appear to be associated with the flowering of food plants, particularly members of the Myrtaceae, such as the genera *Eucalyptus* and *Angophora*, and Proteaceae, for example *Banksia* and *Grevillea*. Populations of the Noisy Friarbird race *monachus* that are migratory appear to move north through east Australia in autumn, returning south in late winter or spring. In addition to probing flowers for nectar, the Noisy Friarbird exploits another plant resource by consuming pollen. The species, like its congeners, also captures arthropods up to the size of cicadas, eats fruit, ingests lerp and manna, and probes for *Eucalyptus* sap. To add to the dietary mix, the species is reported to take eggs and nestlings of the Common Starling (*Sturnus vulgaris*) and even to capture fish up to 30 mm long. The Noisy Friarbird tends to forage alone or in pairs, but small groups are regular and larger flocks of up to 30 birds may congregate at fruiting or flowering trees. Sometimes friarbirds may feed quietly alongside fellow honeyeaters such as Red Wattlebirds (*Anthochaera carunculata*); at other times they may interact in an aggressive fashion.

Keast made some observations also on the effect of weather on calling activity during the austral summer months of December and January. He found that, for example, Yellow-faced Honeyeaters exhibited no significant differences in the amount of dawn song between fine mornings and foggy or dull mornings, but rain reduced the singing rates significantly and delayed the onset of dawn song by 15–20 minutes.

There have been few quantitative studies of seasonal changes in rates of singing. Near Sydney, the White-eared Honeyeater, while vocalizing at generally similar rates throughout the year, showed a major shift in the vocalizations used. Most significantly, the use of chew and two-note calls was inversely correlated, although the function of such a switch was not clear. The decline in use of chew calls and the increase in use of two-note calls corresponded with the beginning of breeding behaviour, and the peak of use of two-note calls was in late winter and early spring, which corresponded also with the peak of breeding. Interestingly, the Yellow-throated Honeyeater, the Tasmanian sibling species of the White-eared Honeyeater, makes a similar switch in use of the two main territorial vocalizations over the year, the "Tonk call", or "Non-breeding Song", being used throughout the year and the "Song", or "Breeding Song", used only during the breeding season. Seasonal changes in singing or in use of different types of song are often associated with breeding and the establishment and defence of territories, both breeding and feeding territories. For example, on arrival on the breeding grounds from the wintering areas, male Tuists establish territories by means of frequent and intense bouts of song, diving displays and song flights, which continue at high levels until the start of incubation. Near Sydney, between late February and late August, calling by Little Wattlebirds exhibited peaks in April, June and August, which were probably associated with the establishment of feeding territories at new sources of nectar.

Dual singing, or duetting, has been widely reported for the family, although, again, there have been few studies of the behaviour. Duetting has been reported for all or most species of the genera *Anthochaera*, *Philemon* and *Melidectes*, and for the Spiny-cheeked Honeyeater in the monotypic *Acanthagenys*. The two well-studied species of *Manorina*, the Bell and Noisy Miners, both duet, as does the Giant Honeyeater but not, apparently, the two other *Gymnomyza* species. Diamond and J. W. Terborgh described dual singing by a range of species in New Guinea and the southwestern Pacific, including the Cinnamon-browed, Belford's, Yel-

low-browed, Wattled and Giant Honeyeaters and the Helmeted and New Britain Friarbirds. Apparent duetting has been anecdotally reported for many other species. The form of duetting, however, varies among these species, and even within genera. Duets by the New Britain Friarbird were unison duets, pair-members repeatedly giving the same song nearly or exactly in synchrony, whereas Helmeted Friarbirds from Madang, of the subspecies *jobiensis*, sang antiphonal duets, the two singing different phrases alternately, although the duetting was not always tightly synchronous. Similarly, Belford's Honeyeaters perform antiphonal duets, two individuals uttering "caw" phrases in rapid and perfect alternation up to 34 times, while the perched singers face each other on a branch. Wattled Honeyeaters of Samoa and Fiji duetted, usually within a metre or two of each other on the same branch, with repeated loud, mellow notes in antiphonal patterns, although they also performed unison duets. In Australia, pairs of Spiny-cheeked Honeyeaters perform well-developed antiphonal duets while perched beside each other, one of the pair immediately beginning to call when the phrase of the other finishes. The first bird to sing points its tail towards its partner and stretches its throat until its head is straight in front of its partner, and then sings a phrase. At the end of the song phrase the second bird adopts the same posture and sings immediately. These duets are used in greeting, apparently to strengthen the pair-bond. Little Wattlebirds likewise perform antiphonal duets in the breeding season and, at least sometimes, when defending feeding territories, the duets often beginning with high-pitched metallic shrieks from the female and lower-pitched chuckling squawks from the male.

Several examples of vocal mimicry are evident within the Meliphagidae, though the function of this phenomenon is not clear. The Tui is an accomplished mimic, and is said to imitate almost every bird species that it hears, often with its own added embellishments. Domesticated individuals were reported as imitating almost every noise heard, and captives were much prized by Maori people, and were taught sentences of welcome, platitudes, and insults (see Relationship with Man). The Tui is thought to mimic the New Zealand Bellbird, especially as there are few bell-like notes in its own song in those parts of the range where bellbirds do not occur, but mimicry of the bellbirds requires confirmation. In Australia, the Regent Honeyeater is an excellent mimic, although such mimicry is almost confined to the non-breeding period, and is typically brief and given by single individuals when foraging with other, larger species of honeyeater. In the non-breed-

It may seem odd that a large honeyeater such as a **Little Friarbird** probes a tiny flower for nectar, but research suggests that meliphagids target flowers that provide the most plentiful nectar. In a study in northern Australia, half of Little Friarbird nectarivorous visits were to flowers with stamiferous cups, such as Eucalyptus; a fifth were to brush inflorescences, for example Banksia; and an eighth to gullet-shaped flowers such as Grevillea. Time of day is also a factor, as nectar is most abundant at dawn. Flowers with little nectar may be visited only when more copious supplies have expired.

[*Philemon citreogularis sordidus*, near Mt Barnett, Gibb River Road, Kimberley, Western Australia. Photo: Don Hadden]

ing season, single Regent Honeyeaters have been heard to mimic larger honeyeater species while associating with them, including nearly the whole repertoire of the Red and Little Wattlebirds, at least two Noisy Friarbird calls, and calls identical to those of the Little Friarbird, some calls of which are, however, very similar to the Regent Honeyeater's own. Some of the wattlebird vocalizations were mimicked less harshly and more quietly, but the imitated Noisy Friarbird calls were excellent, if quieter. All the mimicked calls were given by the Regent Honeyeater as discrete calls, and not as part of song or subsong. There have been reports of mimicry, or possible mimicry, of the calls also of the Olive-backed Oriole, the Grey Shrike-thrush (*Colluricincla harmonica*), the White-browed Babbler (*Pomatostomus superciliosus*) and the Spiny-cheeked Honeyeater. Mimicry has been heard from non-breeding flocks of Regent Honeyeaters, and this species has been heard, rarely, to utter mimicked songs or calls of Grey Butcherbirds (*Cracticus torquatus*) and Noisy Friarbirds in the breeding season. It has been suggested that the function of this mimicry is to deceive the models and to reduce competition for food and possible aggression by the models, and possibly to promote cohesion between Regent Honeyeaters and larger honeyeaters or to help in defence of resources or territories against smaller competitors. The models mimicked generally tolerate or ignore the Regent Honeyeater in circumstances that would otherwise result in aggressive interactions between them. Regent Honeyeaters that utter their own call when foraging with Red Wattlebirds were chased away by the latter. Little Wattlebirds have been heard to respond to mimicked calls made by Regent Honeyeaters.

Spiny-cheeked Honeyeaters, too, mimic a range of species, including the Grey Shrike-thrush, the Olive-backed Oriole, the Regent Honeyeater and the Western Wattlebird, and also, in quiet subsong, the Noisy Friarbird and the Crested Bellbird (*Oreoica gutturalis*), the last a member of the whistler family (Pachycephalidae). In Australia, occasional mimicry has been reported for a number of meliphagids. A Little Wattlebird that associated with Red Wattlebirds over four or so days was not heard to give any of its own calls, but only those of Red Wattlebirds, although not so loudly, and individual White-eared Honeyeaters have been known to mimic a call of the Hooded Robin (*Melanodryas cucullata*) and the call of a Spiny-cheeked Honeyeater. Mimicry of the calls of the Pacific Baza (*Aviceda subcristata*) and the Golden Whistler (*Pachycephala pectoralis*) were once heard from a group of White-plumed Honeyeaters, and White-fronted Honeyeaters are reported as mimicking Australian ringnecks (*Barnardius*) and the Crested Bellbird. A few other species, such as the Singing Honeyeater and the Yellow-throated Miner, are suspected of mimicry.

In New Guinea, the Streak-headed Honeyeater is both a visual and a vocal mimic of the Brown Oriole, which in turn is a visual mimic of the Helmeted Friarbird of the local race *novaeguineae*. The vocal mimicry of friarbirds by orioles itself is also of great interest, and is discussed briefly elsewhere (see pages 698–701).

Meliphagids produce some non-vocal sounds. Many, or perhaps all, honeyeaters loudly snap or click the bill, singly or in clattering series, sometimes as a component of vocalizations or during agonistic interactions, such as chases and fights. Some also perform bill-clicking during distraction displays at the nest or when with fledglings. Unusual among honeyeaters are the wing noises of the two New Zealand endemics, the Tui and the New Zealand Bellbird. Both of these species produce loud, distinctive noises when in flight, that of the Tui described as a whirring or "whurru". These sounds appear to be created by slots in the wing, formed by notches in the eighth primary of the Tui and in the ninth primary of the bellbird, which are larger in males than in females and are lacking or extremely small in juveniles and immatures. The noises are thought to be under the control of the birds, and are heard in flight during chases and displays, most conspicuously during aggressive interactions, but also during rapid aerial courtship chases; an audible noise is produced also when the birds fly from branch to branch and when they sally after insects.

Recently, there has been an appreciation of the importance of behavioural characters, especially vocalizations, in determining

the taxonomy of species, particularly when examining the differences between allopatric forms. The ground-breaking work *A Guide to the Birds of Wallacea*, by Coates and K. D. Bishop, not only provides for the first time descriptions of the vocalizations of many of these species, but also highlights differences between subspecies or island populations. These differences, where they exist, point to fruitful directions for the study of the systematics of some of these species and subspecies, and indicate the kind of observations that ornithologists should be making in the field.

Food and Feeding

Probably all honeyeaters visit flowers to consume nectar. Insects and spiders (Araneae), providing protein, are an essential part of the diet of all species. Fruit, too, features prominently in the diet of several species, especially those living in rainforest. A number of other sweet foods can be important for honeyeaters at times. These are primary or secondary plant exudates that are rich in sugar or other carbohydrates. To some degree, the species' morphology, especially that of the bill, reflects its diet and feeding behaviour. Smaller, long-billed species tend to feed more on nectar than on insects, whereas smaller, short-billed species tend to feed more on insects. The larger, short-billed species often include more fruit in their diets.

Nectar is a very simple food, consisting mostly of sugar and water. A wide range of birds, from Silvereyes (*Zosterops lateralis*), woodswallows (*Artamus*) and trillers (*Lalage*) to crows and ravens (*Corvus*), consumes nectar from Australian plants, suggesting that no major specialization is required. Meliphagids do show some adaptations that presumably increase their efficiency in gaining access to the nectar in flowers (see Morphological Aspects). Generally, the more insectivorous honeyeaters have a longer bill than that of other insectivorous passerines, and nectarivorous honeyeaters are longer-billed than are insectivorous ones, in relation to body weight. A long and relatively narrow bill presumably allows better access to flowers, especially tubular ones. Proportionately, the bills of honeyeaters are much shorter than those of hummingbirds, and even those of sunbirds. This is perhaps due to the importance of insects, and alternative carbohydrates, in the diet of honeyeaters compared with these other nectarivores. The one adaptation to nectar-feeding shown by all honeyeaters is a brush-tipped tongue, the tip of which may be divided into two, four or more clusters of bristles to allow rapid uptake of liquids, such as nectar (see Morphological Aspects). Although many other passerines have a slight brush at the

Although fully mature flowers are most likely to have abundant nectar, it pays meliphagids not to pass up any opportunity.

This **Dark-brown Honeyeater** is reaching down to investigate a flower that is just starting to emerge. Any nectar present will be efficiently extracted with the brush-tipped tongue common to almost all honeyeater genera. The tip of the tongue is split into clusters of bristles, the large surface area of which accelerates the bird's ingestion of the sugary liquid.

[*Lichmera incana incana*,
Rivière Bleue Park,
New Caledonia.
Photo: Roger Le Guen]

tip of the tongue, this is most developed in honeyeaters, being relatively larger in the more nectarivorous species. The digestive systems of honeyeaters also differ slightly from those of insectivorous birds, the former having a less muscular gizzard and shorter intestines. Honeyeaters also have strong legs and claws, a fact appreciated by all who have handled them. These presumably assist the birds in clinging to branches to reach flowers.

Many aspects of the behaviour and ecology of honeyeaters are clearly related to nectar-feeding. Examples include their dexterity in moving among shrubs and trees to reach isolated flowers, and their tendency to be aggressive around rich nectar sources. Moreover, the complex seasonal movements or nomadism of some members of the family are related to a rich resource that varies greatly, and sometimes unpredictably, in time and space. Honeyeaters visit a great diversity of flowers in their search for energy. The decurved bill helps them to probe in flowers, although only the spinebills have a long curved bill and the myzomelas and *Melidectes* species a moderately long bill. Nectar is absorbed onto the brush-tipped tongue, which flicks in and out of the bill at high speed. Unlike hummingbirds, which typically take nectar while hovering, honeyeaters are almost always perched while they visit flowers. Only the spinebills, the myzomelas and the Brown Honeyeater have been seen often to hover at flowers. Such small birds may be able to visit flowers more rapidly and efficiently by using this method of feeding, especially when flowers are scattered around the periphery of a plant. Honeyeaters may ingest significant amounts of pollen, but this passes through the bird largely undigested; pollen consumption appears, therefore, to be largely accidental and it is not a major food source. The heathlands and open forests of coastal Australia are floristically diverse, numerous plants producing regular supplies of nectar, sometimes from showy flowers or inflorescences. These vary in their structure, from being simple cup-shaped flowers, as in the eucalypts, to being narrow tubes and collections of hundreds of tiny flowers in a brush-like inflorescence.

The genus *Eucalyptus*, of the plant family Myrtaceae, has diversified into some 500 species in the drier forests and woodlands, and its flowers are remarkably uniform, a cup with a central style surrounded by rings of stamens. The flowers are arranged in loose clusters, and nectar production can be modest or copious. Insects are the commonest visitors to the smaller-flowered species, but honeyeaters, lorikeets, other passerines, bats (Chiroptera) and even non-flying mammals may consume nectar

from the larger-flowered ones. All of the common honeyeaters of southern Australia, such as Red Wattlebirds and New Holland Honeyeaters, have been seen to probe into eucalypt flowers for nectar, and for shorter-billed species, such as the Yellow-faced and White-naped Honeyeaters, this genus provides the most significant source of nectar. The ironbarks, such as *Eucalyptus sideroxylon*, provide a critical energy source for the globally threatened Regent Honeyeater, and many other birds, on the inland slopes of the Great Divide. A few eucalypts seem to be visited almost exclusively by honeyeaters. *Eucalyptus stoatei* has almost tubular flowers to which access is denied to smaller visitors by the densely incurved stamens, but at which Western Wattlebirds and Brown and Purple-gaped Honeyeaters are able to feed. Bloodwoods (*Corymbia*), closely related to *Eucalyptus* and until recently placed in the latter genus, provide a nectar source for meliphagids, such as Little Friarbirds and Yellow-throated Miners, in northern and central Australia. A number of relatives of the eucalypts in the Myrtaceae have similar individual flowers, but they are arranged into inflorescences that resemble bottle-brushes. Indeed, "bottlebrush" is the common vernacular name for the genus *Callistemon*, which is popular with such honeyeaters as the New Holland Honeyeater. The paperbarks in the genus *Melaleuca*, which are small to large trees forming woodlands and forests in damp areas, especially around the northern coasts, have similar, though usually white or cream, inflorescences to which Helmeted Friarbirds and Banded, Bar-breasted and Brown-backed Honeyeaters are common visitors.

Proteaceae is the other major family the flowers of which provide nectar for birds and which is found almost throughout Australia. In *Grevillea* and *Adenanthos* the petals are reduced to a small bulb, containing the nectar. These are visited by New Holland and Purple-gaped Honeyeaters in southern Australia, whereas *G. pteridifolia* of northern Australia is visited by many species, including White-gaped and Blue-faced Honeyeaters. The most important genus in this family, however, is *Banksia*, in which many hundreds of flowers, similar to those of *Grevillea*, are packed into a tight inflorescence shaped like a bottle-brush. *Banksias* reach their greatest diversity in south-west Australia, but there are a number of species on the eastern coast. The individual flowers may produce only modest amounts of nectar, but this can coalesce along the central stem of the brush to produce a veritable feast for a visiting bird. In the coastal heaths, banksia nectar sustains dense populations of New Holland and White-

For meliphagids such as the **Yellow-spotted Honeyeater** that primarily inhabit rainforest, fruit is a particularly important dietary component, providing a significant source of carbohydrates. In northern Queensland, some 84% of trees produce fleshy fruits, and two-thirds of these species are dispersed by birds. The most common fruit colours are yellow, orange, red and purple, all of which stand out amongst green foliage. The Yellow-spotted Honeyeater usually forages in the mid-canopy or shrub layer, and may glean insects from the fruit surface as well as pecking flesh from the fruits themselves.

[*Meliphaga notata mixta*, Paluma, Queensland, Australia.
Photo: Roland Seitre]

In Australia and New Guinea, many honeyeaters occur sympatrically and in the same habitats, but are able to co-exist by dint of exploiting different ecological niches. A good example involves the **White-eared Honeyeater**, which specializes in foraging on tree trunks and branches, where it probes under flaking bark or into crevices in rough bark to reach sources of sap that leak after insect damage, or to extract honeydew excreted by insects such as aphids (Aphidoidea). At some sites, the White-eared Honeyeater almost entirely forsakes nectar in its quest for manna. It forages mainly on trees of the genus *Eucalyptus* and, indeed, may only venture to other genera when they are in flower.

[*Lichenostomus leucotis*
leucotis,

Lochman Transparencies]

cheeked Honeyeaters, and Little Wattlebirds are rarely found away from banksias. The Western Wattlebird feeds on a wide range of proteaceous flowers, including *Dryandra*, which also has brush-like inflorescences. The coastal forests also may be carpeted by shrubs bearing tubular flowers, typically members of the family of southern heaths (Epacridaceae). Genera such as *Epacris* and *Astroloma* are popular among the longer-billed honeyeaters in winter. Eastern Spinebills, in particular, insert the fine, decurved bill into the red tubular heath flowers.

The coastal heaths and woodlands of south-western Australia contain what is one of the greatest varieties of plants found anywhere on Earth. Although many belong to the families Myrtaceae and Proteaceae, they include representatives of a wide range of families that in eastern Australia are typically insect-pollinated. The kangaroo paws (*Anigozanthos*) are of special interest. These relatives of the lilies present gullet-shaped flowers on stalks growing up from the ground. Smaller honeyeaters, such as the Western Spinebill, cling to the stems in order to probe the flowers, whereas larger honeyeaters, such as the Red Wattlebird, stand on the ground to feed on the nectar. The woodlands and drier forests of northern Australia, New Guinea and Indonesia also have the familiar eucalypts and grevilleas, but several other plants are important nectar sources here. Helmeted Friarbirds feed on flowers of black bean (*Castanospermum*), whereas Silver-crowned Friarbirds visit flowers of *Xanthostemon*, a relative of the eucalypts. The arid regions of central Australia are not without sources of nectar for honeyeaters. There are scattered eucalypts here, as well as shrubs of *Hakea*, a relative of *Grevillea*, which may flower prolifically. Even Crimson Chats feed on *Hakea* flowers, along with Grey-headed and Spiny-cheeked Honeyeaters. One of the most spectacular genera of flowering shrubs is *Eremophila*, a name that means "desert-lover". After good rain, these plants produce masses of red or yellow gullet-shaped flowers, which

draw in honeyeaters from the surrounding areas. The nomadic Black, Pied and White-fronted Honeyeaters are especially associated with *Eremophila* flowers.

Rather less is known about the flowers visited by honeyeaters in the rainforests scattered along the eastern coast of Australia and covering much of New Guinea. This is partly because, in these places, fruit is relatively more important than nectar, and partly because it is difficult to make observations here. A further problem is that identification of the plants is often far from easy. Nectar-feeding honeyeaters are uncommon in the temperate rainforests of Tasmania, with only leatherwood (*Eucryphia lucida*) and the laurel *Anopterus glandulosa* providing significant sources of nectar for Eastern Spinebills. Strong-billed Honeyeaters, too, feed on leatherwood nectar. In the rainforests of New South Wales, Scarlet Honeyeaters and Eastern Spinebills visit mistletoes and a number of small-flowered shrubs. The silky oak (*Grevillea robusta*) also is popular with honeyeaters in this area, although most observations involve trees that have been planted as street trees outside the forest. Despite studies of the foraging ecology of birds undertaken in lowland and highland rainforest in north-east Queensland, there is little published information on the plant species that honeyeaters visit for nectar; nevertheless, *Syzygium*, a large tree related to the eucalypts, is popular with honeyeaters in lowland forest. In New Guinea, most meliphagid visitors to flowering trees and vines are the tiny myzomelas or members of the generalized genera *Xanthotis* and *Meliphaga*. Many of the trees produce thousands of small flowers up to 30 m above the ground and are difficult to identify. The myzomelas appear to be nomadic, moving into the area to feed on the trees, which flower asynchronously or unpredictably and yet produce masses of flowers. *Syzygium*, as in north-eastern Australia, is popular, but flowers only irregularly. The other honeyeaters, members of the genera *Xanthotis*, *Meliphaga* and *Melilestes*, are more sedentary and switch to fruit when few trees are flowering. Belford's and Ornate Honeyeaters, in *Melidectes*, are the most common visitors to flowering *Metastemma yamamotoi* (Rafflesiaceae), and a range of honeyeaters visits flowers of the epiphyte *Schefflera*, which flowers throughout the year. It seems that the nectar-feeding honeyeaters come into their own in New Guinea only in the high-altitude heaths, where the rhododendrons have diversified and are visited by honeyeaters such as species of *Melidectes*. Similarly, honeyeaters visit rhododendrons in the highlands of Lombok and Sulawesi.

Invertebrates are as integral to the honeyeater diet as nectar. This is particularly true of the shorter-billed meliphagids, which are morphologically less well equipped for nectarivory. Insects and spiders are the main types of quarry, but larger honeyeaters such as the **Noisy Miner** also take annelids, chilopods and pseudoscorpions. Insects feature particularly prominently in the honeyeater diet during the breeding season, when protein is in greater demand. Most insects are caught by gleaning, but the Noisy Miner is one of many species that also sally or even sally-hover.

A habitat that has only recently been studied is mangrove. The Mangrove and Varied Honeyeaters are most associated with this habitat in northern and north-eastern Australia and New Guinea. They often feed on flowers, such as those of umbrella tree (*Schefflera*) and coral tree (*Erythrina*), which are outside the mangroves. Red-headed Honeyeaters also are common in mangroves, and near Darwin they feed from a succession of flowering mangroves in the genera *Rhizophora*, *Bruguiera* and *Aegiceras*.

At times, the two New Zealand honeyeaters can be highly nectarivorous, visiting a variety of plants through the year. Some of these plants are related to genera that are important nectar sources in Australia and New Guinea. *Metrosideros* resembles, and is related to, *Eucalyptus* and *Syzygium*, and its sugar-rich flowers are exploited by both of the New Zealand honeyeaters. *Knightia*, a member of the Proteaceae, is also an important nectar source. Some plants, however, do not have Australian counterparts, examples being the lily-like New Zealand flax (*Phormium tenax*) and *Vitex lucens*, the latter a small tree with scattered but nectar-rich flowers. *Fuchsia*, a genus associated more with South America, is popular with New Zealand Bellbirds and Tuis.

Nectar is provided not only within the flowers. Some species of *Acacia* possess nectaries on their phyllodes, and these are visited by honeyeaters when the plant is flowering. Rufous-banded Honeyeaters are often associated with *Acacia*, taking extra-floral nectar, as well as consuming the carbohydrate-rich arils that attach the seeds to the pods. It is often assumed that flowers visited by birds are brightly coloured, often red. Although flowers exploited by honeyeater are sometimes red, as illustrated by, among others, the epacrids, *Eremophila* and *Correa*, it is a fact that white, cream and yellow are very common colours of "bird flowers" in Australia and New Guinea. Perhaps more surprisingly, some bird flowers are quite cryptic, being green, as are some mistletoes, or brown, as are some grevilleas. Perhaps this is because there is a cost in being too showy, in attracting unwelcome visitors, which take the nectar but without pollinating the flowers. Whereas most honeyeaters take nectar by probing the flower and brushing against stamens and stigmas, in a few cases short-billed species may pierce the base, especially of tubular flowers. The Rufous-backed Honeyeater of New Guinea does this when feeding on rhododendron flowers, and Brown-headed

Honeyeaters sometimes exploit *Astroloma* and *Correa* flowers in this way.

Fleshy fruits provide an alternative source of carbohydrate-rich food for some honeyeaters in some habitats. The smallest meliphagids, the myzomelas and spinebills, only rarely take fruit, whereas the medium-sized generalists, such as *Lichenostomus*, include a small amount of fruit in their diet. A handful of species are specialized frugivores. For example, the Painted Honeyeater feeds mainly on mistletoe berries, and MacGregor's Honeyeater prefers podocarp fruits but may also take fruits from low shrubs. The Painted Honeyeater is often found in acacia woodlands where the mistletoe *Amyema quandong* is common. Spiny-cheeked Honeyeaters likewise eat a lot of mistletoe berries in semi-arid woodlands and shrublands, whereas Lewin's Honeyeaters feed on mistletoe berries in rainforests. There are few fleshy fruits in the forests and heaths of southern Australia, perhaps because they grow on soils that are low in many nutrients, such as potassium. Yellow-faced Honeyeaters and the wattlebirds sometimes consume significant amounts of fruit, including those from the epacridaceous genera *Astroloma* and *Leucopogon* and those of the native cherries (*Exocarpos*), and the Yellow-tufted Honeyeater feeds on *Coprosma* fruits (Rubiaceae). Several meliphagids, such as Lewin's Honeyeater and wattlebirds and friarbirds, also consume a variety of exotic berries and fruits, and they may be responsible for the spread of environmental weeds, such as bitou bush (*Chrysanthemoides monilifera*) along the coastal dunes of eastern Australia. Semi-arid habitats can contain a range of fleshy fruits, especially in the shrub-steppes, where the chenopod family dominates. Here, fruit makes up a significant component of the diet of Singing and Spiny-cheeked Honeyeaters. Saltbush berries (*Rhagodia*) are eaten by at least 18 species of honeyeater, including Grey-headed and Pied Honeyeaters. Singing Honeyeaters may also feed on and spread the African boxthorn (*Lycium ferocissimum*) through semi-arid Australia. Seeds pass through honeyeaters intact, allowing for their identification and also demonstrating that honeyeaters play a role in dispersing these plants. Coastal shrub communities may resemble the saltbush plains in having plentiful food throughout the year.

The colours of fruits eaten by honeyeaters cover the whole spectrum, though yellow, orange, red and purple are the most common. Some fruits are even bicoloured, or the fruits contrast strongly with their background. The native apricot (*Pittosporum*

The larger the honeyeater, the more sizeable the invertebrate prey it can take. This Red Wattlebird has caught a cicada (*Cicadidae*), which lies towards the upper end of the insect size range. Wattlebirds tend to increase their capture rate of invertebrates during the breeding season, to meet the demands of females and growing chicks for protein. Red Wattlebirds deploy several foraging techniques when seeking invertebrates. They probe bark, glean from foliage, sally over long distances, and hop along the ground before pouncing on an unsuspecting insect.

phylliraeoides) advertises its orange seeds against a yellow capsule. Some honeyeaters, such as the Singing and Spiny-cheeked Honeyeaters, are occasionally duped by plants, consuming seeds that contain no reward. The deep glossy blue seeds of the sheebush (*Geijera linearifolia*) and the red nuts of *Gahnia sieberana* emerge unaltered after passing through the digestive system of the birds. They apparently mimic edible fruits, with which they co-occur.

In the rainforests of eastern Australia and New Guinea fruit has become a major food source for birds, 84% of tree species in north Queensland rainforests producing fleshy fruits, 68% of which are dispersed by birds. The major frugivores are pigeons, bowerbirds (Ptilonorhynchidae) and, of course, cassowaries (Casuariidae). Honeyeaters are only relatively minor players. Lewin's Honeyeaters are the most frequent consumers of fruit in the south and in the highlands of Queensland, where they may deplete *Myoporum* plants very rapidly. In the Queensland lowlands, and especially in New Guinea, the genera *Meliphaga* and *Xanthotis* become more diverse and consume much fruit. Not only do many tree species produce fleshy fruit, but they are taxonomically diverse, with no one family predominating. Figs (*Ficus*), along with members of the Lauraceae, Meliaceae, Elaeocarpaceae and Araliaceae, are among the more important sources of fruit for birds in rainforests. Both species of honeyeater in New Zealand consume fruit, especially in autumn and winter. Here, *Podocarpus* trees and *Coprosma* shrubs are the most frequently visited, but there are many other plants that produce edible fruit. A rather unconventional "fruit" is presented by some acacias, in which the dry pod opens to reveal black seeds attached by a red or yellow aril; this aril is rich in lipids, whereas the majority of fruits contain mostly sugars. Lewin's Honeyeaters consume the aril and seed and defecate the seed intact. Rufous-banded Honeyeaters, however, remove the seeds of black wattle before consuming the arils.

Seeds have been recorded as the food of a number of meliphagids, such as Striped, White-lined and Singing Honeyeaters. As the majority of these are seeds that have been found in stomachs, it is likely that they are mostly those from fleshy fruits, which are passed by the birds undigested. In a few cases, however, seeds may be the intended food, because the plant does not have fleshy fruits. Banded Honeyeaters have been found with grass seeds in the stomach.

All honeyeaters consume invertebrates, mainly insects and spiders, either as a major food or as a source of protein. Many of the shorter-billed honeyeaters, for instance those in the genera *Lichenostomus* and *Melithreptus*, consume considerable numbers of arthropods throughout the year. The Green-backed and Grey Honeyeaters may be almost exclusively insectivorous. The most frequent foraging method is to glean insects from foliage, often of eucalypts, but also that of acacias. Honeyeaters often move rapidly among the foliage, and quite often hang from twigs in order to take insects from below them. White-naped and Black-chinned Honeyeaters feed on caterpillars that tie leaves together. Macleay's Honeyeaters specialize in foraging on dead leaves and large leaves of rainforest trees, and a few honeyeaters have become specialized for foraging on bark. MacGregor's Honeyeater probes into soft wood and moss, opening its bill to allow access to invertebrates. The myzas of Sulawesi are said to scurry about in the moss-draped branches of highland rainforest trees in the manner of squirrels (Sciuridae). In Tasmania, the Strong-billed Honeyeater probes into the trunk and main branches of trees, just as an Australasian treecreeper does, perhaps enabled to forage in this way by the fact that there are no true treecreepers in Tasmania. It also clings to long strips of bark and prises out insects. The Long-billed Honeyeater in New Guinea sometimes climbs up tree trunks like a treecreeper, gleaning and probing in crevices in bark for insects. Many of the more nectarivorous honeyeaters capture their insect prey by sallying from perches, taking midges (Diptera) and small hymenopterans in the air. The larger species do not appear particularly adept at this. Sometimes they may take insects, even those up to the size of honeybees (*Apis*), from flowers, and this is conspicuously different from when they are imbibing nectar. Tawny-crowned and Rufous-throated Honeyeaters feed on the ground, the former frequently and the latter

Access to water is as imperative for honeyeaters as for most birds, enabling them to drink and ablute. Such resources are all the more valuable in arid areas such as large parts of Australia. The **White-plumed Honeyeater** tackles this particular issue by inhabiting riparian forests or woodlands that border waterbodies such as springs, swamps or lakes. This species has a varied diet, consisting of nectar, arthropods, insect products such as lerp, pollen and fruit. It forages at all levels, favouring the canopy but apparently being forced lower by the **Fuscous Honeyeater** (*Lichenostomus fuscus*) where the two overlap.

[*Lichenostomus penicillatus carteri*, Lyons River, Gascoyne, Western Australia, Australia.
Photo: Stuart Miller/Lochman Transparencies]

occasionally. Most honeyeaters take a wide range of insects and spiders, with little indication of specialization. Beetles (Coleoptera) and ants are common prey, as are various flies (Diptera) and wasps (Hymenoptera) for honeyeaters foraging in the air.

There is a tendency in southern Australia for nectar to be a more important source of energy in winter, whereas insects are more important in summer. In the tropics, honeyeaters tend to consume more nectar in the dry season and more insects in the wet season. These seasonal differences are in part related to breeding. The breeding season places far greater demands on birds for protein. Some honeyeaters, such as wattledbirds and friarbirds, which may feed mostly on nectar during the rest of the year, become more insectivorous while nesting. They then take a wide variety of insects, including, in the case of Noisy Friarbirds, large beetles and cicadas (Cicadoidea). The wide gape of the friarbirds allows them to swallow the largest cicadas, even if at times after a struggle. New Zealand Bellbirds also take cicadas in late spring and summer.

The careful observations made by Paton revealed that many honeyeaters that were assumed to be feeding on insects were, in fact, consuming other foods that are rich in carbohydrates. These are plant products, although insects play a part in making them available to birds. Some plants leak sap, usually after damage by insects. Honeyeaters consume this from such diverse places as the unripe fruits of corkwood bushes (*Hakea divaricata*) in the Australian desert, mangrove buds in northern Queensland, and trunks of beech trees in temperate rainforests in New Zealand. Manna is the best-known of these direct exudates from plants. It consists of high concentrations of simple sugars, initially as a sticky liquid, but later as white crystals. Insects are more directly involved in the production of honeydew, which is excreted by the nymphs of aphids (Aphidoidea), coccids and psyllids. These bugs feed on the sap of plants, but they need to extract far more carbohydrate than they require in order to gain enough protein;

Most birds prefer to drink while perched, as this enables them to take in more water over a long period without needing to rush. Such conditions, however, may not be universally available. For example, the waterbody may be prone to disturbance or may lack suitable low perches. In such circumstances, birds may have to employ other techniques. Honeyeaters such as the **Red Wattlebird** are accustomed to sallying for insects, and drinking in flight is perhaps not so very different. To do so, the bird flies low over the water, dipping its bill into the water and rapidly ingesting liquid before flying off to a safe perch.

the excess, as sugars or other simple polysaccharides, passes out of the insect as a sweet solution. Honeydew is also important to New Zealand Bellbirds and Tuis in beech forests, accounting for about a third of their food in one area. Some psyllids in Australia convert the sugars into more complex carbohydrates, which produce a protective covering, known as the lerp. All of these substances are consumed by honeyeaters as substitutes for nectar, and most honeyeaters that have been studied closely have been found to consume some alternative carbohydrate foods. White-naped Honeyeaters glean blobs of manna from the foliage of eucalypts, whereas White-eared Honeyeaters lap honeydew from under the peeling bark of other species of eucalypt. Alternative carbohydrate sources occur in a wide range of habitats and are available for much of the year. Furthermore, harvesting them can be energetically more profitable than is the capturing of insects, and at times even superior to taking nectar. The short-billed honeyeaters may depend on manna, lerp or honeydew for most of the year, whereas long-billed species, such as New Holland Honeyeaters, may use them when nectar is scarce. Sometimes insects are not responsible for the damage to plants. Thus, Red Wattlebirds and Noisy Friarbirds feed on sap oozing from the scars on eucalypts produced by sugar gliders (*Petaurus breviceps*), and a wide variety of honeyeaters and other birds is known to take sap from the scars made by yellow-bellied gliders (*Petaurus australis*) in forests.

So close is the relationship between some honeyeaters and lerp-producing psyllids that one ornithologist, R. H. Loyn, suggested that Bell Miners behave like farmers towards these insects, as they protect them from other predators. Miners live in dense colonies, from which most other small birds are excluded. As they feed mostly on lerp, Loyn suggested that the sugary coat is harvested from the psyllid insects, which are protected from the predation attempts of other birds. Certainly, psyllids thrive in Bell Miner colonies, often to the detriment of the trees. When Bell Miners were removed from a site, it was invaded by many other insectivorous birds and honeyeaters. Within a few months, the number of lerp-producing psyllids was greatly reduced. This supports the hypotheses that, first, the miners do keep other birds out and, secondly, their impact on the psyllids is less than that of a more diverse bird community. A. Poiani has questioned Loyn's lerp-farming hypothesis, both its appropriateness as a metaphor

and the way in which it may operate. He suggested that the defending of the lerp insects is similar to the defence of any renewable resource, such as nectar, which many honeyeaters defend. The relationship between miners and psyllids, however, may be more subtle than this. Miners sometimes take only the protective lerp, leaving the psyllid nymph to build a new one. If the miner is doing this intentionally, it may be behaving more like a farmer that harvests wool, milk or eggs, while protecting the animal. On the other hand, it could be simply that the psyllid is difficult to take. Even the miner may forage more efficiently if it moves from lerp to lerp, rather than wasting time by trying to take the psyllid as well. A further part to the farming analogy is that miners take only large lerp, leaving smaller ones to grow. Again, there could be benefits to the miners in ignoring less rewarding prey, if richer units are common. It is hard to see how the two more specific hypotheses can be tested. Nevertheless, there is the intriguing possibility that Bell Miners may forgo a small immediate reward, in the form of energy from the psyllid, for a longer-term reward, that of an assured food supply. The high degree of relatedness in miner colonies may be enough to allow this level of co-operation.

A few other foods are occasionally eaten by meliphagids. Several species, among them Brown-headed and Singing Honeyeaters, Red Wattlebirds and Helmeted Friarbirds, have been recorded as breaking the eggs or killing nestlings of other species; the victims include Spangled Drongos, thornbills, waxbills (Estrildidae) and Australasian robins (Petroicidae). Noisy Miners were found to be frequent predators of artificial nests in urban areas. To what extent eggs or nestlings are items of food, as opposed to being destroyed for competitive reasons, is not clear. The Wattled Honeyeater has been recorded as killing and eating a lizard, and small skinks (Scincidae) are sometimes taken by the larger honeyeaters. There are records of the eating of frogs by Noisy Miners, and, even more surprisingly, Noisy Friarbirds have been seen to eat mosquito fish (*Gambusia*). Mangrove and Varied Honeyeaters, both of which live in mangroves, feed on molluscs and crustaceans, such as crabs (Decapoda). Several other honeyeaters have been noted as consuming snails (Gastropoda), possibly as a source of calcium during the period of egg-formation.

Honeyeaters readily take to artificial foods in captivity. These diets consist mostly of honey and water, but meliphagids also need protein sources, usually provided by egg-cake mixture or similar

food. Wild honeyeaters may also accept food offered by humans. Macleay's and Lewin's Honeyeaters, for example, visit cafes to take cream, jam and scones. A wide range of species will visit birdfeeders offering artificial nectar, but these are not uncommonly monopolized by aggressive species. Feeders have sometimes been used in scientific studies in order to examine how increased food abundance may alter the behaviour of species.

In both Australia and New Guinea, many species of honeyeater can occur in the same habitat at the same time. Except when there is a very rich source of food, they tend to forage in different ways and to occupy different ecological niches. There tends to be a separation between the more insectivorous short-billed species, such as those in the genera *Melithreptus* and *Lichenostomus*, and the longer-billed nectarivorous species. This pattern seems to hold in both south-eastern and south-western Australia. In fact, both groups consume nectar and insects, as well as alternative carbohydrates. Members of the *Lichenostomus* genus tend to occupy different habitats, possibly because their generalized foraging habits would make it difficult for them to co-exist. One of these, however, the White-eared Honeyeater, is a specialized bark-forager, and may co-occur with almost any other congener. Among the *Melithreptus* species, the White-naped Honeyeater feeds mostly on foliage, with the Brown-headed and larger Black-chinned Honeyeaters more on branches. The White-throated Honeyeater, found in northern Australia and New Guinea, rarely with any congeners, is a foliage-gleaner. In Tasmania, the Black-headed Honeyeater is the foliage-gleaner and twig-gleaner, while the Strong-billed Honeyeater forages on bark. The different species of miner tend to occur in separate habitats, and owing to their aggressiveness few other honeyeaters are common where miners are established. The more nectar-dependent honeyeaters tend to use different ranges of flowers, the size of the birds to some extent matching the rewards that the flowers offer. Thus, spinebills visit the tubular flowers of epacrids in the south-east and the gullet-shaped flowers of *Adenanthos* in the south-west of Australia. Larger honeyeaters can experience difficulty in gaining sufficient energy from small flowers unless they are abundant. At the other extreme, the wattlebirds and friarbirds tend to visit large-flowered eucalypts or the productive inflorescences of banksias. These rich nectar sources can be defended against smaller visitors.

In many habitats, though, it is the medium-sized New Holland or White-cheeked Honeyeaters that are most abundant for most of the year. Perhaps it is their flexibility in using a wide range of nectar sources and their ability to defend flowering shrubs from most other honeyeaters that make them so successful. Nevertheless, there are exceptions to this pattern of larger honeyeaters in richer areas and smaller species where nectar is more sparse or difficult to harvest. Eastern Spinebills are the most abundant meliphagid species in the uplands of northern New South Wales, despite the fact that numerous and highly productive banksias exist in that region. Although nectar may be abundant in winter at this site, its production depends on the minimum temperature. A series of nights of hard frost results in little nectar being produced, leading to food shortage and loss of weight for the spinebills, and it may be therefore that the food source is too unreliable for larger honeyeaters. In the arid centre of Australia, the generalized *Lichenostomus* species again tend to be separated by habitat, with White-plumed Honeyeaters in the riparian woodland, Grey-headed Honeyeaters in mulga in rocky ranges, and Grey-fronted Honeyeaters in mallee and spinifex. The Singing and Spiny-cheeked Honeyeaters are reasonably sedentary, but they switch among insects, nectar and fruit in their diet. Nectar is an unpredictable food source, tending to be abundant only after substantial rainfall. Not surprisingly, the more nectarivorous Pied, Black and White-fronted Honeyeaters display complex movements, being at any locality common in some years and rare in others.

The New Zealand honeyeaters also partition nectar resources according to richness. The large Tui feeds on rich flowers in trees and large shrubs, which it defends. The nectar-feeding Stitchbird, which is now known not to be a meliphagid (see Systematics), is subordinate and may feed on peripheral flowers of the rich sources, but it tends to visit poor nectar-producers or those with

dispersed flowers. The New Zealand Bellbird occupies a niche between these two in its choice of flowers. All three species may switch to eating many insects or fruits.

Honeyeaters are a far less dominant component of the bird communities of tropical rainforest in Queensland and New Guinea. Lowland rainforest in north-east Queensland has Dusky Myzomelas representing the long-billed, nectarivorous guild. In the uplands, a number of long-billed species move into the forest to feed from flowering trees in the wet season. Only the Eastern Spinebill remains all year, in small numbers, feeding on nectar and insects. In the lowlands, Macleay's Honeyeater specializes on dead and large leaves and the Yellow-spotted and Graceful Honeyeaters are generalists, including fruit, nectar and foliage insects in their diet. The Bridled and Lewin's Honeyeaters are the generalized feeders in the uplands. Honeyeaters living in the drier forests of eucalypts and paperbarks in the Northern Territory have been well studied. Two species of friarbird visit eucalypt flowers and scramble through the foliage to dislodge insects. The Brown Honeyeater is a generalized small nectarivore, which also gleans and flits among foliage for insects, while Rufous-banded and Rufous-throated Honeyeaters capture insects in a similar manner, but are less nectarivorous. Bar-breasted Honeyeaters move roughly among foliage and fidget, apparently to uncover prey; they also sally and hover for insects. Similarly, White-gaped Honeyeaters are fidgeters, but they also like vines and they forage on branches and trunks. The large Blue-faced Honeyeater hovers and probes for insects. There is an absence of foods such as manna and lerp in these regions, and there are no counterparts to the long-billed spinebills of southern Australia.

New Guinea rainforests are home to more than 60 species of honeyeater. Perhaps only ten of these, mostly the tiny myzomelas, are primarily nectarivorous. The majority of the others are generalized feeders, taking nectar as well as insects and fruit. In lowland rainforest in New Guinea, there are three similar species of *Myzomela* and four similar species of *Meliphaga*. How they differ in foraging ecology is yet to be determined. Meyer's Friarbird and the myzomelas feed on nectar in the canopy, the latter also coming down to the ground. Tawny Straightbills glean among the understorey, usually in mixed-species flocks based around New Guinea Babbblers and Rusty Pitohuis (see General Habits). The *Meliphaga* species and two members of the genus *Xanthotis*,

Vocal duets are relatively common among meliphagids such as the **Spiny-cheeked Honeyeater**. Pair members perform facing each other, with the body elongated and neck outstretched. Members of many bird families duet, but almost all inhabit dense vegetation in the tropics, are monogamous, and are resident rather than migratory, thus maintaining a year-round territory over several years. This led ornithologists to suggest that duetting seeks to strengthen pair-bonds. Current thinking, however, suggests that duets serve as territorial proclamations directed at neighbouring pairs.

[*Acanthagenys rufogularis*,

Mornington Peninsula, Victoria, Australia.
Photo: Glenn Ehmke]

Meliphagids tend to collect nest materials from the vicinity of the nest. The smaller species search the adjacent ground and vegetation, whereas the larger ones may venture a few hundred metres distant. In many honeyeaters, the female takes sole responsibility for gathering material and constructing the nest, although she may be guarded by the male. This **Varied Honeyeater** has found a plant fibre for its nest. This coastal species usually locates its nest close to the sea or a couple of metres above tidal waters in mangroves.

[*Lichenostomus versicolor*, Cairns, Queensland, Australia.
Photo: Peter Fuller]

the Tawny-breasted and Spotted Honeyeaters, are mixed feeders, grading from more fruit through to more nectar. Finally, the Long-billed Honeyeater feeds on nectar and insects, specializing in foraging on branches and trunks, especially rotten wood.

The bird communities of the Indonesian and Pacific islands are more simple than those of Australia and New Guinea, rarely having more than three honeyeater species. Fiji and Samoa have a small nectarivorous myzomela, a medium-sized generalist, the Wattled Honeyeater, and a large, scarce and poorly known forest honeyeater. A similar pattern of a small myzomela, one or two generalized medium-sized species, often of the genus *Lichmera*, and up to three large friarbirds is found in the islands of eastern Indonesia, although these await detailed ecological studies.

Nectar-feeding birds such as honeyeaters are suitable subjects for the study of energetics, because the volume and sugar-concentration of nectar are easy to quantify. At times, especially during dry periods, honeyeaters visit flowers with little nectar. Often, nectar is most abundant at dawn and is rapidly depleted by the visits made by birds, so that there may be intense competition for nectar. This can lead to trees or shrubs being defended by individuals or groups, even during the non-breeding season. The large wattled birds and the New Holland and White-cheeked Honeyeaters often defend small territories. These often expand as nectar becomes scarce and contract as it becomes abundant. When nectar becomes very abundant, as, for instance, in coastal banksia heaths in winter, there may be little benefit in defending a territory. New Holland and White-cheeked Honeyeaters often ignore many intruders at such times. This change in behaviour may, however, be partly because defence is greatest in autumn, when territories are being established, rather than being due simply to food abundance.

Perhaps surprisingly, territories are sometimes defended even when they provide inadequate food. A possible reason for this is that the establishing of a territory at such a time makes it easier to defend later, when food has become more abundant. The abundance of nectar also influences behaviour in other ways. When nectar is scarce, honeyeaters can spend 80% or more of their day in foraging, sometimes wandering far from their territories to find food. In contrast, when food is very abundant, they are able to satisfy their energy requirements by spending less than 20% of their day in foraging. Other foods, such as alternative carbohy-

drates and insects, are harder to measure. The former may replace nectar as the major energy source at times. Insects can be an important food, but the small midges and wasps captured by sallying wattled birds and New Holland Honeyeaters do not even replace the cost of this expensive foraging technique. Presumably, such insects are taken in order to provide protein or other dietary needs.

Breeding

Many aspects of the breeding biology of the family are conservative and commonly shared. In common with Australian passerines in general, honeyeaters tend to have small clutch sizes, long breeding seasons with repeated attempts in a season, low nesting success, high adult survival and extended parental care, with a high incidence of co-operative breeding. In general, most honeyeaters build neat and well-made open cup-shaped nests, although nests of some, particularly the larger species, appear loosely constructed and bulky. The eggs are typically pale with fine dark spots, dots or speckling and some blotching, and the typical clutch is of two eggs. The role of the sexes at all stages of nesting varies. In many species only the female collects nesting material and builds the nest, although she is often closely accompanied by the male, and only the female incubates and broods, but both parents feed nestlings and fledglings. In at least some species, however, the male is known to assist with nest-building and with incubation and brooding, but the extent of this involvement is often not well known, and claims of male participation are often compromised by the fact that, for most species of meliphagid, it is not possible to determine the sex of individuals by external appearance.

In contrast to the somewhat conservative nesting behaviour of the Meliphagidae, the social and spatial organization of the family shows more diversity. While nearly all species are socially monogamous, breeding systems vary from solitary pairs that maintain long-term, all-purpose territories, to clumped or colonial breeding by territorial pairs, with occasional co-operative breeding, to the complex and obligate colonial and co-operative breeding of the Australian miners. Interestingly, the breeding biology of MacGregor's Honeyeater, which was formerly considered a bird of paradise (see Systematics), is consist-

ent with that of most meliphagids, rather than with that seen in the Paradisaeidae: MacGregor's are socially monogamous, with apparently permanent pair-bonds, the male accompanies the female as she constructs the nest and on foraging trips during incubation, nests are cup-shaped, incubation and brooding is apparently by the female only, and both female and male feed nestlings.

As with so many aspects of the biology of the family, most detailed studies of breeding and social organization have been conducted in Australia and New Zealand, and there are few or no detailed studies from Wallacea, New Guinea or the islands of the south-western Pacific Ocean, although some detailed reports of individual nesting attempts are available for a few species, such as the Long-billed Honeyeater in New Guinea. The detailed summaries of breeding for the 70 species of honeyeater in the *Handbook of Australian, New Zealand and Antarctic Birds* provide a new and more accurate baseline for comment on the social organization and breeding biology of the Meliphagidae, including detailed analyses of the previously unpublished data held in the Nest Record Scheme run by the Royal Australasian Ornithologists Union. Most detailed studies, however, have been of largely sedentary species, including the Noisy and Bell Miners, in the genus *Manorina*, the Red Wattlebird, in *Anthochaera*, the New Holland and Crescent Honeyeaters, in *Phylidonyris*, the Yellow-tufted Honeyeater, in *Lichenostomus*, the Brown-backed Honeyeater, in *Ramsayornis*, and the Rufous-banded Honeyeater, in *Conopophila*. Other, less sedentary species that have been the subject of detailed study include the migratory Yellow-faced Honeyeater and Noisy Friarbird, and the enigmatic Regent Honeyeater. The breeding biology and life-history strategies of most dispersive or nomadic species, and especially the many arid-zone species, have been little studied.

Overwhelmingly, honeyeaters breed as socially monogamous pairs, even in colonial and co-operatively breeding species. With essentially sedentary species, pair-bonds are often long-term, being maintained throughout the year, and from year to year. In the co-operatively breeding Bell Miner, pair-bonds are typically lifelong, and divorce occurs only rarely, if a mate is ill, although divorce sometimes occurs for no obvious reason. Crescent Honeyeaters maintain pair-bonds for successive breeding attempts in a season, and throughout the year, with no instances of divorce

found in a study over six years. Similarly, White-eared Honeyeaters maintain pair-bonds throughout the year, and from year to year, with partners known to stay together for more than one breeding season; in a two-year study there were no instances of divorce, although several changes of partner were observed following the disappearance of one member of a pair. The Yellow-tufted Honeyeater of the subspecies *cassidix*, known as the "Helmeted Honeyeater", is an obligate colonial breeder, but individuals usually mate for life, and most remain in the same territories. Noisy Friarbirds likewise maintain long-term pair-bonds from season to season. In contrast, studies of the migratory Yellow-faced Honeyeater found that, while mates remain together for the duration of the breeding season and are typically multi-brooded, only 12.5% of pairs consisted of the same individuals in a subsequent breeding season, despite the fact that both partners from a previous season were often alive; a divorce rate of 75% for males and 66% for females was found.

In contrast to the social monogamy of most of the family, both sexes of the Noisy Miner are promiscuous. In this co-operatively breeding species, a female may copulate with more than one male, and a male may copulate with more than one female, often on the same day. The dominant male in a coalition appears, however, to achieve most, but not all, copulations with a female, and broods are normally genetically monogamous. Other complications are noted occasionally. Polygyny was observed once for the non-colonial Rufous-banded Honeyeater of northern Australia. This species normally breeds as simple territorial pairs, but in one season a male was shared by two females that occupied adjacent "subterritories", and he attended young in two nests concurrently in December 1988, when one of the nests was successful, and in February 1989, when both were successful. In the following season, this male appeared to be paired with one female only.

There have been few studies of extra-pair paternity among honeyeaters. Although pair-bonds of the co-operative and colonial Bell Miner are typically lifelong, extra-pair fertilizations have been found to be responsible for at least 4% of nestlings in a range of studies, and levels of extra-pair paternity may be even higher. In the colonial "Helmeted" form of the Yellow-tufted Honeyeater pairs are socially monogamous, usually remaining in the same territory and mated for life, but extra-pair paternity was found to be fairly common, 10% of broods of this

Animal hair is commonly used by meliphagids for their nests. Being warm and soft, it serves as a lining, and its strength and suppleness also renders it a useful binding material. Moulted mammal hair can be found on the ground or on objects against which the animal has rubbed. Alternatively, fresh hair can be tweaked from a live animal, as in the case of this **Brown-headed Honeyeater**, which is making good use of a western grey kangaroo (*Macropus fuliginosus*).

Both sexes of this honeyeater collect nesting material, but only the female is thought to build the nest, which is a small, neat, deep cup.

[*Melithreptus brevirostris pallidiceps*,
Adelaide, South Australia,
Australia.

The typical meliphagid nest is a neat, open cup. That of the **Brown Honeyeater** is round or elliptical in shape, with external dimensions of around 6 cm in diameter and 5 cm in depth. Grass and bark form the most part of building materials, with paper or leaf-skeletons as alternatives. The binding is provided by spiders' webs, hair or plant fibre. Plant down, fine grass and hair make for a comfortable heat-retaining inner layer. The Brown Honeyeater tends to place its nest in dense foliage a metre or so above ground, often close to water.

subspecies containing extra-pair young. Some species exhibit behaviour that indicates the possibility of extra-pair copulations. For example, female Crescent Honeyeaters may wander into neighbouring territories, and males make only a modest contribution to parental duties, suggesting that some extra-pair copulations may occur. Similarly, while pairs of migratory Yellow-faced Honeyeaters defend all-purpose territories and nest within the boundaries of them, paired females were occasionally observed within the territories of neighbouring males, which were not seen to react aggressively to intruding females. As with Crescent Honeyeaters, these intruding females may present opportunities for extra-pair copulations, although it is not yet known whether the monogamous social pair-bonds accurately reflect genetic pair-bonds.

Whereas the mating system of the family is fairly simple, the spatial organization of breeding honeyeaters is far more complex, although it is worth noting that most studies have concentrated on resident or sedentary species, rather than migratory or nomadic species. The majority of meliphagids appear to breed as simple pairs in discrete, defended territories, either permanent all-purpose territories or smaller and short-term breeding territories. For example, studies of both Crescent and White-eared Honeyeaters revealed that these species defend permanent, all-purpose territories throughout the year, the boundaries of neighbouring territories abutting and with little overlap. Males rarely intruded into neighbouring territories, when they usually behaved furtively, although female Crescent Honeyeaters were occasionally observed in neighbouring territories.

In studies of migratory Yellow-faced Honeyeaters in Victoria, in the south of their distributional range, it was found that the birds arrived at the end of the austral winter, in late August, and from then until about the end of October males and females moved over a wider local area than that which they would later defend. They began to establish territories by the end of October, corresponding with a decrease in flowering mistletoe, neighbouring territories typically abutting. After a female joined a male on a territory, both partners defended the territory from intrusions by both conspecifics and other species, although males were significantly more likely to be involved in aggressive acts than females. By early February, territorial boundaries were less aggressively defended and territories gradually dissolved before

most of the population left, in April. No pair was ever observed to change territory within a season, even though pairs usually made several nesting attempts. Among breeding individuals known to have survived from one season to the next, males were significantly more likely than females to return to the territory of the previous season.

A number of species are colonial nesters. All four miners are obligate colonial, and co-operative, breeders. Noisy Miners possibly have the most complex social and spatial organization of any meliphagid. This species gleans food from foliage and the ground, eating insects and a range of non-nectar carbohydrates (see Food and Feeding), and lives in large, structured colonies, ranging in size from a few individuals to several hundred birds. These obtain virtually exclusive use of an area, and the resources within it, by indiscriminate aggression against nearly all other bird species, including non-predatory ones, that intrude into the colony. Intruders are nearly always attacked and are sometimes killed, although a few larger species, such as Laughing Kookaburras (*Dacelo novaeguineae*), are sometimes tolerated in colonies, usually close to the edges.

Within Noisy Miner colonies, males outnumber females significantly, by a factor of 3:1, and the spatial arrangement differs between the sexes. Most males have small activity spaces, or core areas of their home range, which tend to overlap with those of other males. Clusters of neighbouring and nearby males tend to form associations, typically of 10–25 individuals, termed "coteries". These are the most stable unit within a colony, particularly in the non-breeding season, and membership changes little. In some circumstances, a colony may behave as if consisting of only a single coterie. Members of coteries unite to drive off intruders belonging to other coteries. Within coteries, subgroups of males form, comprising individuals involved in the same activities; termed "coalitions", they usually contain 5–8 males, but sometimes as few as two and, during mobbing, up to 40–50 individuals. Coalitions move freely within the area occupied by their coterie, and membership of coalitions changes as individuals leave when a coalition moves beyond the boundaries of their activity space, and other males enter as the coalition passes into their activity space. Female Noisy Miners use activity spaces that overlap those of males but not those of other females, so that, while females will join coalitions of males that form in their own

The nest of the **Little Wattlebird** is usually saucer-shaped, but deeper cups and even rough domes are fairly frequent. The structure is solidly built from sticks, grass and plant stems. Other plant material such as bark and moss may be woven in, as may wool or artificial materials such as plastic twine. For the soft inner lining, the Little Wattlebird seeks out shredded bark, plant down and feathers. Whereas most honeyeater nests are suspended from the rim, those of larger species such as wattlebirds tend to be placed in a vertical fork of a tree. The nest tree is usually short and replete with foliage, and the nest is normally placed about 3 m above ground.

[*Anthochaera chrysoptera chrysoptera*, French's Forest, New South Wales, Australia.
Photo: Graeme Chapman/Ardea]

activity space, there is rarely more than one female in a coalition. Within Noisy Miner colonies, young females may be driven from their natal area more often than are young males, probably at least partly because female activity spaces do not overlap and so young females cannot settle in their natal territory. Emigration of males is thought not to occur until the density within a colony reaches some critical level. Female vacancies within colonies appear to be filled by emigrants from other colonies.

Similarly, Bell Miners defend stable colonies that consist of a number of breeding pairs, each occupying a permanent and discrete foraging range or core area within the colony, and a larger number of non-breeding members, which include the offspring of the colony's breeding members and immigrants from other colonies. The non-breeders occupy foraging ranges that overlap extensively with those of one or more breeding pairs. Colonies remain in the same areas for many years, but sometimes individuals move as a colony to a new site, especially to exploit food resources, or a new colony may be started by a few individuals from an existing colony. Colonies range in size from five to more than 50 birds; one colony in Victoria, over a period of six years, contained an average of 29 members but ranged from nine to 58 birds, and had 3–9 breeding pairs. The area of the colony is defended by all of its members, which co-operate to drive conspecifics and almost all other birds from the communal territory, resulting in almost sole occupancy of a site by the miners. Young males nearly always remain in their natal core area with their parents until they gain a breeding position of their own, usually within the same colony. Female offspring, however, share the core area of their parents only until they reach sexual maturity, at about 8–9 months of age, at which point they try to disperse to neighbouring colonies in order to obtain a breeding position. If they are unsuccessful in obtaining a breeding position, they return to the natal range before making further forays in search of one.

A number of other honeyeaters, in a diverse range of genera but including several species of *Lichenostomus*, nest in small colonies. Apart from the miners, however, only the Yellow-tufted Honeyeater appears to be an obligate colonial breeder. Yellow-tufted Honeyeaters that breed successfully as single pairs apparently do so only when they constitute a remnant of a former colony. Yellow-tufted Honeyeater colonies consist of several pairs that

maintain separate all-purpose territories, but the colony itself has a well-defined boundary, which may persist for many years, although the numbers of pairs and individuals within the colonies can vary. Various other meliphagids sometimes nest colonially. Fuscous Honeyeaters will nest solitarily or semi-colonially, the neighbouring pairs interacting without aggression. It was found that nests with close neighbours were much more likely to succeed than were isolated nests, and it has been suggested that, while resources may be sacrificed by a clumped distribution of breeding pairs, the increased rate of detection of and defence against threats increases success. Yellow-plumed Honeyeaters, too, are possibly colonial, with some indication that the birds live in colonies like those of Yellow-tufted Honeyeaters, although colonial breeding has not been confirmed. Black-headed Honeyeaters breed in small loose colonies, as also do Painted Honeyeaters, the latter in groups of possibly up to twelve pairs, though most reports are of smaller numbers. Brown-backed Honeyeaters, too, tend to nest in loose groups or colonies, containing up to ten or even 21 nests, but they also successfully nest solitarily. This species' sole congener in *Ramsayornis*, the Bar-breasted Honeyeater, while very poorly known, is thought also to nest sometimes in loose colonies. Black Honeyeaters similarly tend to nest in groups or loose colonies, and White-streaked Honeyeaters may also nest in small groups, possibly with synchronous breeding, but further study of this is required.

While some species are colonial or loosely colonial breeders, there are many isolated instances of close nesting by other species. Such observations have often led to claims that these species are colonial or loosely colonial when, in fact, this behaviour appears far from normal. For example, the Blue-faced Honeyeater has been said to be loosely colonial, but there appears to be only a single instance of pairs nesting close together. This was a note concerning two pairs with nests in one tree and another two pairs in another tree not far away, all appearing to nest without aggression towards one another. It seems that this observation is the basis for the suggestion in subsequent literature that this species may be loosely colonial. Some claims of apparent colonial breeding appear to refer to clumped breeding simply as a result of restricted habitat preferences.

Co-operative breeding has been reported for 24 species of honeyeater, all of them from Australia. Of these, however, only

the four species of *Manorina*, the Bell, Noisy, Yellow-throated and Black-eared Miners, are obligate co-operative breeders. In addition to the miners, co-operative breeding, or co-operative behaviour, has been reported for a further eight genera. In an earlier review, Dow listed five species for which co-operative breeding was regular and well described, and eight others for which it had been reported only once or twice. Subsequently, in 1991, D. C. McFarland and H. A. Ford, while not listing individual species, identified co-operative breeding by 22 species in nine genera. A decade later, the summaries published by P. J. Higgins and colleagues, including the analysis of the Nest Record Scheme, and studies subsequent to the earlier analyses, have clarified the extent of co-operative breeding and behaviour in the family. For example, all the instances listed as "suspected" by McFarland and Ford appear to be definite examples of co-operative behaviour, although apparently not representing co-operative breeding as such by the species in question.

Two of the co-operatively breeding species have perhaps the most complex social organization of all the honeyeaters. As detailed above, Bell Miners are colonial and always breed co-operatively, assisted by up to 20 auxiliaries, although the mean numbers of auxiliaries at two study sites were, respectively, 7.5 and 6.5. Auxiliaries, or helpers, can be juvenile siblings of the brood being helped, being offspring from the previous nesting attempt and no more than 1.3 months old; or they can be unpaired immatures, subadults typically first helping when 3 months old, or unpaired birds of breeding age; or they can even be neighbouring breeding adults simultaneously raising their own young. Auxiliaries are overwhelmingly males, and usually close relatives of one or both members of the breeding pair, more often the breeding male, and are thus siblings or half-siblings of the young being provisioned. Auxiliaries assist with defence of the nest and its contents from predators, feed the nestlings and fledglings, remove faeces and ectoparasites from the nests and nestlings, and, rarely, feed the sitting female. They may assist at up to three different nests simultaneously, male auxiliaries assisting more pairs than do female auxiliaries. Unpaired Bell Miners of breeding age provide the greatest proportion of all aid given by auxiliaries; in order of proportion of help contributed, they are followed by independent juveniles, by paired birds and, last, by dependent young.

Noisy Miners are also colonial and obligate co-operative breeders, with up to 22 auxiliaries recorded at a single nest. In one study, however, nests were attended by an average of 4.6 males, and in another study a maximum mean of 11.5 marked males visited nesting females through the breeding period. Again, auxiliaries are nearly always male, but they are usually not closely related to the breeding birds that they assist, although young males preferentially visit nests of their mothers. The number of auxiliaries at a nest varies with the number of nests begun by a female and the stage of nesting, nests with young usually having higher levels of attendance than do those with eggs. Auxiliaries, even breeding males, often help at several other nests, and at up to 14 nests, in a single breeding period. Unlike the situation with Bell Miners, the breeding female always had the greatest or the second-greatest levels of attendance at her own nest, and, among males, fathers provide most food for the nestlings; juveniles do not assist in the season in which they hatch. All auxiliaries feed nestlings and remove faecal sacs, and all feed the young for 1–3 months after they have left the nest.

Co-operative breeding has been recorded for 20 meliphagids other than the four miners, but for only a few of these is it known to occur regularly and to be of any significance in the social organization of the species. All six species of *Melithreptus* appear to breed co-operatively at times, and the phenomenon is known to be regular for Black-chinned, Brown-headed and White-naped Honeyeaters. In these three, co-operatively breeding groups usually consist of up to four or five adults attending nests, all members of the group contributing to the feeding of nestlings and fledglings, although as many as twelve White-naped Honeyeaters have been seen to be feeding the same young. Co-operative breeding has been reported at least occasionally for the less-studied Strong-billed and Black-headed Honeyeaters, and nestlings of the latter have been observed to be fed by adult auxiliaries, which are possibly males, and by juveniles or immatures from the previous brood. Additional individuals occasionally feed nestling and fledgling White-throated Honeyeaters, but the breeding behaviour of this species is poorly known.

Auxiliaries are observed regularly but uncommonly at nests of the colonial Yellow-tufted Honeyeater, up to five birds feeding the nestlings or fledglings and removing faecal sacs. In the case of the "Helmeted" subspecies *cassidix*, auxiliaries are of-

The Yellow-tinted Honeyeater suspends its neat cup-shaped nest from a branch or horizontal fork in the outer crown of trees such as *Eucalyptus* or, as here, *Acacia*. Accompanied but not assisted by her partner, the female firmly weaves a nest from fine grass, spider web, bark fibre and plant down. Some nests are left unlined, and others given a covering that may comprise feathers, rootlets or fine grass. The Yellow-tinted Honeyeater has been recorded breeding in all months of the year in Australia, with a peak in the dry season, and in most months in New Guinea, where the peak appears to be between September and November.

[*Lichenostomus flavescens flavescens*, Port Moresby, SE New Guinea. Photo: Brian J. Coates]

In common with other members of the genus *Meliphaga*, the **Graceful Honeyeater** usually elects to nest close to the ground, at a mean height of 1.5 m. Occasionally, birds nest much higher, up to 15 m above ground in Australia and up to 21 m in New Guinea. The deep, cup-shaped nest tends to be suspended from its rim and is lodged in the fork of a small branch towards the outside of a shrub or tree. The basic structure comprises moss, vines, roots and bark fibre. Plant down and fibre provide the inner lining, and the whole unit may be covered with moss, lichen or even insect cocoons.

Dawn Frith]

ten, and possibly always, adults. They may be paired, and some are related to the breeding pair which they are helping, in which case they are often offspring, whereas others are apparently unrelated. In detailed observations at seven "Helmeted Honeyeater" nests, auxiliaries were present at two. At one of these nests, the auxiliaries consisted of three mature siblings of the nestlings and these, in combination, made at least 30% of the feeding visits to chicks and removed 25% of the faecal sacs; at a second nest, an extra female made at least 32% of the feeding visits.

Whereas several detailed studies have shown that New Holland Honeyeaters do not breed co-operatively, it was found in one study that a small proportion of fledglings were attended by more than two adults, although the circumstances of these observations appear complex and vary. Sometimes, members of adjacent breeding pairs perched together near the nest of one of the pairs, and in at least some of these instances these were parents breeding alongside their offspring from the previous year. Further, fledglings were usually attended only by the parents, but in several cases broods of neighbouring pairs amalgamated and adults of two breeding pairs carried food to a single site; in most of these amalgamated broods, the two neighbouring breeding males were likely to have been father and son. In these amalgamated broods, adult males sometimes fed both their own and their neighbour's young. Territorial males without young have been seen also to feed young of neighbouring broods. Young males in territories adjacent to their natal territory, and breeding for the first time, seem often to have some assistance from neighbouring males, probably their fathers, which feed their fledglings. It is possible that this system results from amalgamation of broods and familiarity, rather than being due to the paternal relationship. Apparently similar observations of co-operative behaviour or amalgamation of broods have been reported elsewhere, with individuals other than the parents seen to attend young. Similarly, White-cheeked Honeyeaters do not breed co-operatively, but birds other than the parents have occasionally been observed to feed young. The system may be similar to that pertaining to the closely related New Holland Honeyeater.

A number of other meliphagid species have been reported as having auxiliaries at the nest. These are the Red and Little Wattlebirds, five species of *Lichenostomus*, namely the White-plumed, Fuscous, Varied, White-eared and Yellow Honeyeaters,

the Little Friarbird, the Rufous-throated Honeyeater, the Blue-faced Honeyeater and the Striped Honeyeater. Most of these species, however, are reasonably well known and do not normally breed co-operatively. Indeed, instances of co-operative breeding by these species are exceptional, and often involve a third bird feeding nestlings or fledglings. For example, Fuscous Honeyeaters have been well studied and are not co-operative breeders, but there have been two instances of young being fed by birds other than the parents; in both cases, the feeding was attributed to misplaced parenting, and not to co-operative breeding. In the single observed instance for the Striped Honeyeater, three individuals, thought to be the breeding pair and a single auxiliary, fed nestlings, but only two, thought to be the parents, brooded the young. Of 61 feeding visits to this nest, 25 were made by each of the parents and only five were identified as by the auxiliary; in the remaining six cases, the visitor was not identified. There were several aggressive interactions, which were possibly between the male parent and the auxiliary. In the case of the Red Wattlebird, there are occasional observations of dependent fledglings begging for food and being fed by immature wattlebirds, as well as by their parents. The immatures are believed to be young from previous breeding attempts in the same season.

Several further examples of possible co-operative behaviour are of interest. At a White-lined Honeyeater nest with eggs, a male and a female with a brood patch, thought to represent a breeding pair, were caught near the nest on one day; on the following day, a third, unsexed, individual was also caught within 1 m of the nest. While it was suggested that the third bird might have been an auxiliary, it cannot be accepted at this stage as evidence of co-operative behaviour. In another instance, this involving the Yellow Honeyeater, an offspring from the previous year was once seen to assist a female in the construction of a nest. While most instances of co-operative breeding involve the feeding of nestlings and fledglings, the removal of faecal sacs, and the defence of the nest or young, auxiliaries sometimes assist with other aspects of breeding. For example, in one group of Brown-headed Honeyeaters consisting of the breeding pair, two unsexed adults and a juvenile, all except the juvenile assisted with incubation, although the adults of the breeding pair undertook most of this task, and all members of the group fed the breeding female while she incubated.

Most honeyeaters appear to have a long breeding season, and make multiple breeding attempts in a season, even after having successfully raised young. The peaks of breeding activity, however, vary over the broad latitudinal range of the family, and the duration of the season appears also to vary with the pattern of movements of a species and the local abundance of resources. A few species, especially inland ones, appear to be opportunistic, breeding when conditions are suitable.

In temperate and subtropical Australia, most breeding occurs from late winter through spring to early summer, but in southern Australia and New Zealand breeding seasons are shorter. A few other Australian meliphagids, particularly the few migratory species studied, also have a shorter season. In a study of New Holland Honeyeaters and White-cheeked Honeyeaters at a site near Sydney, in temperate eastern Australia, both species laid through autumn and winter, with breeding centred on the period of peak nectar availability, which occurred in June–July. New Holland Honeyeaters laid clutches from mid-February to early September, most starting by late March and continuing to mid-August, and had 1–7 clutches per territorial male over the year; White-cheeked Honeyeaters laid from early April to early September, most starting by mid-April and continuing to mid-August, and had 1–4 clutches per territorial male. There was, however, a strong seasonal change in nesting success, all clutches laid before 1st April failing, whereas 57% of clutches laid after that date were successful in producing at least one fledgling; this is discussed in more detail below.

On the New England Tableland of eastern Australia, two species of large honeyeater had significantly different breeding seasons. Red Wattlebirds are sedentary at this site and had long breeding seasons characteristic of most honeyeaters, with first clutches completed in August and last clutches in January, and the latest young fledging in February. In contrast, Noisy Friarbirds, which are migratory at this site, arriving in early August and leaving in April, had a shorter season, with the first clutches completed in early November and two late clutches laid in January. The calculated number of “equally good months” (EGM) was 4.3 months for Red Wattlebirds and 2.1 for Noisy Friarbirds. When comparing data from throughout these species’ ranges, breeding seasons for both were longer than those observed on the New

England Tableland, with EGM of 5.9 and 4.1 months, respectively, Red Wattlebirds laying from July to February, with outliers in May and June, and Noisy Friarbirds from mid-August to January, with no outliers.

A curtailed breeding period similar to that of the Noisy Friarbird was observed also for the migratory Yellow-faced Honeyeater. In the south of its range, breeding began in mid-November, about two months after the return from migration, and the overall breeding season lasted some 3.5–4 months, with last clutches laid in mid-January to early February. Breeding pairs of this species were multi-brooded, producing an average of 2.14 clutches per season, and always renested within the same territory and with the same partner within a season. Pairs renested after successful attempts, as well as after failure.

In New Zealand, the two members of the family have short breeding seasons. Tuis on Tiritiri Matangi Island, in the Hauraki Gulf of the North Island, had clutches in November–December, and construction of nests coincided with the earliest availability of nectar from New Zealand flax and rewarewa (*Knightia excelsa*), the first nests being built by those birds that had home ranges near available sources of nectar. Similarly, on the Chatham Islands, clutches of the local Tui subspecies *chathamensis* have been recorded from mid-November to early December, with the onset of breeding likely to be influenced by the flowering of flax. On the North Island generally, clutches have been recorded from October to mid-January, with fledglings as late as March, and outlying records of unspecified breeding in August and of nestlings or fledglings in April–May. Tuis only occasionally raise two broods in a season. On the Poor Knights Islands, New Zealand Bellbirds laid from late September to late November, with a peak from mid-October to mid-November, with fledglings recorded to late December. On the Poor Knights the bellbirds were probably single-brooded, but they sometimes re-laid after failure.

Noske and D. C. Franklin, who analysed breeding in coastal and subcoastal Northern Territory, in the monsoonal tropics of Australia, found that breeding by landbirds reached a peak during the austral spring, from September to November, although many species were recorded as breeding in most or all months of the year. Among the Meliphagidae, the Rufous-banded Honeyeater was found to breed throughout the year in urban Darwin, with a prolonged but distinct peak from September to March. In contrast, the two smallest honeyeaters, both nectarivores, both bred during the dry season, the Red-headed Myzomela, a mangrove specialist, mainly in June–September, and the Brown Honeyeater, a habitat generalist, in May–August. Most other honeyeaters appeared to breed throughout the year, with records in nearly all months: these included the nectarivorous Dusky Myzomela, with breeding recorded in all months except January and June; the White-gaped Honeyeater, all months except June; and the Helmeted Friarbird, all months except May and July. Although there were few records, White-throated Honeyeaters appeared to have a bimodal seasonality, with peaks in April and September. Noske and Franklin argue that the restricted breeding seasons of such species as the Red-headed Myzomela suggest that their resources are predictably good at certain times, whereas the nearly year-round breeding for other species, such as the Dusky Myzomela, indicates that their resources may be available throughout the year, though not necessarily superabundant at any time. Red-headed Myzomelas breed when their major nectar source, the rib-fruited mangrove, is in flower. The Bar-breasted Honeyeater, which is strongly associated with paperbark woodlands, breeds predominantly during the wet season, coinciding with the major flowering seasons of the two dominant species of paperbark in the region.

There is little information on the breeding seasons of Wallacean honeyeaters. Nevertheless, Noske has analysed breeding seasons for landbirds on Timor, and J. A. J. Verheijen has done so for Flores. For all landbirds on Timor, breeding occurs throughout the wet season, from November to April, with a possible peak in activity in November, although there are few data for August–November, whereas breeding in western Flores is concentrated between April and June. The few data that exist for the three honeyeaters occurring on Timor appear to fit within this broad general pattern, but with a breeding record for the

Not surprisingly, there are far fewer breeding data recorded on the meliphagids of New Guinea than on those occurring in Australia and New Zealand. The Rufous-backed Honeyeater, a New Guinea endemic, is a case in point, as very little information is available on its breeding ecology. The nest seen here in a Casuarina tree is one of the few nests of this species so far reported. Indeed, an old published description of a nest initially attributed to this species is now thought more likely to have belonged to the congeneric Black-backed Honeyeater (*Ptiloprora perstriata*).

[*Ptiloprora guisei*, New Guinea.
Photo: Clifford & Dawn Frith]

Streak-breasted Honeyeater in October. The Helmeted Friarbird on Flores exhibited a double peak of laying, late in the wet season to the dry season, in February–May, and again late in the dry season, in October–December; there was a sharp decline in December–March, a period usually characterized by continuous heavy rain. The greatest peak in breeding was at the beginning of the dry season, in April–May, and this was then followed by a gradual decline.

Far less detailed information is available for New Guinea. H. L. Bell found the breeding season of honeyeaters in rainforest and savanna near Port Moresby to be at a peak in the late dry season, in August–September, and again in the early wet season, in November–December, with lowest levels of breeding activity in January–June. This peak in the austral spring is generally similar to that for northern Australia, with the culmination of breeding before substantial wet-season rains. There are also many scattered anecdotal reports for New Guinea. For example, a pair of Long-billed Honeyeaters, which was assumed to consist of the same two partners throughout, was observed in detail at the Baiyer River Sanctuary, in the Western Highlands. A nest under construction in mid-October, had a complete clutch of two eggs on 13th of that month; the eggs hatched on 29th October, 16 days after the completion of the clutch, and young successfully fledged on 13th November, 15 days after hatching. A second nest was built in exactly the same spot, and a second clutch of two eggs was completed on 17th December; these hatched on 4th or 5th January, 18–19 days after laying, and young fledged on 19th January, 14–15 days later. The total incubation–nestling period was 31 days for the first attempt and 32–34 days for the second. No breeding took place during the height of the wet season, but another nest was built in the same place, with a clutch of two eggs present on 4th May. These eggs hatched on 12th May and the young fledged on 29th May, 17 days after hatching. If the same pair was involved, it successfully raised two broods between October and mid-January, and then a third in the subsequent May–June. In New Guinea, breeding of MacGregor's Honeyeater, which is a specialist frugivore (see Food and Feeding), appears to be synchronized with the local production of ripe fruit of its preferred species, *Dacrycarpus compactus*, which does not always occur annually. Even so, a nest with a single chick has been found when there was almost no *Dacrycarpus* fruit available.

Throughout the south-western Pacific Ocean, breeding tends to occur in all months of the year, although it is known well for only a few species. The Wattled Honeyeater is known to breed throughout the year on Fiji, and pairs are multi-brooded, but there appear to be peaks in activity in February–April, June–July and September–October. In Fiji, breeding by Orange-breasted Myzomelas has been recorded in all months except March–April, and pairs are possibly double-brooded.

Detailed observations of nest-site selection are few. Male New Holland Honeyeaters appear to perform song flights and they dive into vegetation, where they are joined by the female, the two then moving about in the vegetation, with occasional quiet calling. The males appear sometimes to perform song flights when the female is at a potential nest-site. In observations of Black Honeyeaters, the female has been seen to settle in a suitable site and to turn and twist for a variable period, from several seconds up to several minutes; the male called near a nest-site until the female returned, when both flew to the nest-site and briefly twisted and turned, before flying off, the male chasing the female.

Copulation and the pre-copulatory behaviour of meliphagids have been observed only occasionally, and appear to be characteristically brief. Copulation by ringed Yellow-faced Honeyeaters has been recorded twice. The partners perched beside each other on a branch and began much bill-clapping, before the male jumped over the female and back on to the branch two or three times; he then mounted the female for less than half a second, doing so twice in one observation. In both observations, the entire event lasted for less than five seconds before one of the pair left. These copulations occurred three days and one day, respectively, before the laying of the first egg.

The roles of the sexes in the construction of the nest appear to vary. Typically, however, the nest is built either by both sexes or by the female alone, in the latter case usually with the male in close attendance but not gathering material or doing any building work. Among those members of the family in which both sexes build, the contribution by the male is often much less than that of the female and sometimes trivial. When dealing with sexually monomorphic species, caution needs to be exercised in assessing claims, based on anecdotal observations of unmarked individuals, that both sexes build, as it is possible that the close attendance of the male is confused with physical assistance with

The only meliphagids that do not share the family trait of cup-shaped nests are the two species in the genus *Ramsayornis*. Both build bulky, domed nests. That of the **Bar-breasted Honeyeater** has a hood, as well as a side entrance which often encompasses a landing pad. Unlike the neat nest of other meliphagids, this is a ragged affair, with long strips of bark hanging from the sides and base. The nest materials are broadly the same as for other honeyeaters, but the notable proportion of paperbark (*Melaleuca*) reflects the Bar-breasted Honeyeater's close association with such forests.

building. Equally, detailed studies of marked honeyeaters have shown that, even for species in which the female had been thought to do all of the work, the males do sometimes assist to some extent. Such studies are needed for most species before a proper assessment can be made of the roles of the sexes throughout the family. The details evidently vary even within genera. For example, in *Lichenostomus*, nest construction appears to be done mainly or solely by females, although males of some species contribute. In detailed studies of Fuscous Honeyeaters, it was found that usually only the female builds, but males occasionally brought material; females returned to the nest 16 times per hour, each visit being of about 27 seconds in duration, whereas males returned only 1.8 times per hour and their visits were brief, about 7 seconds. Within *Conopophila*, both sexes of the well-studied Rufous-banded Honeyeater collect material and build, contributing roughly equally to the task, whereas in the Rufous-throated Honeyeater it is said that only the female builds the nest, although there are also anecdotal observations that both sexes collect material and build. In the three *Phylidonyris* honeyeaters, the female alone collects nesting material and builds; during nest construction, the male New Holland Honeyeater often accompanies his mate as she collects material, often sitting above her on an exposed perch, and sometimes performing a song flight as she approaches the nest, descending to perch above it. As with the Rufous-banded Honeyeater mentioned above, both sexes of the Bar-breasted Honeyeater, in the genus *Ramsayornis*, and both sexes of the Painted Honeyeater, in *Grantiella*, collect nesting material and build the nest. Among other species, even though both sexes build, there is some variation in their contributions. In the case of Scarlet Myzomelas, for example, construction was by the female alone at one nest but mostly by the male at another. In the co-operatively breeding miners, only the female gathers material and builds, but with another co-operative breeder, the Black-chinned Honeyeater, the roles of group-members in nest construction vary. At some nests of the latter species all members of the group appear to build, whereas at others apparently

only one individual, assumed to be the breeding female, does all of the building, although sometimes others may collect material or accompany her.

Nesting materials are collected from an area around the nest, up to 200–400 m away for larger species but typically much closer to the nest for smaller species. Material is gathered from the ground, often around the base of shrubs and trees or around fallen trees, and from live or dead trees and shrubs, and is carried to the nest-site in the bill. For example, Crescent Honeyeaters collect material from within 20–50 m of the nest-site, mainly within their own territory but sometimes from neighbouring territories, the female making up to six trips with material before sitting at the nest-site and positioning and working material, while turning slowly in nest. On the second day of building, females made an average of 32 visits per hour to the nest, and 5.5 visits per hour on the fifth day. Female New Holland Honeyeaters in Victoria travelled a mean of 40 m from the nest to collect material, making an average of 2.1 collecting trips per hour, with fewer trips during the early stages of construction than later. The larger Red Wattlebird gathers nesting material from up to 300–400 m from the nest, and Noisy Friarbirds gather material from up to 200 m away. One female Scarlet Myzomela tore strips of red bark from an *Angophora* by grasping the bark in her bill, clinging to the stem of the tree with her feet and claws and spreading the rectrices against the stem for support, and then tugging at the bark. As bark began to peel, she held on with the bill alone and rapidly fluttered her wings until a shred of bark was torn off. Another female of this species collected spider web from trees and then flew back, with a bill full of web, to a partly built nest; she then hung by one leg from foliage and, while using the other leg to hold foliage down against the nest, bound the leaves into place. Red Wattlebirds used twigs of specific shape and size for different parts of the nest: twigs were first worked together and locked into place around branches of the nesting plant, and bound with hair, plastic, fine bark and thread; an inner cup was then constructed from naturally curved twigs, interlocked with a few vertical pieces, and the lining finally added.

Studies of Fuscous Honeyeaters revealed that, for 46 nests, the time taken for building varied from 3 days to 11 days, the average being 5.3 days. For 14 nests of New Holland Honeyeaters, the building work took 10–45 days, with the average 25 days. Some species appear intolerant of disturbance during construction. Tuis will abandon both complete and incomplete nests if disturbed by an observer, although they sometimes complete a nest and then abandon it before laying. White-eared Honeyeaters, when disturbed or observed too closely during nest construction, have been seen similarly to continue working on the nest until it is finished, or nearly so, but then to abandon it before laying; they sometimes reuse the material to construct a new nest nearby.

Nests of the Meliphagidae, where known, are almost universally cup-shaped, although they are sometimes described as bowl-shaped, as baskets or, when the diameter at the rim is slightly narrower than the widest point of the nest, as pouches or as being purse-shaped. The only exception to these cup-shaped nests is the domed nests of the two species of *Ramsayornis*. Thus, the Brown-backed Honeyeater has a bulky, elongated, penduline and domed nest, with a side entrance near the top and, usually, a hood, and the Bar-breasted Honeyeater builds a bulky domed nest with a side entrance and, typically, a landing at the entrance. A few species occasionally have partly covered nests, those of the Little Wattlebird, for example, at times having a roughly domed roof. Although almost always cup-shaped, meliphagid nests vary greatly in size and shape, and in the neatness and robustness of their construction. In conspicuousness they range from being fairly obvious to being well hidden. The five species of wattlebird in the genus *Anthochaera*, all large to very large honeyeaters, build a typical deep, open cup, but the nest of several of these species can be almost flat or saucer-shaped; it has been suggested, however, that these flatter structures are the result of flattening of the cup-shaped nest during a breeding attempt. Friarbird nests, where known, are large, loosely constructed and open cups or bowls. The nest of the Striped Honeyeater is fairly deep, with the opening of the cup often slightly smaller than the lower parts of the nest and with attach-

In those meliphagids for which data are available, clutch size appears to be universally small, with the most frequent number of eggs being two. The mean clutch size for the Yellow-faced Honeyeater fits the norm, at 2.35 eggs; clutches comprising a single egg are rare. The typical meliphagid egg is ovoid, smooth-shelled and slightly glossy. It is pale in colour, ranging from white to pale pink, and often spotted. Yellow-faced Honeyeater eggs are typical in shape and texture, vary in colour from white to light pink, and are marked with darker blotches. Pairs bonds in this well-studied species appear to be relinquished after a single breeding season, even when both partners are still alive and return to the breeding area.

[*Lichenostomus chrysops*, Photo: W. R. Taylor/Ardea]

When incubating or brooding, honeyeaters often sit very tight, some birds even allowing themselves to be touched. Alternatively, the **Eastern Spinebill** may perform a distraction display if it feels that its nestlings are under threat. Across the family, duration of the nestling period varies within the range of 11–20 days; in the Eastern Spinebill, it takes 12–15 days. This species may raise up to four broods in a season. A new nest is built for each clutch, no mean feat given that each construction may take up to a week to produce.

[*Acanthorhynchus tenuirostris*,

ment points running up from the nest rim to the nesting plant, so that the structure appears rather untidy and festooned. Nests of Rufous-throated Honeyeaters are neat, fragile and purse-shaped, usually suspended by one side from a fork of a branch, with the unattached side of the rim hanging lower.

Unusually, the Blue-faced Honeyeater prefers to utilize the nests of other species, especially the large, domed stick nests of Grey-crowned Babblers (*Pomatostomus temporalis*), although they have been seen also to reuse old nests of Noisy, Silver-crowned and Little Friarbirds, Noisy Miners, Red Wattlebirds, Australian Magpies (*Gymnorhina tibicen*) and Magpie-larks (*Grallina cyanoleuca*). When using babbler nests, they usually enlarge the existing entrance and build a round, open nest of bark and grass inside, or they build a new nest in a depression on the top or side of the babbler's nest. Blue-faced Honeyeater nests not in or on nests of other species are typical cup-shaped honeyeater nests, although it seems that this species usually builds its own nest only at sites where the babblers do not occur.

As would be expected, nest size varies with the size of the species. Nests of Scarlet Myzomelas are small neat cups, with an average external diameter of about 5 cm and external depth of 3–8 cm, and those of Red-headed Myzomelas are similarly small, with an external diameter of 5–5.8 cm and external depth of 3–4.3 cm. At the other extreme, friarbird nests are among the largest in the family. Helmeted Friarbirds build a large, open cup-shaped structure with external diameter and depth of 20–23 cm and 18 cm, respectively, the corresponding measurements for Noisy Friarbird nests being 12.7–17.8 cm and 7.6–10.2 cm. The mean external diameter of 17 Red Wattlebird nests, another large honeyeater, was 21.7 cm, with a range of 12–36 cm, these details excluding two extraordinary nests that were as much as 80 cm in diameter. The bulk of nests of medium-sized species fall between these extremes. For example, the medium-sized White-eared Honeyeater builds nests with an average external diameter of about 9 cm and external depth of approximately 5 cm, and those of the medium-large Striped Honeyeater have an external diameter of some 6–10.4 cm and an external depth of 6.5–12.3 cm.

Looking at the family as a whole, the honeyeaters use a wide variety of materials in their nests, as also do individual species. Nests are often made from, or include a large component of, bark or bark fibre, broad and large strips or pieces in nests of larger

species and smaller and finer strips or pieces in those of smaller meliphagids. Twigs and grass are commonly included in nests with bark; larger nests often have a large proportion of sticks or twigs, and smaller nests often include much grass. Other materials used in constructing the main cup-shaped structure include leaves, phyllodes, casuarina and pine needles, fern fronds, fine plant stems and fibres, pieces of vine and vine tendrils, rootlets, egg cases of moths (Lepidoptera) and spiders, and soft material such as wool, feathers, including those of Emus (*Dromaius novaehollandiae*), and fluffy seedheads. Some Helmeted Friarbird nests are made entirely from sticks or twigs, while the nests of Mangrove Honeyeaters consist of dried grasses and seagrass. In several species, nests built in paperbarks are often made with the bark of this tree. Foliage of the nesting plant is sometimes incorporated into the sides of the nest.

Nests are often bound externally, from tightly to loosely, with spider web or, less often, wool or other materials. The exterior is sometimes covered or festooned with moss, lichens or liverworts or other materials that appear to match the surroundings. Nests of Crescent Honeyeaters in Tasmania, for example, are occasionally adorned with small clumps of moss, which are of the same colour as that of the surroundings. Other nests have spider egg sacs and cocoons attached to the outside, and nests with wool woven untidily to the outside, hanging from the sides and bottom, have been reported. Striped Honeyeater nests often have a layer of wool so thick as to obscure the grass framework entirely, and they often also have Emu tail feathers worked into the upper part, which may partly hide the sitting bird but frequently serve to make the nest more conspicuous, at least to humans. The nests of some species can be thick-walled, while those of others may appear thin and frail, although they are usually sturdy and well made. For example, nests of Painted Honeyeaters are usually frail-looking, with eggs and daylight often visible through the sides, but they are in reality quite strong, and some are substantial structures. The nests of Black-chinned Honeyeaters are sometimes so finely woven, including the lining, that they will hold water when damp.

Meliphagid nests are usually lined with soft materials, which typically extend a little way up the sides. For instance, the lining in New Holland Honeyeater nests, which have an internal depth of 3–3.8 cm, extends about 1 cm up the side of the inner wall.

Species which usually line their nests, however, sometimes leave them unlined. In the case of Red Wattlebirds, it has even been suggested that there is a geographical variation in this respect, nests in Western Australia usually being unlined, whereas those elsewhere tend to be lined. Lining materials include shredded bark or strips of bark, fine grass, plant down from banksias, ferns, thistles and cycads and other plants, hair and fur from a variety of mammals, including possums (Petauroidea), kangaroo and wallabies (Macropodinae), rabbits (*Oryctolagus cuniculus*) and cattle, and wool from sheep and goats, feathers, leaves and leaf shoots, including casuarina needles, soft downy seeds, often of grasses, soft hairy buds, moss, fine rootlets, flowers and flower calyxes, small twigs and other plant material, such as bracts and stamens from banksias, and spider web. The lining of nests of larger species sometimes consists of much the same material as that of the external structure of the nests of smaller species, such as small sticks and twigs and coarse stalks of grass. One New Holland Honeyeater nest was lined with about 100 *Leucopogon* flowers, more than 20 banksia bracts, 2–3 feathers, and a piece of wool, and another was lined with more than 100 banksia bracts. Feathers lining the nest may sometimes cover the eggs. One Eastern Spinebill nest was lined with 25 Crimson Rosella (*Platycercus elegans*) feathers.

Hair is sometimes plucked from live animals, including koalas (*Phascolarctos cinereus*), cattle and even people. The White-eared Honeyeater is renowned for its habit of collecting hair or fur from live mammals, and regularly gathers materials from the head, body or clothing of humans, or accepts material offered by people, such as clippings of hair, wool or cotton wool. Around human habitation or places of human activity, artificial materials make their way into the nest structure and lining of meliphagid nests; these include such items as string, twine, rope fibres, paper, paper tissues, pieces of plastic, scraps of cloth, pieces of fibre from carpet, felt carpet underlay, and cigarette filters. Again, White-eared Honeyeaters have been seen to take strands from hessian or rope, fibres from a blanket on a clothes-line, and fibres from socks, and wool from clothing, and individuals have even attempted to take the laces from an observer's shoe.

When examined closely, at least some meliphagid nests appear to have a dual structure in the external layer, although this

varies among species, or perhaps is dependent on the interpretation of the observer. At Golton Vale, in Victoria, nests of New Holland Honeyeaters had three distinct layers: an outer layer of dead, often branched, twigs, a middle layer of strips of bark from messmate (*Eucalyptus obliqua*), and a lining of soft plant material and wool. At another Victoria site, Cranbourne, where less bark was available, the middle layer of nests was composed mainly of *Cassytha* vines and bark from tea-trees (*Leptospermum*) and paperbarks. Similarly, a Yellow Wattlebird nest had an external layer of twigs and rootlets, an inner layer of leaves, bark and grass, and a lining of wool. On the other hand, nests of Red Wattlebirds, while also of three distinct parts, consist of a concave substructure of sticks or grass, with a cup built in the hollow of the substructure and made of smaller sticks, bark or grass, and a soft inner lining of wool or fur. Twelve New Holland Honeyeater nests, when taken apart, were found to contain an average of 384 items of material in the outer layer, these ranging in length from less than 15 cm to 30 cm or more, and an average of 1713 banksia bracts; the number of items in the outer layer ranged from 225 to 610, and the number of banksia bracts from 250 to as many as 4000.

Most honeyeater nests are suspended by the rim, often from a horizontal or angled fork in a thin branch or branchlet in dense foliage towards the outer edge of a tree, sapling or shrub. Many are built among drooping outermost foliage and branches. Larger nests, such as those of friarbirds, are often, however, firmly woven over fairly thick branches, and nests can be suspended in a vertical fork or cluster of twigs or branches. Some species build closer to the centre of the nesting plant. A number of species commonly build the nest over water, the Bar-breasted Honeyeater of northern Australia being one such example. While the miners have been said to stand apart from other honeyeaters in that, among other things, the nest is supported and not suspended, supported nests are a common feature of a range of other species, including those, such as the Crescent and New Holland Honeyeaters, which more typically build a suspended nest. For example, in an analysis of nests of Singing Honeyeaters, 146 were suspended and 42 were supported, and 14 of 19 nests of White-eared Honeyeaters were suspended and the rest supported. Nests of Blue-faced Honeyeaters are often supported, especially when sited in palms, where they can be built on top of fronds,

Unlike most members of the family, **Scarlet Myzomela** pairs appear to be flexible in their division of breeding responsibilities. Either sex may build the nest, in contrast to almost all other honeyeaters, where the female takes charge. The female probably incubates alone, but is fed on the diminutive cup-shaped nest by the male. Once the eggs have hatched, both parents feed the nestlings. In common with other *Myzomela*, this species is strongly sexually dichromatic, the male being brightly attired and the female comparatively drab.

[*Myzomela sanguinolenta*, Goomboorian, SE Queensland, Australia. Photo: Cyril Webster]

often close to the trunk on top of a base of fronds. Similarly, a nest of the Long-billed Honeyeater was supported between the trunk and multiple leaf bases of a palm-like *Pandanus* tree. Some nests, while suspended, can in fact rest on the ground, as is the case with some White-cheeked Honeyeater nests.

Nests of this family are usually built in a live tree or shrub, but the nest-site varies much, as does the height of the nest above the ground. Some species tend to build in prickly shrubs, such as *Hakea* or *Acacia*. Other recorded sites are in mistletoes, dead shrubs, grass tussocks, clumps of rushes, bracken (*Pteridium esculentum*), among tangles of creepers and vines, in small palms, in grass-trees (*Xanthorrhoea*) and even on a fallen branch among grass. Mangrove Honeyeaters nearly always nest in dense mangrove shrubs or small trees. The Regent Honeyeater almost invariably uses rough-barked trees, mainly eucalypts. Exceptionally, nests have been recorded between a dead mallee eucalypt stem and the peeling bark, with the nest bound around the bark. On Solomon Island, off southern New Zealand, where petrels (*Pterodroma*) return to their nests at night, Tuis place their nests in sites protected by a small branch or cluster of twigs strong enough to deflect descending petrels.

Artificial sites are occasionally used. For example, a pair of Lewin's Honeyeaters attached its nest to a clothes-line beneath a house, and the site was used each season for an unknown number of years. In New Guinea, the little-known Long-billed Honeyeater has been seen to nest repeatedly in roofing material on the underside of a thatched roof in a well-used building.

Heights of nests vary considerably, from close to, or occasionally on, the ground, to 45 m above it in the crowns of tall trees. In general, most members of the family tend to build reasonably close to the ground, at 3–6 m, and there seems to be little correlation between height of the nest above ground and size of the species. Some species invariably nest low down. For example, the mean height of 120 Tawny-crowned Honeyeater nests throughout the species' range was 30 cm, varying from being on the ground to 1.2 m above it; and the mean height of 181 White-cheeked Honeyeater nests was 0.58 m, with the range 0.15–3.6 m, and 96% of these nests below 1 m. The generally medium-sized *Lichenostomus* and *Meliphaga* species of Australia tend also to nest close to the ground, but Fuscous and White-plumed Honeyeaters often or nearly always nest high up, mostly in the crown of a eucalypt or a tall acacia, and less often in a shrub. The medium-sized Bell Miner, while usually occupying tall forest habitats, usually nests in the shrub understorey; the height of 305 nests throughout the species' range was 0.30–25 m, with a mean of 2.6 m, and at one site 175 nests were 1–20 m above ground, the average being 2.8 m, with most nests 1–3 m above ground. The larger Noisy Miner tends to nest somewhat higher, with a mean of 6.3 m for 649 nests. In one study in the Northern Territory, the average height above ground of 195 nests of the small Rufous-banded Honeyeater was 5 m, varying from 1.6 m to 11 m, though with significant differences depending on nesting plant. The similarly small Eastern Spinebill tends to nest fairly high at some sites, although the mean height of nests throughout the geographical range was 3.1 m.

Among the larger species of honeyeater, nest height varies, although a few nest quite high up. The average height of nests of three of the four Australian friarbirds, the Helmeted, Silver-crowned and Little, ranges from 6.3 m to 7.3 m above ground; that of the Noisy Friarbird is 9.1 m. Similarly, the height of wattlebird nests varies. The means for the two smaller species, the Little and Western Wattlebirds, are 2.9 m and 3.5 m, respectively, although sample sizes for the latter are small, whereas that for the larger Red Wattlebird is 6.4 m. The Yellow Wattlebird usually nests quite high in trees, the average for 15 nests being 17.9 m. The remaining wattlebird, the Regent Honeyeater, nearly always nests high up in the crowns of tall trees. In the Bundarra-Barraba area of northern New South Wales, Regent Honeyeater nests were at an average height of 13.4 m, in trees which were about 18 m tall and were significantly taller than all trees measured in the surrounding 1 ha of woodland. In the Capertee Valley, in central-eastern New South Wales, in 1997, the mean height of nests in riparian sites was 12.8 m, whereas in woodland sites it was 7.8 m.

A number of species appear to have nesting associations with other breeding birds, although none seems to be an obligate association. The Striped Honeyeater, for instance, often associates with Grey Butcherbirds; of 27 of its nests at one site, 22 were noted as being near those of butcherbirds, and there are at least eight documented records of Striped Honeyeater nests having butcherbirds nesting nearby, once as close as 3 m. The Helmeted Friarbird evidently has a close nesting association with three species in Australia, the Australasian Figbird (*Sphecotheres vieilloti*), the Spangled Drongo and the Metallic Starling (*Aplonis metallica*). The same friarbird species in New Guinea has twice been reported as nesting in the same tree as a pair of Brown Orioles, and it has nested also in the same tree as White-bellied Cuckoo-shrikes (*Coracina papuensis*). Noisy Friarbirds and Leaden Flycatchers (*Myiagra rubecula*) also appear to have a nesting association, although the flycatchers probably seek out a nesting site near the friarbirds, rather than the reverse, and potentially benefit from the friarbirds' harassment of predators. In one study, however, flycatcher nests built within 26 m of a friarbird's nest were no more successful than were those built more than 48 m away.

Aside from these associations, there are many examples of various species of honeyeater nesting in the same tree as other bird species, although whether most of these are simply fortuitous events or represent closer but as yet unidentified associations is not known. For example, the Striped Honeyeater, in addition to its association with Grey Butcherbirds, has been recorded as nesting in the same tree as eight other species, most commonly black-and-white ones, including Willie Wagtails (*Rhipidura leucophrys*) and Magpie-larks. There are further records of nearby nesting of these and other species, though not in the same tree.

Honeyeaters, in common with many of the old endemic passerines of Australasia, tend to have small clutch sizes. It must be remembered, however, that there are virtually no accurate determinations of clutch size from regions beyond Australia and New Zealand, and not all Australian species are properly known. Thus, we probably have an accurate idea of clutch size for some

Nearly all members of the Meliphagidae are socially monogamous, but this characteristic does not preclude colonial or even co-operative breeding. All six members of the genus *Melithreptus* are known to have bred co-operatively, and the **Brown-headed Honeyeater** does so regularly. One such group comprised the breeding pair, two adult auxiliaries and a juvenile. The four adults shared incubation responsibilities, although the breeding pair assumed this role for three-quarters of the time. While incubating, the breeding female was fed by the other four group-members. Nestlings tend to be fed by both parents and any helpers.

Ardea]

one-third of the total number of species. For example, there are reasonable estimates of clutch size for only four of the 16 friarbirds, and whether the estimates of those four, all Australian species, are representative of the genus elsewhere throughout its predominantly tropical range is not known. The most frequent meliphagid clutch is of two eggs, even for large species such as the Red Wattlebird, which has a mean of 1.97 eggs. However, clutches of three or four and, rarely, five eggs are laid by species of friarbird and miner. Clutches of Helmeted and Noisy Friarbirds contain from two to five eggs but tend to be mainly of three or four, whereas the usual clutch of Silver-crowned and Little Friarbirds seems to be of two or three eggs, and occasionally four. Noisy and Yellow-throated Miners normally lay two to four eggs, the latter rarely five, and the mean for both is about three: throughout the species' ranges, the mean clutch size of Noisy Miners was 2.9 eggs and that of Yellow-throated Miners was 3.16. The usual clutch size of Bell Miners, however, is of two eggs; in five studies, the average ranged from 1.8 to 2.01 eggs. The two New Zealand endemics likewise have larger clutches, usually of three or four and, occasionally, five eggs. While there are few accurate determinations, Tuis on Tiritiri Matangi Island lay 2–4 eggs, with a mean of three, but first-year females laid more clutches of two and four than did older birds. Bellbirds on Poor Knights Islands had a mean clutch size of 2.87 eggs and those on Tiritiri Island a mean of 3.6 eggs.

While exceedingly poorly known in general, some island endemics of the south-western Pacific Ocean appear to lay single-egg clutches, or at least mainly do so. For example, Barred Honeyeaters are said to have a clutch of one egg, but clutches of the Vanuatu Honeyeater are said to consist of two eggs, although the basis of this claim is not certain. The clutch size of the Wattled Honeyeater is reported as usually one egg, but is said sometimes to consist of two or three eggs, while the Kadavu Honeyeater, too, is said to lay only one egg. Further, while the clutch size of the Giant Honeyeater is not known, only single dependent juveniles have ever been recorded.

Clutches larger than the usual, as recorded for the Blue-faced Honeyeater, among others, are thought to have been the result of more than one female laying in the same nest. At nests of Bell Miners, microsatellite analysis of parentage of 50 nestlings in 31

clutches found that five nestlings were the result of intraspecific brood parasitism.

There is some evidence that the clutch size of Noisy Miners increases slightly through the course of a breeding season. Similarly, in north-western Australia, early clutches of Yellow-throated Miners are said to be almost all of three eggs, whereas many later clutches contain four or more. At one site, the mean size of first clutches of Noisy Miners in a harsh year was significantly lower than that in a better year. In eastern Australia, clutch size of New Holland Honeyeaters appears to increase from north to south.

Eggs of the Meliphagidae are typically oval, and usually elongate oval, but they range from being almost spherical to being rounded ovals or thick ovals to elliptical and pointed ovals. They are usually close-grained, finely textured and smooth; and slightly lustrous or glossy, although some are said to be lustreless. Ground colours range from white, through cream and buff to pink and salmon, and eggs are often spotted, varying from finely so to heavily blotched, with light to dark lilac or purple, purplish-brown, reddish-brown or red, brown or black. Eggs are typically more heavily marked at the large end, where the markings sometimes form a well-defined zone or cap. The eggs of many species also have underlying spots and blotches, often of violet or grey.

Laying intervals have been found to be approximately 24 hours for the few species that have been studied. With some larger species, however, the intervals may be more than 24 hours. The Noisy Friarbird lays its eggs at intervals of 24–48 hours, and laying intervals thought to be greater than 24 hours occur at least sometimes with Little Friarbirds. There are no data for the other friarbirds, nor for the wattlebirds, other than a laying interval once of between 29.5 and 34 hours for a Little Wattlebird.

Incubation periods range from 12 to 17 days, and nestling periods from 11 to 20 days, occasionally longer. While the range for these periods across the family is not great, they tend to be shorter for smaller species and longest for the large species. For example, the mean incubation period at eight nests of Rufous-banded Honeyeaters, a small tropical species, was 14 days 7 hours, ranging from 13 days 13 hours to 15 days 5 hours, and the mean nestling period was 14 days, ranging from 13 days 4 hours to 14 days 21 hours. In the medium-small Yellow-faced Honeyeater,

Larger honeyeaters tend to have longer incubation and nestling periods than smaller species. The **Noisy Friarbird** incubates for 15–19 days and broods for 16–19 days. The lower ends of these ranges are longer, for example, than the equivalent mean figures for the considerably smaller Rufous-banded Honeyeater (*Conopophila albogularis*). Noisy Friarbirds are aggressive parents, readily attacking predators that venture near their nest. As such, they make useful neighbours, so species such as the Leaden Flycatcher (*Myiagra rubecula*) apparently often breed near friarbirds for protection.

[*Philemon corniculatus monachus*,
Goomborian,

Photo: Cyril Webster]

the incubation period was 14–16 days, with an average of 14.4 days, and the nestling period lasted 11–15 days, with an average of 13 days. The mean incubation period of the medium-sized Singing Honeyeater of arid and temperate regions was 13.2 days, ranging from 12 to 14 days, although at least once it was greater than 14 days. In temperate northern New South Wales, the incubation period of Noisy Friarbirds, a large species, was 15–19 days and the nestling period 16–19 days. In most instances, the sample sizes are small.

Among most species, incubation of the eggs and brooding of nestlings is carried out primarily or exclusively by the female. Even among the colonial and co-operatively breeding miners, the female alone incubates and broods. Some claims of incubation or brooding by males of monomorphic species within genera in which these duties are otherwise undertaken solely by the female require confirmation, especially in cases when the birds were not individually ringed. For example, within the genus *Lichenostomus*, incubation is solely by the female, or nearly so, but it has been variously claimed, in the case of White-gaped Honeyeaters, that both parents brood and that the female alone broods. With a few species, however, males do assist with incubation or brooding. Both sexes of the Painted Honeyeater incubate and brood, the male also sometimes feeding the female on the nest. In *Melithreptus*, both sexes of the Brown-headed Honeyeater are known to incubate, and both sexes are thought to do so at nests of the Black-chinned, Strong-billed and White-throated Honeyeater, although there are few observations for these three. For White-naped Honeyeaters, it has been suggested that probably only the female incubates, and for Black-headed Honeyeaters it has been variously suggested that incubation is by the female alone or is shared between the sexes. Further, there can be variation within a species. Sometimes both sexes of the Black Honeyeater incubate the eggs, although incubation was mainly by the female at one nest, with the male seen on the nest only once, yet at other nests of this species incubation was done solely by the female. Both sexes also brood the young, but the female does the greater share.

Occasionally, even auxiliaries of co-operatively breeding species may participate in incubation. In detailed observations of a co-operatively nesting group of Brown-headed Honeyeaters that consisted of the breeding pair, two unsexed adult auxiliaries and a juvenile auxiliary, the primary pair incubated for 73% of the time, shared about equally between them, the two unsexed adult auxiliaries for 24% and 3% of the time, and the juvenile did not incubate at all; over eight days, this nest was unattended for only 1% of the time.

Incubation seems usually to begin with completion of the clutch, but even when this is normally the case it may begin earlier. For example, female Bell Miners occasionally began incubating after laying the first egg of a two-egg clutch or the second of a three-egg clutch. In other species, asynchronous hatching indicates that incubation probably began before the clutch was complete.

All honeyeater chicks are altricial and nidicolous. The young hatch blind and naked, or almost naked, but soon develop a light covering of down. The time spent in brooding them during the day decreases over the nestling period, although nocturnal brooding often continues to the end or close to the end of this period. For example, in Crescent Honeyeaters, in which brooding is solely by the female, nestlings are brooded for 50% of the day on the first day, but the brooding time declined steadily, until diurnal brooding had almost stopped on the eighth day. Among Bell Miners, the brooding behaviour of the breeding female, which carries out all of this duty, varied with a number of factors. Thus, the mean number of bouts decreased as nestlings grew older; brooding decreased as ambient temperature rose, although with a small increase at 36–40°C, presumably when the female shaded the young; and larger broods were brooded significantly less than were smaller ones, even though the number of nestlings ranged only from one to three. The number of brooding bouts also increased significantly with an increase in the numbers of auxiliaries attending the nest. During incubation and brooding periods, sitting birds will leave the nest for short periods during the day in order to forage.

While incubation and brooding are done almost solely by the breeding female, both parents, and also, in co-operative breeders, auxiliaries feed the nestlings and fledglings, guard them from predators, and remove or eat the faecal sacs. At Crescent Honeyeater nests, both male and female parents fed the nestlings, removed faecal sacs, and tended the chicks by removing remains of faecal sacs, food and feather scales from them; females, however, made more feeding visits than males, 69% as against 31%, and females removed more faecal sacs and tended the young more. The two sexes of the Yellow-faced Honeyeater fed the young and removed faecal sacs at about equal rates. In the case of co-operatively breeding Bell and Noisy Miners, both parents and auxiliaries feed, guard and care for nestlings, but most of the nest-sanitation work is carried out by the breeding female.

Evidence from a few species indicates that young become independent from 26 to 42 days after fledging, although this is a progressive process, the young starting to feed themselves in about half of this time. There are, however, few hard data. In Victoria, the mean age of independence of young New Holland Honeyeaters was 37.6 days, with a range of 22–52 days. Fledglings of the Rufous-banded Honeyeater stay with the parents for at least 30 days after leaving the nest, and they may continue to beg at that stage, with two fledglings seen to be fed by the parents 35 days after leaving the nest. Fledgling Bell Miners are wholly dependent on the parents or auxiliaries for food for at least eight days after they leave the nest, and they are fed for an average of 10.6 weeks after fledging. In northern New South Wales, juvenile Red Wattlebirds were still being fed by their parents 15 days after fledging, and elsewhere another brood was noted to be largely independent one month after fledging.

A Rufous-banded Honeyeater pair may

raise up to five broods in a season, with an average of just under one fledgling leaving the nest per attempt.

Such breeding success requires considerable parental investment, so it is not surprising that members of the pair share breeding responsibilities. Both adults play a roughly equal role in collecting material for and subsequently constructing the nest. Both sexes also feed the nestlings and fledglings. The diet of the adults is mainly arthropods such as insects and spiders, and it is likely that such protein sources also form the bulk of the young birds' calorie intake.

[*Conopophila albogularis*, Darwin, Northern Territory, Australia.

Photo: Raoul Slater/Lochman Transparencies]

Like many meliphagids, the **Tawny-breasted Honeyeater** conceals its nest deep in the dense foliage of a shrub or tree, a tactic aimed at avoiding the attention of predators. During the two-week nestling period, the most perilous moments are when the parent returns to the nest-site with food. The adult thus does so quickly, quietly and with the minimum of fuss. Both sexes of the Tawny-breasted Honeyeater are thought to feed the nestlings and fledglings, and insects such as beetles (Coleoptera) and grasshoppers (Orthoptera) provide the bulk of the species' diet.

Dawn Frith]

Interestingly, broods of New Holland Honeyeaters in New South Wales sometimes join together to form larger groups. Of 44 broods of fledglings, seven amalgamated with a neighbouring brood, the adults of both breeding pairs then carrying food to a single location.

During the incubation and nestling stages, meliphagids can sit very tightly, not leaving until almost touched or, in some instances, until they are physically touched. Brooding and incubating female Black Honeyeaters, for example, did not leave the nest until almost touched by the observer, and one brooding female had to be lifted from the nest for the observer to inspect the young. When approached, an incubating female Black Honeyeater sinks down into the nest, with the bill and tail held vertically.

Distraction displays by honeyeaters, designed to lure a predator or potential predator away from nests or away from fledglings, have been reported widely, including for some New Guinea genera such as *Melidectes* and *Melilestes*. Most observations, however, involve responses to human observers. Distraction displays include the feigning of injury or juvenility by making fake falls and tumbles from branches close to the source of the perceived threat, sometimes with the wings spread, fluttering in the vegetation, fluttering along the ground with one wing dragging in the so-called "broken-wing display", or flopping about on the ground with both wings spread, flapping and calling weakly. In New Guinea, a Long-billed Honeyeater performed a broken-wing distraction display along the ground, moving quickly away from a nest with eggs. The birds also utter alarm or distress calls, with bill-snapping, and they may attack or mob a human observer or other perceived threats.

For well-studied meliphagid species in Australia, breeding success in terms of the number of nests fledging at least one young ranges from as low as 5.6% to as high as 76%. The low value is for Noisy Miners. The high one was for Rufous-banded Honeyeaters breeding in a tropical urban environment; of 78 complete clutches, 63, or 81%, produced nestlings and 55, 71%, produced fledglings. Rufous-banded Honeyeaters produced 5.82 young per pair per season, and there was no significant difference in success between clutches of two and of three eggs, between nests built in the same tree as the previous nest and those in a new site, and between nests above 5 m and those below 5 m from the ground. Moreover, productivity did not vary signifi-

cantly during the three-year study period or among four periods within the breeding season. For Crescent Honeyeaters in Victoria, during one season, of 76 eggs in 27 nests, 55 hatched and, from these, 22 young fledged, with overall breeding success of 29.6%. At one site in Victoria, 34.6% of Bell Miner nests fledged at least one young; at another site, a mean of 0.62 fledglings per breeding attempt was achieved, and females had a mean lifetime productivity of 3.83 fledglings.

The causes of failure are the same as those for many other bird species. A proportion of eggs are, of course, infertile; for example, in one study of Bell Miners 3% of eggs were infertile. Other eggs become addled during incubation. Poor weather can cause failure, with nests blown down or their contents blown out during strong winds, storms or cyclones; further, nestlings often die in cold, wet weather, and persistently bad weather and rain eventually causes females to abandon eggs. Predators are responsible for many losses, and reptiles are considered an important cause of failure. Nestlings are known to have been taken by monitors (*Varanus*), including Gould's monitor (*Varanus gouldii*), and by snakes, including the eastern brown snake (*Pseudonaja textilis*) and the copperhead (*Austrelaps superbus*). D. P. Armstrong and G. H. Pyke, in a study of nesting attempts made by New Holland and White-cheeked Honeyeaters north of Sydney, concluded that the patterns of success and failure that they observed were not a result of seasonal changes in availability of food energy in the form of nectar, but were due to the effects of predation, which may prevent successful breeding over the warmer months.

Avian predators are also responsible for losses. Eggs or nestlings of meliphagids are taken by birds of prey, including Australasian Goshawks (*Accipiter fasciatus*), Spotted Harriers (*Circus assimilis*) and Black Falcons (*Falco subniger*), and by kookaburras, currawongs (*Strepera*), crows and ravens, butcherbirds, Common Blackbirds (*Turdus merula*) and Common Mynas (*Acridotheres tristis*). Further, Spiny-cheeked Honeyeaters are known to take eggs of Painted Honeyeaters. Mammalian predators include domestic and feral cats, common brush-tailed possums (*Trichosurus vulpecula*), black rats (*Rattus rattus*) and, in New Zealand, stoats (*Mustela erminea*) and Pacific rats (*Rattus exulans*). Predators also cause nest failure when they kill sitting adults. Nestlings may be attacked by green tree-ants

(*Oecophylla*), and nests are sometimes abandoned or the nestlings killed by other ants.

Nests are sometimes abandoned when disturbed, either by human observers or by other sources, such as attacks by White-winged Choughs (*Corcorax melanorhamphos*). Tuis may desert a newly laid clutch if disturbed by an observer, or some other potential threat, but they do not abandon well-incubated clutches. Nests appear sometimes to be simply abandoned for no obvious reason. Formerly, many eggs were taken by collectors, and eggs are still occasionally damaged by researchers. Nestlings are also sometimes infested with parasites, such as larvae of botflies (of the genus *Passeromyia*), or die from disease. Ectoparasites, however, probably only rarely cause mortality. Infanticide and egg destruction by other species have been recorded.

Occasionally, fate intervenes. A Painted Honeyeater abandoned a clutch of three eggs when these became stuck to the bottom of the nest by a liquid dripping from an overhanging mistletoe, which made it impossible for the female to turn the eggs. At two nests, nestling Helmeted Friarbirds died when their legs became entangled in polypropylene twine incorporated into the nest rim, although, at one nest, two young thus entangled and hanging upside-down outside the nest still accepted food from the parents. One nest built next to a door failed when the door was opened, smashing the nest, and another nest with eggs failed after the tree in which it was placed was cut down.

For Bell Miner nests at one site in Victoria where cause of total failure of nests was known, the details were as follows. Of 63 nests, 53.9% were preyed on, 9.5% were partly preyed on and then deserted, 28.5% were deserted by the parents, in 3% the young were killed by disease and, in single nests, the eggs were infertile, the eggs were broken, or the nestlings were deserted.

Honeyeaters are hosts to a number of cuckoos. They are one of the main hosts of Pallid Cuckoos (*Cuculus pallidus*) in Australia, meliphagids comprising some 66% of 1052 records of nest parasitism by this cuckoo or of adults feeding the cuckoo fledglings, though the latter are not definitive instances of brood parasitism. Pallid Cuckoo eggs or chicks have been recorded in nests of *Acanthorhynchus*, *Anthochaera*, one *Meliphaga* species, twelve *Lichenostomus*, three *Manorina*, five *Melithreptus*, one *Lichmera*, three *Phylidonyris*, two *Philemon*, one *Ramsayornis* and in nests of the monotypic *Purnella*, *Gliciphila*, *Acanthagenys*, *Plectorhyncha* and *Entomyzon*. The larger species, such as the friarbirds and wattletails, in addition to being hosts of Pallid Cuckoos, are parasitized by the larger Common Koel (*Eudynamys scolopacea*), and in New Zealand eggs of the Long-tailed Koel (*Eudynamys taitensis*) have been found in nests of Tuis and New Zealand Bellbirds. Brush Cuckoos (*Cacomantis variolosus*) also parasitize nests of small and medium-sized honeyeaters, such as those of *Conopophila*, *Lichenostomus* and *Ramsayornis*. Honeyeaters are only occasionally parasitized by bronze-cuckoos, but eggs or nestlings of the Shining (*Chrysococcyx lucidus*) and Horsfield's Bronze-cuckoos (*Chrysococcyx basalus*) have been found in nests of species of *Acanthorhynchus*, *Lichenostomus*, *Melithreptus*, *Phylidonyris*, *Lichmera*, *Myzomela* and the monotypic *Purnella*, *Gliciphila* and *Sugomel*. Honeyeaters are also, no doubt, parasitized by some of these, and other species, elsewhere in their geographical ranges, but there are few reports outside Australia. Honeyeaters mob or attack cuckoos. Helmeted Friarbirds, for example, have been seen to attack Common Koels near a nest, and one chased a Pheasant Coucal (*Centropus phasianinus*), which is not a nest parasite, and then returned to its nest. A Dusky *Myzomela*, along with other species of honeyeater, was seen to attack a Brush Cuckoo, fluttering above it and scolding it.

While not known in any detail for most species, many members of the family probably breed in their first year, in the season subsequent to the one in which they hatched. There are many instances of first-year Regent Honeyeaters nesting successfully. Yellow-tufted Honeyeaters first breed in the year after they fledge, with successful breeding attempts recorded for an 11-month-old female, as well as unsuccessful attempts by both first-year males and first-year females. North of Sydney, New Holland Honeyeaters are able to establish territories, attract a mate and successfully breed when one year old; in Victoria, females are able to breed when about one year old and most probably do so,

whereas males first bred between the ages of one and at least two years, two aged 1.5–2 years having not yet bred. In northern Australia, Immelman claimed that White-gaped Honeyeaters could breed before finishing the post-juvenile moult, although confirmation of this is needed.

Honeyeaters, like many Australian passerines, can be long-lived, and there are many records of longevity greater than 10 years. For all members of the family in Australia and New Zealand for which relevant data are available, the mean longevity is just over 9 years 11 months. The longest-lived individual was a White-plumed Honeyeater, which had a lifespan of 15 years 10 months.

Movements

With a few exceptions, there is no simple categorization for the movements of meliphagid species. Analysis of the movement patterns of Australian birds is severely limited by the combination of huge land areas and the low density of human populations, and even lower densities of ornithologists and bird-ringers. The situation is even worse in New Guinea, and there have been few analyses of movements on the islands of Wallacea and the south-western Pacific Ocean. The majority of honeyeaters, however, could be considered sedentary, with no large-scale seasonal movements observed for many of the Australian species and for nearly all of the others. Least identified rainforests as having the greatest proportion of sedentary species among Australian honeyeaters, and this is a pattern likely to be repeated throughout the range of the family. Nevertheless, all species probably undertake some, usually ill-defined, local or regional movements to exploit food resources, with such movements more prominent among the more strongly nectarivorous species. The extent of these movements varies, but they are often described as nomadic.

Honeyeaters can be broadly classified under three headings. The majority are sedentary, or resident, most individuals of the species usually remaining in a stable territory or home range; some are migratory, all or most individuals moving regularly between breeding and non-breeding ranges; and some are nomadic or dispersive, their movements and occurrence apparently unpredictable, but not necessarily random, within suitable habi-

Black Honeyeaters are diligent parents. Although many incubating meliphagids sit tight on the nest when approached, one female Black Honeyeater took this to an extreme by having to be physically lifted from the nest for the human observer to inspect her eggs. Black Honeyeaters also employ a quite different strategy towards intruders, performing distraction displays, and, on at least one occasion, even attacking the observer.

Both sexes incubate, brood and provision their offspring, although the female probably performs the bulk of the first two functions and the male most of the last.

[*Sugomel nigrum*,
Bollon, Queensland,
Australia.
Photo: Raoul Slater]

Breeding success among honeyeaters varies considerably. One investigation revealed that just 5.6% of nests of the studied species produced one or more fledglings, whereas research into a different species produced an equivalent figure of 76%. **Lewin's Honeyeater** appears to tend towards the upper end of the scale of breeding success, with a mean of one fledgling raised for every two nests. To be successful, adults must run the gauntlet of nest predation by Pied Currawongs (*Strepera graculina*) and brood parasitism by Fan-tailed (*Cacomantis flabelliformis*) and Pallid Cuckoos (*Cuculus pallidus*).

[*Meliphaga lewinii lewinii*, Goomboorian, SE Queensland, Australia. Photo: Cyril Webster]

tat, and these can be considered to be intermediate between the previous two patterns. Other types of movement made by honeyeaters include irruptions, sometimes beyond the normal range of a species, dispersal of young from their natal range, and vagrancy, which is characterized by the occurrence of individuals beyond their normal range or habitat. The last is of little biological importance, other than when it may represent the beginnings of a species' range expansion.

There is, however, some intraspecific variation in the patterns of movements, at local, regional and continental scales. In common with other regions at middle latitudes, partial migration is well developed among Australian birds. K. Chan, who recently reviewed partial migration by Australian landbirds, listed 25 species of honeyeater as partial migrants, having both sedentary and migratory components, which represents 36% of the Australian meliphagid species. Further, nearly all species considered sedentary have been recorded as moving locally at some sites. Such variation makes it difficult to generalize about the patterns of movement at a species level, as birds respond to availability of resources, especially food, or climatic or other factors, such as drought or fire, on local and regional scales. While there have been studies that show a correlation between abundance or occurrence of honeyeaters and nectar production or numbers of flowers, others have failed to detect a correspondence between meliphagid presence and nectar or other resource production.

Nomadism and nomadic movements are perhaps the most problematic category of movements of Australian birds, and of honeyeaters in particular. The mobility of nectarivores at local or regional scales, often in apparent response to the distribution of flowering plants and nectar production, is well known for the Australasian avifauna as a whole. Nomadism is a response to highly varying distributions of resources in time and space, and diet is commonly perceived as an important predictor of nomadic behaviour, although mass and other factors have also been identified as possible predictors. The term "nomadism" is frequently associated with the movements of honeyeaters, even to the extent that some authors have listed all or nearly all Australian honeyeaters as nomadic, whether partially, locally or seasonally so. The term is often used to describe apparent movements of some honeyeaters in Wallacea, New Guinea and the south-west-

ern Pacific. The description of movements as nomadic or dispersive, however, often reflects a lack of knowledge of the true patterns of movement within a species, and is often used indiscriminately as a convenient catch-all classification to explain observations that do not readily fit other patterns. Further, while local movements, and the species performing them, are often described as being nomadic or locally nomadic, such movements can be interpreted as residence within a large home range. As has been pointed out, the expression "local nomad" is virtually a contradiction of terms. Although beyond the scope of this discussion, the concept of nomadism is the source of some debate in respect both of its extent within the Australian avifauna, and elsewhere, and of the drivers of such movements. In summary, nomadic movement can be distinguished from migratory movements by having one or more of the following characters: no return journey to a fixed breeding area; much overlap of breeding and non-breeding areas; irregular timing of movements; unpredictable or less predictable timing of movements; and movement often occurring over a large proportion of the lifetime of an individual. It is apparent that many species of honeyeater, and Australian birds in general, that have been labelled as nomadic do not have patterns of movements with these characteristics. Use of the term "nomadic" to describe movements often implies that the movements are random, but there is no evidence to suggest that such is the case. Indeed, one needs to question whether purely random movements would be an evolutionarily adaptive strategy. Although movements may appear unpredictable to human observers, this is not to say that there is no underlying pattern. For example, other mobile species that have been thought of as highly nomadic, such as the Budgerigar (*Melopsittacus undulatus*) and the Zebra Finch (*Taeniopygia guttata*), seem to have an underlying pattern to their movements. Detailed knowledge of the spatial scales over which a species may be moving and of the phenology of resource abundance over large spatial scales and long time-scales is required before the so-called unpredictability or otherwise of the movements can be assessed.

In recent years, there have been a number of continent-wide reviews or analyses of the patterns of movements of Australia's birds. The *Handbook of Australian, New Zealand and Antarctic*

Both **White-throated Honeyeater** parents feed the chicks for the 14 or so days that they are in the nest and provision the fledglings once they have left the nest. Breeding data for this species neatly demonstrate the contrast between the extent of meliphagid research in New Guinea and Australia. There are very few observations of White-throated Honeyeaters breeding in New Guinea, but quite detailed information is available from Australia. Studies suggest that the breeding seasonality in the latter is bimodal, peaking in April and September. The standard clutch size is two, and the cup-shaped nest is usually suspended from a horizontal branch of a tall tree.

Birds provides a summary of the published literature on the movements of all Australian species, including the honeyeaters. Earlier, in 1968, Keast reviewed the seasonal movements of Australian honeyeaters, this based on an examination of the literature to that time and on his own and others' unpublished observations. Keast distinguished seven patterns of seasonal movement. Of the 69 meliphagid species which he recognized, 34 were considered resident, some with local movements, and 25 were split between his three classes of nomadism: moderately well-developed nomadism, blossom nomadism, and desert nomads. The remaining species were north-south latitudinal migrants or altitudinal migrants. As already stated, Chan also reviewed partial migration by Australian landbirds. Few studies, however, have directly examined the actual movements of the birds discussed. Most analyses of the movements of Australian honeyeaters have relied largely on scattered local or regional studies of avian-community composition and any changes, seasonal or unpredictable, in presence or absence within those communities. Almost invariably, claims of movements, and especially of nomadism, are based simply on the occurrence or absence of a species in an area. Whereas the continuous presence of a species in a given area can often be reliably interpreted as indicative of that species' residence or sedentariness, its absence indicates movement from the site but, in isolation, provides little or no information on the extent and timing of the species' movements; admittedly, continuous presence does not rule out migration or dispersion of local populations, which are then replaced by similar populations from elsewhere, but such changes are often noticeable.

With data from sufficient sites over similar periods, it would be possible to make better analyses of patterns of occurrence and conclusions on the movements of species. The two bird-atlas projects in Australia, the first conducted between 1976 and 1981 and the second between 1998 and 2002, produced a huge amount of data on the overall and seasonal distribution of birds. The subsequent ground-breaking work of P. A. Griffioen and M. F. Clarke, combining the use of bird-atlas, count and ringing databases to analyse the large-scale movements, or lack of them, of the birds of eastern Australia, has provided a much better understanding of the broad-scale patterns observed for many species with suffi-

cient data. For many meliphagids, however, there were insufficient data to indicate movements, or the data were sufficient only to suggest probable patterns of movements. As a quantitative analysis, the work of Griffioen and Clarke supersedes much of the qualitative, and often inadequate, analyses made earlier. Of the 51 species of meliphagid listed by Griffioen and Clarke as having sufficient data for analysis, 39, or 76.5%, exhibited no movements, three showed local movements, four showed a confused pattern of movement, and for five species, 9.8%, there was strong evidence of long-distance movement, though the patterns showed by each of these varied. For two species, the Painted Honeyeater and the Bar-breasted Honeyeater, there were insufficient data.

The high proportion of sedentary species identified here contrasts with that indicated in earlier analyses, but the scale of the analysis must be considered. At the grid-scale of 200×200 km, species showing no movements may still be mobile, even highly mobile, at scales of less than this. For example, the analysis by Griffioen and Clarke found evidence suggesting an absence of movement by the Regent Honeyeater, yet this species is highly mobile and makes complex movements, at least on regional scales, throughout its range.

Nevertheless, most species of honeyeater appear to be primarily sedentary, albeit with the possibility of local movements. Virtually all except the most restricted-range ones, however, exhibit a range of movements at different sites throughout their ranges. Noisy and Bell Miners are notably sedentary and colonial, but colonies can show some shifts in location over time; the other two miners, the Yellow-throated and Black-eared, appear also to be sedentary. The rainforest species of north-eastern Australia are poorly known but seem to be largely sedentary, albeit with possible altitudinal movements by a small proportion of the populations of some species. In a detailed study in woodland north of Sydney, it was found that White-eared Honeyeaters defended permanent all-purpose territories, with no indication of movement of established pairs beyond the territory. This species is considered sedentary and territorial generally throughout its range, but in all areas it has been observed to undertake some, apparently local, movements. At several localities, individuals make local seasonal movements between habitats. At two sites in Vic-

An essential element of parental care is to keep the nest free of disease. This includes the removal of the nestlings' faecal sacs soon after their excretion. This adult Spiny-cheeked Honeyeater is extracting the shiny white sac from the nest in order to dispose of it a safe distance away. Some meliphagids also ingest their offspring's faecal waste as it contains substantial quantities of undigested nutrients. For hygiene reasons, honeyeaters also remove unconsumed food and feather scales from the nest. This brood of three chicks is typical for the Spiny-cheeked Honeyeater. The nestling period lasts at least two weeks, and parents continue to provision their young for a further twelve days or so.

[*Acanthagenys rufogularis*, Uluru, Northern Territory, Australia.

Lochman Transparencies]

tor, White-eared Honeyeaters were territorial when breeding but moved locally when not breeding: at Yellingbo they dispersed locally within the study area in late autumn and early winter, and in the Brisbane Ranges their foraging areas broadened in winter, extending to open woodland of open slopes. Similarly, in a study in northern New South Wales, White-eared Honeyeaters were recorded only in March–July and October, although the birds appeared to be moving only locally from adjacent grassy forest and open woodland to the open-layered forest of the study area. In the Southern Highlands, however, White-eared Honeyeaters are altitudinal migrants, and elsewhere they are considered occasional visitors at a couple of sites, although the extent of the movements involved is not known.

Lewin's Honeyeater is another species considered generally sedentary throughout its range, with the possibility of some altitudinal migration in the north-east. As with White-eared Honeyeaters, however, Lewin's Honeyeater undertakes some local movements, mostly in autumn–winter, primarily between habitats. For example, in northern New South Wales, some appear to move into dry sclerophyll forest from neighbouring wetter forests, where they are common throughout the year. This species is sporadic in occurrence at some sites and is a vagrant at others.

Other species exhibit more complex variation in patterns of movements across their ranges. Regent Honeyeaters are highly mobile and appear to have a quite complex pattern of movements, in large part governed by the flowering of a small group of eucalypts, but with three main trends. First, there is movement in autumn into parts of northern New South Wales and south-eastern Queensland, and formerly also South Australia, with a subsequent contraction to core breeding areas on the inland slopes of the Great Divide in New South Wales and north-eastern Victoria in late winter, sometimes earlier in Victoria. Secondly, a corresponding movement out of southern Victoria and the high country of south-eastern Australia occurs from late autumn to early spring. The third trend is the regular use of sites with predictable annual peaks in nectar production. The movement patterns of

Red Wattlebirds are also complex and not well understood, varying much from one site to another. This species is apparently sedentary at sites through much of its range, but this is overlaid with various poorly understood movements, including migration or partial migration of some populations, altitudinal migration in the Southern Highlands of south-eastern Australia, and possible nomadism or unpredictable movements in places. It is also considered a partial north–south migrant in Western Australia. In Brisbane Water National Park, north of Sydney, White-cheeked Honeyeaters are present all year but there is much movement of individuals, mostly subadults, through the area at times, and there are also significant seasonal changes in rates of capture.

The five species exhibiting long-distance movements in eastern Australia were the Noisy and Little Friarbirds, the Yellow-faced Honeyeater, the Scarlet Myzomela and the Black-chinned Honeyeater. All five had previously been recognized as undertaking long-distance movements, although all are partial migrants, with parts of their populations sedentary. Perhaps the best-known and best-studied migratory meliphagid is the Yellow-faced Honeyeater of eastern Australia. From extensive work, especially by U. Munro and her colleagues, we know a good deal about the patterns and timing of movements and behaviour of this species. Even this well-known latitudinal migrant, however, demonstrates the complexity in patterns of movements of Australian honeyeaters: whereas part of the population undertakes regular large-scale migration to and from south-eastern Australia, with at least 20% of the population moving north in autumn and returning in spring, populations throughout the range are also sedentary, with local populations seasonally augmented by passage migrants. Individuals leave coastal Victoria and the Great Divide from areas on the Victoria–New South Wales border and the Southern Tablelands, the main stream of migration following the Great Divide and the eastern coast, tending north-eastwards during the early autumn passage in north-east New South Wales and south-east Queensland, and then changing to a north-westerly direction during the latter stages of autumn migration, birds wintering in northern New South Wales and inland. Orientation and behavioural tests of captive Yellow-faced Honeyeaters revealed an increase in hopping activity during March–July and September–December, coinciding with the species' usual migratory periods; and at the time of early autumn passage, in March–April, the birds tended towards a north-easterly course, whereas in later stages, in May–July, they tended towards a north-westerly direction, reflecting the migrational route along the Great Divide and the east coast. The birds also showed an increase in activity in the early morning and early afternoon, and a smaller peak during the late afternoon, which corresponded to the times of most movement during migration.

The other species identified as long-distance migrants had different patterns of movement. Those of Noisy Friarbirds and Scarlet Myzomelas are characterized by passage along the eastern coast, the friarbird with an obvious movement extending along the entire east coast, whereas the myzomela has a pattern like that of the Yellow-faced Honeyeater during the winter months. The remaining two species showed inland patterns of movements. The Little Friarbird evidently moves through the inland areas or along the coast towards the north, with some movement from the northern extremes of its range in the summer wet season. The Black-chinned Honeyeater appeared to be the sole representative of a suspected inland west–east movement: the south-eastern populations of this species seemed to be sedentary, but the population of the eastern Northern Territory and adjacent north-west Queensland greatly increased in the northern dry season, that increase possibly a result of movement of birds from northern Western Australia and western Northern Territory. All of these observations are consistent with more general observations throughout the ranges of the species concerned, but it is apparent that all of these species are only partial migrants.

Altitudinal migration is evident in some areas. In the Southern Highlands of south-eastern Australia, in subalpine woodland at about 1500–1800 m in the Snowy Mountains, two species of meliphagid, the White-eared and Brown-headed Honeyeaters, were found to be present in winter above the winter snow-line, while five were spring migrants. These five are the Eastern

Spinebill, the Red Wattlebird, and the Yellow-faced, White-naped and Crescent Honeyeaters, the timing of arrival of which varied annually, with return occasionally in late winter, and a general increase in numbers from arrival to October. At these sites, *Grevillea victoriae* is an early spring foodplant for honeyeaters and may flower while snow remains on the ground, so long as the plant projects from the snow and temperatures are warm enough. For all birds, the proportion of *Grevillea victoriae* inflorescences with open flowers was a good predictor of the numbers of bird species present. Species that were not latitudinal migrants, such as Crescent and White-eared Honeyeaters and Eastern Spinebills, were thought to descend to nearby tablelands. There is some indication of winter movement also from the tablelands of the wet tropics of north-east Queensland. For example, part of the Bridled Honeyeater population of the uplands descends to lower altitudes in winter, both to the east towards coastal lowlands and westwards into drier areas. Similarly, small numbers of Lewin's Honeyeaters move in winter to lower altitudes in north-eastern Queensland, occasionally even reaching sea-level. Altitudinal migration has been reported also in Tasmania, with a descent from the highlands in autumn–winter. For example, Crescent Honeyeaters are common visitors to lowland and coastal areas in autumn–winter, usually arriving in March and leaving in September, most of the population then returning to the highlands.

Most species have been recorded as vagrants beyond their normal range, but some of the records seem unusual. For example, Bell Miners are sedentary and colonial, but vagrants have been recorded hundreds of kilometres from the nearest populations, up to 320 km west of the normal range in Victoria, for instance, although such individuals rarely survive.

There are, however, even further complications to the patterns of movements of this family. K. French and her colleagues conducted a detailed four-year study of nectarivorous bird assemblages in woodlands in the Capertee Valley of central-eastern New South Wales, an area of about 100,000 ha and an important region for the globally threatened Regent Honeyeater. This study highlights some of the difficulties in assessing community-wide patterns of bird movements in Australia. The study recorded 20 species of honeyeater, some constantly and others only occasion-

ally; the large Noisy Friarbird, Noisy Miner and Red Wattlebird were regularly recorded, and the most abundant species were the medium-sized White-plumed, Fuscous and Yellow-faced Honeyeaters. There was no predictable temporal variation, and numbers fluctuated erratically at all sites and in the valley. Birds appeared to be moving from site to site within the valley, or between the valley and neighbouring areas, or both; for example, numbers of some species, such as the Noisy Miner and White-plumed Honeyeater, remained about the same in the valley but fluctuated dramatically at individual sites, suggesting movement between sites within the valley. Other species, however, were usually present in low numbers but were occasionally recorded in large numbers at a couple of sites, suggesting an influx into the valley. There were no seasonal patterns in the movements observed, the birds appearing to move unpredictably, using a range of habitats.

Further, the study did not find a relationship between the abundance of honeyeaters, or of Regent Honeyeaters alone, and the presence of flowering trees, even though large increases in honeyeater numbers were sometimes associated with flowering events. It was suggested that honeyeaters were tracking all food resources, and not just nectar production, as insects are an important resource. Of the 20 species of honeyeater observed in this study, other than the few migratory species, most are, however, otherwise typically considered sedentary, which is not how the populations of these species appear to be behaving in the valley, even though some individuals may be.

In north Australia, J. C. Z. Woinarski and his colleagues examined the complex patterns of spatial and temporal variation in nectar availability across the entire landscape of the Northern Territory. They found a much greater nectar resource in the monsoonal north than in the arid south of the Territory; a peak of nectar production in the dry season associated with extensive tropical eucalypt forests, and a rich but spatially limited nectar resource in riparian and swamp-forests dominated by paperbarks in the wet season; and a peak of invertebrate and fruit resources at times of minimum nectar production in the monsoonal north. Nectarivores seem to persist in the region through the wet season, when nectar is otherwise in short supply, by exploiting the spatially restricted nectar production of paperbark-dominated

In many meliphagids, parental care continues after the chicks have left the nest, usually for a period of several weeks, and in the case of the **Scarlet Myzomela** at least ten days. During this time, the young bird continues to beg for food from its parents while at the same time learning to forage for itself, with the result that independence is a gradual process.

[*Myzomela sanguinolenta*, Australia.
Photo: Ken Griffiths/
NHPA]

Juvenile **Blue-faced Honeyeaters** remain with their parents for several weeks after fledging, most being dependent on their parents for food, although some are capable of foraging just one day after leaving the nest. This species is unusual in that it prefers to breed in or on abandoned nests of Australasian babblers (*Pomatostomus*) or meliphagids such as friarbirds (*Philemon*). The Blue-faced Honeyeater will purloin material from old or active nests, and even evicts other species from their nests. It engages in communal breeding, and there are records of more than one female laying in the same nest.

[*Entomyzon cyanotis cyanotis*, near Brisbane, SE Queensland, Australia. Photo: Brian J. Coates]

forests, and possibly through diet-shifting to utilize the increased seasonal abundance of insects and fruit. The nectarivores in this system may also increase their year-round access to nectar resources by making large-scale movements or by adjusting their local distributions to utilize local-scale variation in vegetation and availability of resources.

The difficulties of ringing studies in Australia are well illustrated by the examples of the Yellow-faced and White-naped Honeyeaters. Yellow-faced Honeyeaters have been the subject of major ringing studies along the Murrumbidgee River and in the Brindabella Ranges of the Australian Capital Territory, and elsewhere. Along the Murrumbidgee, a total of 12,927 individuals ringed during March–May between 1963 and 1977 produced only four recoveries, one at the ringing site and the others at distances of, respectively, 3 km, 18 km and 240 km; five others, ringed elsewhere, were also retrapped. Overall, a total of 66,774 Yellow-faced Honeyeaters was ringed between 1953 and 1997, with 4553 recoveries, most of them at the site where they had first been ringed. In a subset of 1628 recoveries during July 1984 to March 1999, only four were at more than 100 km, these in the range 160–600 km and over a period of 10–109 months; two earlier retraps or recoveries farther than 100 km away were at 240 km and 745 km after, respectively, 36 and 45 months. Similarly, White-naped Honeyeaters were the subject of a major study in the Australian Capital Territory between 1961 and 1983. A total of 7057 individuals was ringed at 34 locations: of 3677 ringed during autumn migration on the Murrumbidgee River, only two were recovered, 22 km and 190 km from the ringing site, and there were no recoveries at more than 10 km for the 3380 ringed at other times or at other sites. The study was abandoned owing to the paucity of data gathered, despite the intensity of the ringing effort.

Hitherto, this discussion has concentrated on Australia, for which most detailed observations and data are available. The problems with analysing avifaunal movements are even more evident through New Guinea, Wallacea and most of the islands of the south-west Pacific. The bird populations in these regions are smaller and more sparsely distributed, ornithologists are scarcer, and bird-ringing has been far more limited and with fewer chances of returns on effort. For most species, there are very few hard data or observations to support any claims of

patterns of movement. Nevertheless, there appears to be no evidence of any large-scale seasonal movements of honeyeaters through these regions, and little or no evidence of any other significant movements. Further, many species restricted to islands cannot undertake any long-distance movements without leaving the island, and they must therefore be regarded as sedentary, with only local or regional movements to be considered. The majority of meliphagids in these parts of the family's range are described variously as resident or sedentary, with local movements or some dispersive movements associated with some species. A few are described as being partly or wholly nomadic, though the true extent and pattern of such movements are not known.

Among New Guinea forest birds in general, there is little migration and only a low rate of dispersal, this lack of movement being reflected in the broken and patchy distributions of large numbers of the island's species, and also in the high degree of speciation and subspeciation seen there. Equally, another important ecological sorting mechanism within the New Guinea avifauna is altitudinal segregation, with many pairs of congeners separated by altitude. Such segregation indicates that there is little, if any, altitudinal movement by such species. For example, in the genus *Ptiloprora*, the Rufous-backed Honeyeater is confined to low altitudes and the Black-backed Honeyeater to higher elevations, with no known vertical movement made by either species.

There is, nevertheless, considerable evidence of at least local movements, in large part to exploit food resources, particularly sources of nectar. It is also possible, for instance, that many *Myzomela* species are fairly mobile and may move over greater distances than those covered by other species, and the possibility that some movements are regularly seasonal cannot be discounted. Much study is needed, however, before conclusions can be drawn. For example, the Orange-breasted *Myzomela* in Fiji is said not to be sedentary but is locally mobile and also locally irruptive, being absent at sites for many months before suddenly reappearing. These small honeyeaters also congregate in large numbers in flowering trees. Conversely, while Red-throated *Myzomelas* are thought to be nomadic, an individual ringed at Brown River, in southern New Guinea, was retrapped one year later at the site where it had been ringed.

Even well-grown fledgling meliphagids can be dependent on adults for food. In the case of the **Black-eared Miner**, the use of the word "adult" rather than "parent" is important, because this species, in common with its three congeners, is an obligate co-operative breeder, nesting in loose colonies where nests may be about 25 m from each other. At least three different Black-eared Miners have been recorded incubating at a single nest, and there is no guarantee that an adult feeding a fledgling is even related to the young bird, let alone its parent.

Further details of the species' system are not known, as this threatened taxon has been little studied. However, the pattern may follow that of commoner congeners, such as the Bell Miner (*Manorina melanophrys*), pairs of which are helped at the nest by up to 20 auxiliaries. Helpers may be juvenile siblings from a previous brood, unpaired immatures a few months old, unpaired adults, or even breeding neighbours that are also raising a brood nearby. The Black-eared Miner breeds in the austral spring and summer and may continue nesting until the autumn. The standard clutch size is two or three eggs, but there are no data available on the proportion that fledge successfully.

Finally, there seem to be no regular movements by meliphagids between Australia and New Guinea or New Zealand. Nevertheless, Red Wattlebirds have turned up as vagrants in New Zealand, with historical records of single individuals in the North Island in about 1865 and about 1885, and an unconfirmed report of a singleton in the South Island some time before 1938.

Relationship with Man

As already stated, the honeyeaters are conspicuous and characteristic elements of the avifauna of Australasia, Wallacea and the south-west Pacific, although they seem not to feature prominently in the consciousness of the largely European cultures that colonized the region. Further, they seem not to be significant in the indigenous cultures of the region, beyond any importance as food, although D. Hicks has investigated Indonesian myths involving the Helmeted Friarbird of Timor and how it acquired its helmet. Such aspects of the relationships of honeyeaters with man appear to be little published.

Nevertheless, most honeyeaters are well known, and individual species are distinguished and named in most indigenous cultures. As conspicuous and vocal members of the Australasian and Pacific avifauna, they often have a rich array of colloquial names associated with them. For example, the Little Wattlebird, with its loud, often unmusical vocalizations, has many names that derive from such calls, both Aboriginal names, such as *Goo-gwar-ruck*, *Djung-gung*, *Dun-gur-uk* and *Tur-dal-l*, and the European "Cookay-cock". Throughout New Guinea and the islands of the south-western Pacific, most meliphagids have indigenous names, such as *Éro*, *Koyáge* and *Yoborusuábe* for the Long-billed Honeyeater in the Eastern Highlands of New Guinea, *Delakula*, *Bicibicikula*, *Sommsammatí* and *Matí* for the Orange-breasted Myzomela of Fiji, and *Segasegamau'u* for the Cardinal Myzomela of Samoa. On Manus, in the Admiralty Islands, the local onomatopoeic name for the loud, garrulous endemic White-naped Friarbird, *Chauka*, has been given also to the radio station, "Radio Chauka".

Many species of honeyeater are well established in human environments or, less commonly, have adapted to human activities. Within the cities of eastern Australia, one of the commonest

birds, and arguably the most common native species, is the Noisy Miner. Other commonly encountered species are the Red and Little Wattlebirds, and in the subtropics and tropics the Blue-faced Honeyeater. Whereas these species are all large to medium-large, smaller species are also frequently found in urban environments: the White-plumed Honeyeater is a common inhabitant of cities, and is, for example, ubiquitous in urban Melbourne; and, in Darwin, Rufous-banded Honeyeaters are among the commonest native suburban birds. Honeyeaters are an important element of the urban bird community of Townsville, in the tropics, with eight species recorded and Brown and Yellow Honeyeaters the most abundant. Many species of *Myzomela* are common inhabitants of cities, towns and villages and agricultural land and plantations through New Guinea and on the islands of Wallacea and the Pacific. They are often conspicuous when foraging in gardens and parks in these situations, and readily forage on native and exotic vegetation. The Cardinal Myzomela, for example, is one of the few indigenous species that is common in urban areas in Samoa, and it readily exploits foraging niches created by human modification in urban or agricultural landscapes. The Wattled Honeyeater shares these habitats with the Cardinal Myzomela. Coconut plantations, in particular, appear to provide a significant source of nectar for a number of species throughout the tropics.

This adaptability to modified habitats has also meant that a number of meliphagids, such as Red Wattlebirds, have been or, at least, have been thought to be pests in orchards, vineyards and some other crops, and they were formerly shot, sometimes in large numbers. At Aruluen, in south-east Australia, Red Wattlebirds and Noisy Friarbirds are not, however, considered pests in orchards of nectarines and peaches, as they eat only over-ripe fruit left on the trees. Lewin's Honeyeater was likewise sometimes considered a pest of soft fruits, citrus and bananas, and it sometimes raided orchards in large numbers; in the Hunter region of New South Wales, up to 50 birds of this species still congregate around orchards when fruit is ripe.

Few species of honeyeater are subject to significant hunting pressure of any kind, let alone at levels that have an impact on their populations. Hunting is, however, a potentially threatening process for MacGregor's Honeyeater in the high mountains of the Central Range of New Guinea, a threat exacerbated by the

Many species of honeyeater occur in urban areas and are well known to human residents. Whilst normally inhabiting dry, open woodland, the **Yellow-tufted Honeyeater** sometimes visits gardens where the species' gregarious nature and vibrant coloration command attention. The subspecies featured here, *cassidix*, is sometimes called the **Helmeted Honeyeater** on account of the short crest formed by distinctive, elongated forehead feathers. Being restricted to a single site and adjudged to be a critically endangered taxon, this subspecies is also the subject of conservation activity, which explains the rings on the birds' legs.

[*Lichenostomus melanops cassidix*, Yellingbo Nature Conservation Reserve, Victoria, Australia. Photo: Dean Ingwersen]

Slightly more than half of the 175 members of the Meliphagidae are restricted-range species, each occurring over an area of 50,000 km² or less. Most occur only on single islands or small groups of islands. The **Yellow Wattlebird** is a case in point, being endemic to Tasmania and the Bass Strait Islands. Although the species is not currently considered to be globally threatened, one of the two subspecies is endemic to King Island and would probably qualify as Vulnerable were it a full species. This population of this race is reckoned to number fewer than 1000 mature birds but is probably stable, despite habitat clearance.

[*Anthochaera paradoxa paradoxa*, Mt William National Park, NW Tasmania. Photo: Dave Watts/Lochman Transparencies]

species' small fragmented population. MacGregor's Honeyeater is hunted as game in parts of its range because it is large, confident, conspicuous and site-faithful, and it is therefore fairly easy to find and kill. Hunters visiting the upper fringes of montane forest to hunt wallabies in alpine grasslands will build a hide beneath a favoured fruiting tree, usually MacGregor's preferred food tree, *Dacrycarpus compactus*, and kill one to several as they come to roost or forage. Other large species are similarly hunted for food. At the other extreme, on islands of Sapwuahfik Atoll, the Micronesian Myzomela, despite its tiny size and a weight of only 10.5–18 g, is hunted as game by local people and was found to be less abundant on Ngatik Island, the largest and only permanently settled island in the group, than it was on the other, more sparsely populated islands of the group.

In an exhaustive analysis of the birds of Nokopo, in the Finisterre Range of New Guinea, C. K. Schmid described the species hunted and the methods of capture. All three species of *Myzomela* present, the Red, Mountain and Red-collared *Myzomelas*, were hunted and, despite their small size, were considered good food with much body fat and tender meat, and they could be caught in large numbers in flowering trees. The medium-sized Black-throated Honeyeater and *Meliphaga* species were also hunted, but a *Ptiloprora* species, probably the Rufous-backed Honeyeater, was considered inferior, with the meat watery, in addition to which its feathers were too drab for use as ornaments. A number of different hunting methods were used, depending on the species targeted. During the dry season, parts of small creeks through the forest were covered with leaves and other material, leaving only a small patch of water: when catching Huon Honeyeaters, the hunter built a small conical hut beside these small pools of water, placed a stick across the pool, and then, using a hollow bamboo tube projecting from the hut, shot the birds on the perch; Spangled Honeyeaters were caught in small traps built around these drinking sites, but were also hunted with a bow and arrow and trapped at foodplants. Helmeted Friarbirds were hunted with bow and arrow, the adults lured towards the hunter by presumably captive fledglings; and friarbirds were trapped at their preferred foodplants. Both Hill-forest Honeyeaters and *Myzomela* species were snared with bird-lime.

Formerly, the Tui was hunted by Maori in New Zealand, and a skilful hunter could catch up to 100 in a day. The hunter called in the birds by imitating their vocalizations, and then hit them with a long flexible stick, or he speared or snared them. Tuks were said also to be easily caught on frosty nights, when "their claws were contracted by the cold, and they could not fly". Maori preserved them in their own fat and ate them at feasts. This species was also hunted for food by European explorers and early settlers. Similarly, many Australian species were eaten by early settlers and non-Aboriginal Australians. Yellow Wattlebirds were commonly eaten, and early in the twentieth century they were still being sold in markets. Yellow Wattlebirds were shot during open seasons, and such large numbers were killed that the species was thought to be in danger of extinction; it was afforded full protection in 1902–1903, but it was later returned to the list of game species until at least the 1970s. Red Wattlebirds, another large species, were also shot, both for sport and for food, as they were renowned as being "the best eating bird in the bush".

Honeyeaters at Nokopo, in New Guinea, are used for ornamentation by local people. The feathers of Spangled Honeyeaters, along with those of other birds, are used for feather-poles, or *sekan*, long, slender bamboo tubes with feathers arranged spirally around the tube, stretches of darker feathers alternating with stretches of paler, speckled ones. In this area, the plaintive calls of the Rufous-backed Honeyeater are an omen of mourning and death. While their meat is watery and largely not eaten, the association of this species with death may also be a reason for not eating it. While MacGregor's Honeyeater is hunted over most of its range, it is seemingly common and tame above 3000 m in the Star Mountains, where the Ketengban people protect it for cultural reasons.

The Tui was one of the few honeyeaters to be used for ornamentation by Europeans. Skins were illegally exported for ornamentation on women's hats, one dealer in Wellington sending up to 500 skins to London. Tuks were often kept as pets by early

settlers in New Zealand, and sometimes by Maori, especially as the species is such a remarkable mimic. Captive birds were prized by the Maori for their ability to mimic, and were taught sentences of welcome, platitudes and insults. A compliment to a good orator was "*me he korokoro tui*", meaning "How eloquent he is; he has the throat of a Tui". Owing to their ability to imitate, they were also taken to Australia as cagebirds.

In Samoa, legend had it that hearing the wails and screams of the Mao around a village meant that misfortune or a death was about to happen, and Samoans often shot this bird when they saw it near villages. A further superstitious belief among the native Samoans was that the calling of the Mao heralded rain, or foretold of some calamity.

Status and Conservation

Of the 175 species of the Meliphagidae currently recognized, eight, 4.6% of the total, are listed as globally threatened, four of these being considered Endangered and four Vulnerable. A further five species are considered Near-threatened and two are Data-deficient, and a range of taxa have been identified as regionally threatened in Australia. Although, as a proportion of the total number in the family, relatively few species are threatened at present, there is a wide array of ongoing threatening processes working over the range of the family that, if unchecked, will adversely affect the conservation status of many species in the future.

While on this subject, it should be stressed that five species confined to Hawaii, and until recently considered to be honeyeaters, are believed to be Extinct, although two of these, the Kauai O'o and Bishop's O'o, remain listed as endangered by the US Fish & Wildlife Service. They were described and discussed, as meliphagids, by E. Fuller (see HBW7, pages 48–51). These five species, in the endemic Hawaiian genera *Moho* and *Chaetoptila*, have since been found not to be closely related to the Meliphagidae (see Systematics) and are not considered further here.

Outside Australia, many species of honeyeater have small ranges, often confined to single islands or small island groups or, in the case of New Guinea, isolated montane regions. Of the eight threatened members of the family, four are island species and

No Endemic Bird Area (EBA) has more restricted-range bird species than the Solomon Group. Meliphagidae is strongly represented, with nearly ten per cent of the family's restricted-range species occurring in this EBA. These include the **Scarlet-naped Myzomela**, a Least Concern species that is common or very common on a handful of islands in the north of the Solomons. This species' predilection for small islands means that it is considered a "supertramp"—a species with broad habitat requirements that disperses efficiently, and readily colonizes new areas.

[*Myzomela lafargei*, near Panguna, Crown Prince Range, Bougainville, Solomon Islands. Photo: Don Hadden/Ardea]

two are confined to montane New Guinea, and all except one, the Regent Honeyeater, are restricted-range species. In total, fully 89 species, just over half of the family, are restricted-range species, distributed across 32 endemic bird areas (EBAs) and five secondary areas. The worldwide distribution of the Meliphagidae covers 45 EBAs. One of these, the Solomon Group EBA, has more restricted-range bird species than any other EBA.

In common with most other bird families, the Meliphagidae have suffered previous declines of species primarily and most significantly as a result of the loss, fragmentation and degradation of habitat through human land-use practices, and these remain the greatest threat. Throughout the tropics of Wallacea, New Guinea and the south-western Pacific, loss of forest habitats, primarily rainforest, is the most significant threatening process. To date, the greatest loss has been that of lowland and foothill rainforests, whereas montane forests have largely remained intact owing to their inaccessibility. Logging for industrial timber production, both legal and illegal, is a significant cause of loss and degradation of forest and one of the biggest ongoing threats to the rainforest habitats of these regions. The forests of New Guinea and the south-east Asian islands, including those of Wallacea, have become the world's main source of tropical timber since the 1970s. In Indonesia, while timber is obtained mainly by selective logging, plans and regulations are rarely followed and forests are therefore badly damaged by harvesting, and areas that should be left uncut are often logged.

Even where logging is not currently occurring, huge areas have been allocated in timber concessions for potential future logging. In Wallacea, for example, commercial logging enterprises are now concentrated on islands in the Moluccas, especially Halmahera and Seram, where most remaining forest is covered by such concessions. Further, in some regions of New Guinea and many islands, small-scale but widespread selective logging, which is usually illegal, using portable or "walkabout" sawmills, also results in some loss of or disturbance to forest habitats. Clear-felling and the creation of logging roads also provide access to areas that were previously inaccessible, including highland forests, and the further creation of settlements and cultivation. Road-building for mineral and oil exploration provides similar opportunities. Moreover, as areas are opened up and settled, there is an increased risk of predation from introduced predators, such as rats, cats, dogs and pigs.

Traditional subsistence agriculture is, and has been, widely practised in the region. More recently, however, traditional practices have been replaced by slash-and-burn methods, and the scale of clearance for both shifting cultivation and grazing has increased greatly, in association with growing human populations, and there is also increasing commercial agricultural production. All of these agricultural activities are frequently associated with repeated burning, particularly hot dry-season fires, as a means of augmenting the production of fodder for livestock or to clean up cultivation fields. On New Caledonia, bushfires started on grazing or cultivation lands threaten the remaining native vegetation where they spread unchecked. Further, the fallow period between successive agri-gardens, and thus the age and structure that the regrowth attains, is reduced so as effectively to increase the area of available land for subsistence farming. There has also been much clearing for plantation-cropping, including coconut palms, oil palms (*Elaeis guineensis*), sugar cane, bananas and cacao, and, in some places, exotic timber, including pines (*Pinus*). Other cash crops include cloves and other spices, maize and rice, and, on some Micronesian islands, kava (*Piper methysticum*). In parts of New Guinea, swamp-forests are being cleared for conversion to rice fields, and mangroves and tidal swamp-forest are being cleared for development of shrimp and fish ponds, as, for example, in Bintuni Bay. Unsustainable harvesting of firewood and, in some regions, other forest products also causes loss or degradation of forest habitats.

The government programme of internal transmigration within Indonesia, moving people from the densely populated islands to less developed regions, creates new settlements or greatly increases the size of existing ones. While the immediate area of forest lost for settlements is often not great, it is typically followed by further clearing around settlements, both legal and illegal, the development of roads into formerly undisturbed areas, and the harvesting of timber for firewood and building materials. The risk of introduction of species is also high, and of particular concern is the introduction of taxa that had not naturally crossed Wallace's Line. For example, macaques (*Macaca*) could potentially outcompete frugivorous birds, and other species, that had evolved in the absence of primates.

In combination, these factors commonly result in several adverse situations. These include the persistence of forest only in highlands and inaccessible landforms, such as gorges and steep

The **Orange-breasted Myzomela** is one of a handful of restricted-range family members that occur in the Fiji Endemic Bird Area. This striking bird is generally considered common or abundant and inhabits both of Fiji's main islands as well as many smaller islands. It is found in all habitats, being equally at home in primary forest and mangroves as in roadside scrub and gardens. Its ability to utilize a wide range of habitats, combined with its comparative abundance, means that it is presently at little risk of global extinction.

[*Myzomela jugularis*,
Fiji.

Photo: Michael Gore]

valleys; the fragmentation of remaining areas of lowland forest, which are often small; and the conversion of large areas of the landscape, particularly lowlands and foothills, to grassland or monoculture crops and plantations. Conversely, some plantation crops provide an important source of nectar for many species. Coconut palms in particular, when they are in flower, are frequented by many species of honeyeater. In addition, the frequent use of secondary forest, forest edge and modified habitats such as gardens by many meliphagids reduces the level of threat from loss of primary forest alone.

Several more localized but possibly significant threats can be identified. They include the proposal to construct a large dam in the Mamberamo River gorge in northern Papua; Brass's Friarbird is known only from a few observations in the upper Mamberamo and Wapoga River Basins. In New Caledonia, open-cut nickel-mining has destroyed large areas of forest and maquis habitats, and mining will continue to cause loss and degradation of habitat in many regions.

A major threat in Micronesia is the possible spread of the introduced brown tree-snake (*Boiga irregularis*). This species is a highly effective predator and colonizer, and is considered responsible for the extirpation of many bird species on Guam, including the only honeyeater of the region, the Micronesian Myzomela. Introduced birds may also be responsible for some local declines. In American Samoa, for example, Wattled Honeyeaters appear more common around villages on the Manua Islands, where there are no introduced birds, than on Tutuila, where the introduced Red-vented Bulbul (*Pycnonotus cafer*), Common Myna and Jungle Myna (*Acridotheres fuscus*) are common, although in Fiji, conversely, there is no evidence that introduced species have restricted the distribution of this or any other honeyeater species.

Honeyeaters are often killed by introduced animals, especially mammals such as feral and domestic cats, foxes (*Vulpes vulpes*) and stoats. In addition, they are sometimes killed by cars or by flying against windows of houses. It has been found that birds feeding on refined sugar at artificial feeding stations in gardens sometimes die from thiamine deficiency. Early collectors also took a great many individuals of some species: two such collectors, referring to a single species, the Dark-brown Honeyeater, stated "We have slaughtered so many that our conscience pricks us, though we have faithfully skinned every bird."

Human disturbance can create further imbalances. For example, on Manus, in the Admiralty Islands, the White-naped Friarbird appears to have undergone a population explosion associated with human colonization and clearance. It has been suggested that this population increase has been detrimental to the Manus Fantail (*Rhipidura semirubra*), which is said to persist on the tiny islet of Tong owing to the absence there of the friarbird. In New Guinea, two species of *Melidectes*, Belford's and Yellow-browed Honeyeaters, commonly hybridize wherever they meet. While the two are typically separated altitudinally, hybridization probably occurred to some, albeit probably minor, degree where the species met in undisturbed habitat. Hybridization, however, now occurs extensively, and probably at an accelerated rate, at mid-montane altitudes, where natural forest has been extensively disturbed or modified through human activities, particularly for agriculture.

In Australia, the main cause of species declines, and the single most important ongoing threat, is loss, fragmentation and degradation of habitat, primarily for agricultural production, including grazing, crops and plantations. Australia is reported to have one of the highest rates of clearance of native vegetation in the world. It is estimated that some 82% of all bird taxa from mainland Australia and Tasmania have been affected by land clearance at some stage. Unlike the situation in New Guinea and the islands of Wallacea and the south-west Pacific Ocean, however, over 40% of taxa affected by loss, fragmentation or degradation of habitat occupy subtropical or temperate sclerophyll forests and woodlands, rather than rainforest. For example, it is estimated that some 30% of Australia's woodlands, and 80% of temperate woodlands, have been cleared, with less than 5% of the original vegetation remaining in some areas of southern Australia. Nevertheless, there has been extensive loss also of rainforest in Australia, particularly lowland rainforest in north-eastern Australia, although this, while a threat to many faunal taxa, has not been a significant threat to honeyeaters.

Forest and woodland in Australia are dominated by the eucalypts and, to a lesser extent, some other groups, which provide a major source of nectar and an important resource for honeyeaters. In temperate Australia, this nectar-rich system has been severely disrupted by loss of forests and woodlands throughout eastern, southern and south-western parts. The tropical wooded habitats of northern Australia have not, as yet, been fragmented or degraded to the extent that has occurred in temperate Australia, but

The **Micronesian Myzomela**, seen here at a flowering Java plum (*Syzygium cumini*), is distributed over four Endemic Bird Areas, all of which comprise small islands in the west Pacific. The seven subspecies are generally common or abundant, but density estimates vary considerably between archipelagos. This myzomela's tolerance of disturbed habitats suggests that forest destruction has relatively little impact on overall population numbers, although there is some fear that modified habitats may not provide suitable nesting sites.

[*Myzomela rubratra kobayashii*,
Koror Island, Palau.
Photo: Mandy Etpison]

it is estimated that these habitats are being cleared at an increasing rate. Much of this clearing is of semi-arid tropical forest or woodland for pasture development for cattle grazing. Tropical forests and woodlands are also being degraded by ongoing grazing, and by increased dry-season burning.

The four Endangered meliphagids include two medium-large Australian species, both inhabitants of the temperate eucalypt woodlands of south-eastern Australia. The Black-eared Miner is one of Australia's rarest birds, and almost certainly the rarest meliphagid. This colonial species is confined to semi-arid mallee eucalypt woodlands of the lower Murray–Darling Basin of south-eastern Australia, and was formerly widespread in eastern South Australia, north-west Victoria and south-west New South Wales. It is now lost from most of its former range, with most surviving colonies confined to mallee north-west of Renmark, in eastern South Australia. The decline of the species is a direct result of hybridization with the Yellow-throated Miner. Before European settlement, it is thought that Black-eared Miners occupied dense, continuous and extensive tracts of mallee, whereas the Yellow-throated Miner occupied more open and fragmented habitats within the mallee, such as edge habitats and naturally occurring clearings, as well as a range of other habitats bordering or within extensive stands of mallee. While the mallee regions occupied by Black-eared Miners were settled in the 1860s, widespread clearance for cropping and grazing began in earnest after World War I and greatly accelerated in the 1950s. Further, dams, and drains to fill them, were dug through the mallee to provide watering points, and vegetation around dams was extensively cleared. The clearing and modifications resulted in continuous tracts of mallee being fragmented, creating much suitable habitat for Yellow-throated Miners and extensive zones of overlap between the two species. This was followed by widespread hybridization between them, and genetic swamping of the Black-eared Miner population. The species was at one stage considered Critically Endangered, but its conservation status has now been reassessed as Endangered. The discovery of significant numbers in mallee north of the Murray River in eastern South Australia has greatly enhanced the prospects of survival of this species. The Bookmark Biosphere Reserve, which holds most of the known population of Black-eared Miners, is estimated to support 501 colonies containing 3758 phenotypically pure Black-eared Miners, 2255 hybrid Black-eared × Yellow-throated Miners, and small numbers

of Yellow-throated Miners. A smaller population persists in the Murray-Sunset National Park, in north-west Victoria, consisting of 53 Black-eared Miner or hybrid colonies. The estimated effective population, however, is an order of magnitude smaller, owing to the male-biased sex ratio and the complex colonial and co-operative social organization of the species. The effective population in the Bookmark Biosphere Reserve is estimated to consist of 390 pure Black-eared Miners and 234 hybrids. The species appears to require mallee vegetation unburnt for at least 45 years, and wildfire remains a major threat to the continued survival of Black-eared Miners, given the concentration of the population in a single region. In fact, in late 2006 some 100,000 ha of prime mallee habitat within the Bookmark Biosphere Reserve was burnt. The recovery plan for this species has included translocations of Black-eared Miner colonies to the Murray-Sunset National Park from Bookmark, five translocations having been conducted in 2001 and 2002. These “new” colonies have bred and they persist. In addition, a captive-breeding programme was begun in 1996, and eventually succeeded in breeding the species. In 2003, a trial release of 45 captive-bred individuals, in two groups, resulted in breeding in the wild almost immediately and, over the following years, the establishment of at least three breeding colonies, and some have joined the remnant wild population at the release site.

Equally problematic is the conservation of the Endangered Regent Honeyeater. This species is highly mobile over large areas, but the details of its movements and the habitats upon which it may depend are poorly known; its range in non-breeding periods is not known. It has a small estimated total population of 500–1500 individuals, which appears to be in continuing decline. Regent Honeyeaters were formerly widespread in eastern and south-eastern Australia, but their range and numbers have contracted greatly, probably beginning in about the 1940s. The main reasons for this decline appear to be loss, fragmentation and degradation of its habitat, an estimated 75% of which has been destroyed for agriculture; particularly badly affected have been its preferred high-quality lowland habitats on most fertile and productive soils, which are preferred also for agricultural production. This has, in turn, resulted in poorer and unreliable supplies of nectar. Remaining habitats have also been, and continue to be, degraded by increased dieback and decline of trees in pastoral areas; lack of regeneration of eucalypt through grazing by live-

The Yellow-eared Honeyeater is one of several meliphagids that are exclusively or primarily restricted to the Endemic Bird Area encompassing the islands of Timor and Wetar. This particular species occurs only on Timor, where it is common, if rather patchily distributed.

The honeyeater uses several different wooded habitats, from monsoon forests to riparian and eucalyptus (*Eucalyptus*) woodlands, from the lowlands up to 2000 m. This combination of a wide altitudinal range and broad habitat tastes means that the species is not globally threatened at present.

[*Lichmera flavicans*, Timor, Lesser Sundas. Photo: Morten Strange]

stock and rabbits; silvicultural practices that promote dense, pole regrowth of immature trees and remove large spreading trees in box-ironbark woodlands; and removal of trees for fence posts, firewood and timber. Further, remnants, including much of what currently exists in the conservation reserve system, are highly fragmented and often degraded. Degradation of habitat may also have caused declines of Regent Honeyeaters by facilitating the expansion of populations of large aggressive honeyeaters, such as friarbirds and miners, possibly resulting in interference with Regent Honeyeaters at sources of food and nesting sites. This species was recorded in large numbers in the nineteenth century, and occasionally in very large flocks during influxes, but there are very few current records of large flocks. Regular breeding is concentrated in only four key areas.

Conservation partnerships, involving government agencies, BirdLife in Australia, community groups and landowners, have sought to protect the Regent Honeyeater's habitat and to ensure the species' survival in the wild. Efforts are focused on protecting and restoring habitat at sites regularly used by the species. Moreover, captive-breeding has recently produced some success. In 2008, a total of 27 Regent Honeyeaters, all fitted with radio transmitters, was released in the Chiltern National Park, in Victoria. Very soon thereafter, one was observed next to a wild individual, the first wild Regent Honeyeater seen in the park for 18 months. Since then, several other wild Regent Honeyeaters have been seen in association with the released individuals, and there are hopes that the species will once more breed in the area.

The remaining two Endangered meliphagids are large species of *Gymnomyza* of the south-west Pacific. Both the Crow Honeyeater, of New Caledonia, and the Mao, of Samoa, have very small populations and appear to be continuing to decline. The Crow Honeyeater's population was put at between 1000 and 3000 individuals in 2000–2002, this probably an overestimate, and the species is thought to be in continuing decline. The population is thinly distributed and fragmented and appears to be localized, and the species is uncommon even in its preferred habitat of dense, humid, primary rainforest, usually on ultrabasic soils. It is sometimes recorded in dry forests and in isolated stands of stunted forest within maquis, up to 2 km from more extensive stands. The reasons for its absence from apparently suitable habitat are not understood, but an unknown specialization has been suggested, and continuing loss and degradation of forest from log-

ging, nickel-mining and fires are likely to pose some minor threat. The estimated total population within the Rivière Bleue Park is 160 pairs, this again likely to be an overestimate, and the species is apparently declining, with no successful nests or juvenile birds observed. The Crow Honeyeater is represented also in the Réserve Speciale de Faune et de Flore de la Ni-Kouakoué and Réserve Speciale de Faune et de Flore de Mt Panié.

Why the Crow Honeyeater is continuing to decline is not known for certain. Predation by introduced rats has been suggested as a possible cause, but the congeneric, and smaller, Giant Honeyeater of Fiji appears to be unaffected by rats. The ecology of the species is very poorly known, and basic research on its habitat requirements and breeding biology are needed as a first step in the required conservation measures.

The Mao has an estimated total population of 1000–2500 individuals, which is fragmented and apparently declining. Although its former distribution is not fully known, its range has been dramatically reduced and it appears that it was once more widespread in lowlands than it is at present. It is found mainly in primary rainforest, and is currently confined to foothill and montane forests, with its greatest densities at high altitude in the least disturbed forest. It has been seen in other habitats, including heathland scrub and forest edge, and it sometimes visits coconut trees near the coast, probably in periods of stress after cyclones, but it appears dependent on primary forest. The Mao's decline has been attributed largely to habitat loss and the degradation of remaining forest. The surviving areas of upland forest in Samoa are under threat from slash-and-burn cultivation, with farmers using forestry roads from logged lowland forest as means of reaching formerly inaccessible land. Forest quality has been further reduced by the invasion of aggressive exotic trees, their spread aided by cyclones and by planting. Cyclones are a significant threat also in that they destroy forest habitats, as well as causing deaths of individual birds. During the two most powerful recent cyclones, "Ofa" in 1990 and "Val" in 1991, forest canopy cover was reduced from 100% to 27%, and the Mao's populations were reduced; for example, the species disappeared from lowland forests in O Le Pupu Pu'e National Park, on Upolu, between 1982 and 1991 following the two cyclones. Fires in low-rainfall forests, hunting and introduced rats may also pose a threat to the species. It is a sad fact that the illegal hunting of native birds and bats continues, despite the national bans that have been

The Bismarck Archipelago holds three restricted-range friarbirds (*Philemon*).

The New Ireland Friarbird is endemic to the island of the same name. This monotypic species inhabits montane forests from 750 m upwards to at least 2200 m, and within these altitudinal confines it is considered to be common. As such, it is classified as of Least Concern. In common with many other species on New Ireland, little is known about the ecology of this large, dark honeyeater. Indeed, no information at all is available regarding its diet, foraging preferences or breeding characteristics.

[*Philemon eichhorni*, New Ireland, Bismarck Archipelago. Photo: Len Robinson/FLPA]

in place for more than ten years. The Mao occurs in some proposed and existing protected areas, but these have suffered damage from cyclones. Furthermore, O Le Pupu Pu'e National Park is threatened by logging and cattle-farming.

Montane New Guinea is the home of two of the Vulnerable meliphagids, MacGregor's Honeyeater of the Central Range and the Long-bearded Honeyeater. The other two are island species, the Dusky Friarbird of Morotai, Halmahera and Bacan, in the northern Moluccas, and the Rotuma Myzomela, found on the island of that name north of Fiji. MacGregor's Honeyeater is a poorly known species with small disjunct populations scattered in geographically restricted habitat along the peaks of the Central Range, with little or no interchange between these isolated populations. There are no estimates of its global population, though it is thought to be small and slowly declining. The species' absence from large areas of apparently suitable habitat in montane New Guinea suggests past extirpation of populations in these areas, possibly in part through hunting pressure or changes to the habitat. Its numbers fluctuate periodically and dramatically, however, as a result of movements combined with its apparent dependence on unpredictable fruiting of *Dacrycarpus compactus* for food and, possibly, breeding. MacGregor's Honeyeater is protected by law, but continued hunting in parts of its range is a threat, particularly as it is confiding, conspicuous and site-faithful, making it easy to kill (see Relationship with Man). Conversely, it seems to be common above 3000 m in the Star Mountains, where it is protected for cultural reasons. Its subalpine habitats are also under threat from global warming.

Similarly, the Long-bearded Honeyeater is apparently patchily distributed and very poorly known. There are no estimates of its global population, although it is thought to be small, and confined to a few sites within a small overall range. The species occurs near the tree-line of the Central and Eastern Highlands, which have a dense human population; although cultivation stops below the altitudinal range of the species, there may be some loss and degradation of habitat through fires and possibly other human activities. This honeyeater is, however, considered to be fairly common at most sites within its known range. There are no known conservation measures underway for it.

Another very poorly known, restricted-range species, with few recent records and no estimates of its population, the Dusky

Friarbird appears to be an uncommon meliphagid. Its numbers are small, although it was earlier thought to be widespread and common. All recent records of the species are from Halmahera, whereas most museum specimens, all collected before 1950, come from Morotai, and the occurrence of the species on Bacan needs confirmation. This friarbird is considered Vulnerable owing to potential or actual declines in its populations from past and ongoing habitat loss and degradation. While much forest in the northern Moluccas remains intact, and about 90% of the total area of Morotai, Halmahera and Bacan was still forested at the start of the 1990s, these areas are under increasing threat from continued clearance, particularly in the lowlands, for settlements, agricultural crops and plantations, and timber-harvesting. Recently, the Aketajawe Nature Reserve and Lalobata Protected Forest, on the north-eastern peninsula of Halmahera, were together declared a national park covering some 167,300 ha of hill and lowland rainforest, and the Gunung Sibela Strict Nature Reserve, on Bacan, covers just over 10,000 ha. Both reserves, however, are at risk from mining developments, and Gunung Sibela is also at risk of encroachment of agriculture. Surveys are needed on Morotai and Bacan to assess the status of this species there and to determine further sites that could be targeted for long-term conservation.

The last of the eight globally threatened meliphagids, the Rotuma Myzomela, is restricted to the island of Rotuma and associated offshore islets, in Fiji. Nearly all native forest on Rotuma has been cleared for agriculture and plantations, but the myzomela appears to occupy all habitats found on the island, including remaining primary forest, secondary forest, forest edge and modified habitats, and it is thought to be the most abundant bird on Rotuma. It is nevertheless considered Vulnerable because it has a tiny global range of just 43 km², with most of the population on a single island, and is thus at risk of some catastrophic event, such as the introduction of exotic predators or the occurrence of disease. Pacific rats are already present. The wide range of habitats used by this myzomela, and its abundance, should, however, reduce the risk to the species from cyclone damage to the islands.

In addition to the above, the Chatham Island subspecies *melanocephala* of the New Zealand Bellbird is Extinct. This taxon is treated as a separate species by some authors. It occurred on Chatham, Mangere and Little Mangere, in the Chatham Group, but has not been recorded since 1906. The reasons for its demise are not properly known, but they are probably connected with the destruction of forest on these islands. It has also been suggested

Meliphagids form roughly one-fifth of the restricted-range species present in the New Caledonia Endemic Bird Area, among them the **New Caledonian Friarbird**. This large honeyeater occurs on the main island of Grande Terre and on Lifou and Maré in the Loyalty Islands. While common in forests, it appears to prefer open and disturbed areas, and often forages in gardens. Although scarce on Lifou, its relative abundance on the large island of Grande Terre means that it is probably secure for the present.

[*Philemon diemenensis*, Farino, New Caledonia. Photo: Roger Le Guen]

Five meliphagids are considered Near-threatened: two occur in Wallacea, and one each in New Guinea, the Solomon Islands, and eastern Australia. The last of these is the **Painted Honeyeater**, which has suffered a long-term population decline and may now number as few as 50,000 birds. The major factors behind the decrease are deforestation for agriculture, and subsequent grazing by introduced herbivores, which prevents forest regeneration. The species' apparent need for mature, closed-canopy forest with abundant mistletoes further complicates potential population recovery.

[*Grantiella picta*, Clunes, Victoria, Australia. Photo: Chris Tzaros]

that introduced predators, such as rats and cats, and over-zealous collecting for museums may have contributed to its extirpation.

A further six members of the Meliphagidae are considered Near-threatened. These are Brass's Friarbird, endemic in the upper Mamberamo and Wapoga River Basins in north-west New Guinea; the Bismarck Honeyeater of the mountains of New Britain; the Black-breasted Honeyeater and the Crimson-hooded Myzomela, both of which are confined to Wetar, in Wallacea; the Red-bellied Myzomela of Malaita, in the Solomon Islands; and the Painted Honeyeater of eastern Australia. A further two species, the Tagula Honeyeater and the White-chinned Myzomela, are Data-deficient. A number of other species, however, almost certainly warrant classification as Data-deficient. This applies particularly to some of the forms recently elevated to species rank, such as the Grey Friarbird of Kisar, Leti and Moa, in the eastern Lesser Sundas, and the Tanimbar Friarbird of the Kai and Tanimbar Islands. The range and status of a number of other meliphagids are likewise poorly known.

The *Action Plan for Australian Birds 2000* identified threatened avian taxa of Australia, including a number of honeyeater species, in addition to the globally threatened or Near-threatened species mentioned above. These include the "vulnerable" King Island subspecies *kingi* of the Yellow Wattlebird; and four "near-threatened" taxa, namely the Torres Strait form *saturation* of the Tawny-breasted Honeyeater, the eastern, nominate subspecies of the Black-chinned Honeyeater, and the Torres Strait forms of the Dusky and Red-headed Myzomelas, respectively *fumata* and *infuscata*.

Of significance, however, is the "critically endangered" and morphologically distinctive subspecies *cassidix* of the Yellow-tufted Honeyeater, which is confined to a single site in western Gippsland, in Victoria. A major conservation effort has been made to save the last population of this distinctive subspecies, which has declined markedly as a result of extensive destruction of its habitat. Sometimes treated as a separate species, the "Helmeted Honeyeater", this meliphagid formerly occurred throughout much of south-western Gippsland, over an area of 2000–3000 km², but since 1983 three of the four remaining populations have almost certainly become extinct, with two colonies ultimately extirpated by bushfire, and it is now confined to a small section of creek-line near Yellingbo, an area of about 5 km². The total population in 1999–2000 was estimated to consist of 37 breeding pairs and 36 fledglings. This honeyeater has been adversely affected by a cas-

cading series of processes resulting from clearance of natural habitat for agriculture: clearing of hillside vegetation changed the patterns of runoff, increasing the stress on remaining trees, which in turn left trees more susceptible to infestation by defoliating psyllids and encouraged colonization by Bell Miners. Miners are aggressive towards "Helmeted Honeyeaters", causing them to spend increased amounts of time in defending territories, and possibly leading to reduced breeding success. Conservation actions include revegetation programmes, beginning in 1978, with revegetated areas seen to be used for foraging and breeding; captive-breeding and management, with 15 breeding pairs in captivity in 2000; and reintroduction to another creek-line. The honeyeater, however, remains under threat from the proximity to colonies of Bell Miners, a shortage of high-quality breeding territories near existing colonies, and rapidly spreading dieback of eucalypts.

The declines of the "Helmeted Honeyeater" and the Black-eared Miner highlight two aspects of the ongoing conservation of Australia's woodland and forest avifauna. The first is the major effort that has been put in to the revegetating and regenerating of cleared or degraded temperate woodland and forest habitats, and the creation of habitat corridors between remnant patches. The second is the widespread impact of colonial and aggressive miners on the avifauna of revegetated habitats and of remnant habitats. The miners also dominate many urban habitats. For example, Noisy Miners dominate many areas of remnant vegetation, forest edges and planted wildlife corridors, from which they competitively exclude small birds.

Recent studies have highlighted some ways of dealing with the problem of miners. In one study, whereas Noisy Miners were found to dominate corridors of eucalypts to the virtual exclusion of all small birds, corridors vegetated with native acacias, exotic conifer and exotic deciduous trees had small birds and no resident Noisy Miners. The greatest abundance and richness of small birds occurred in plantings combining eucalypts with at least 15% acacias, and it was recommended that plantings of eucalypts be supplemented with both acacias and a shrubby understorey in order to increase the avifaunal diversity of a site. Another study examined revegetation of slow-growing native buloke woodlands, which usually include faster-growing eucalypts in plantings. The probability of Noisy Miners occurring in buloke woodland increased markedly where eucalypts were present at a density of about five

Of the eight meliphagids that are globally threatened, two Vulnerable and restricted-range species occur only in montane New Guinea: MacGregor's Honeyeater (*Macgregoria pulchra*) and the Long-bearded Honeyeater. The latter species occurs either side of the tree-line, generally at 3000–3800 m. It is patchily distributed, and is known to be present at very few sites. Thus, while it is fairly common, its population is thought to be fairly small. Moreover, its numbers may be declining as a result of human activity in the densely populated Central and Eastern Highlands.

The **Mao** is a restricted-range honeyeater that occurs only on Upolu and Savai'i in the Samoan Islands Endemic Bird Area. This species is also one of four honeyeaters classed as Endangered. The Mao is thought formerly to have been widespread in Samoa's lowland forests, but to have been forced by forest destruction and degradation to retreat upslope into remaining habitat enclaves. Cyclones, fires and hunting pose additional threats to a population that is already as low as 1000–2500 birds, and thought to be declining and ever more fragmented.

[*Gymnomyza samoensis*,
Samoa.
Photo: Patricio Robles Gil/
Oxford Scientific Films]

The **Black-eared Miner** is a restricted-range species that occurs only in the South-east Australia Endemic Bird Area. This Endangered honeyeater has vanished from most of its range due to two potent and interrelated pressures: anthropogenic habitat modification; and hybridization. Widespread clearance and fragmentation of the Black-eared Miner's mallee habitat opened up areas for the congeneric Yellow-throated Miner (*Manorina flavigula*), a species of edge and open habitats. The ranges of the two species soon overlapped, and subsequent extensive hybridization has diluted the rarer species' genetic purity.

[*Manorina melanotis*, Gluepot Reserve, South Australia, Australia. Photo: Peter Fuller]

per hectare, the presence of miners changing both the structure and the composition of the avifaunal assemblage of the woodland. Small insectivorous birds were recorded much more often where Noisy Miners were absent. Thus, a small difference in the composition of the habitat of these revegetated woodlands can result in substantial changes in the conservation value of the woodland.

The Noisy Miner seems to be the only meliphagid to have been introduced outside its country of origin. The species was recorded as breeding on the Three Sisters Islands, in the eastern Solomons, probably in the 1930s, but details of its introduction there are not known. It was not observed in 1990 and appears to have died out. Noisy Miners were also introduced, again unsuccessfully, in New Zealand. Bell Miners were imported into New Zealand in 1874, but it is not known if any were released into the wild; if they were, they certainly did not become established.

On a somewhat more positive note, it is worth mentioning here the newly described species of meliphagid, the Wattle Smoky Honeyeater. This was discovered by Beehler and his colleagues in a 2005 expedition to the Foja Mountains, in north-western New Guinea, although observations of a *Melipotes* species in the remote and little-visited region some 24 years earlier probably represent the first sightings of this new species (see Systematics). There are many other isolated regions of New Guinea where the discovery of new forms of honeyeater are likely to be made. For example, in 1992, D. Gibbs made what was only the second ornithological visit to the Fakfak Mountains in the twentieth century. There, he observed a *Melipotes* apparently unlike the three described species known at the time. The relationships of these Fakfak *Melipotes* with *M. fumigatus*, *M. gymnops*, *M. ater* and the recently described *M. carolae* are not known, and await further investigation.

The sole species of bird discovered in northern Melanesia since 1937 is the Bismarck Honeyeater, collected in the mountains of New Britain in 1958. In Australia, the most recently described bird species is the Eungella Honeyeater, formally named in 1983 after its initial discovery in a collection of museum skins of Bridled Honeyeaters at the Australian Museum, and subsequent observations of live individuals in Queensland in 1978. In 1989, Schodde separated the Kimberley populations of the White-lined Honeyeater as a subspecies, *fordiana*, distinct from populations of the Northern Territory. More recently, however,

molecular analyses have indicated that the two forms warrant specific status, with *fordiana* now recognized as the Kimberley Honeyeater.

The **Regent Honeyeater** was formerly widespread in eastern and south-eastern Australia, and was clearly once common, given the flocks of thousands that were recorded during the nineteenth century. However, since the 1940s in particular, its range and population have decreased markedly, and it is now listed as *Endangered*. Three-quarters of the species' Eucalyptus woodland habitat has been destroyed for agriculture, and only 500–1500 birds now remain. Conservation efforts are hindered by the mobile nature of the species, with its poorly understood movements thought to be in search of the nectar of flowering Eucalyptus trees.

Family MELIPHAGIDAE (HONEYEATERS) SPECIES ACCOUNTS

Genus *ACANTHORHYNCHUS* Gould, 1837

1. Eastern Spinebill

Acanthorhynchus tenuirostris

French: Méléphage à bec grêle **German:** Rotnacken-Honigfresser **Spanish:** Picoespina Oriental
Other common names: (Victorian) Spinebill, Slender-billed/Spinebill/Spine-billed Honeyeater; Tasmanian Honeyeater (*dubius*)

Taxonomy. *Certhia tenuirostris* Latham, 1801, Nova Hollandia = region of Port Jackson, New South Wales, Australia.

Forms a superspecies with *A. superciliosus*. Proposed races *trochiloides* (from Bunya Mts, in SE Queensland) and *loftyi* (Mt Lofty, in S Australia) considered synonyms of nominate, and *regius* (King I, in Bass Strait) synonymized with *dubius*. Four subspecies recognized.

Subspecies and Distribution.

A. t. cairnsensis Mathews, 1912 – NE Queensland (uplands of Atherton, Carbine and Windsor Tablelands), in NE Australia.

A. t. tenuirostris (Latham, 1801) – coastal and subcoastal E & SE Australia from Queensland (Clarke Range) S, inland to W slopes of Great Divide, to Victoria and SE South Australia.

A. t. halmaturinus A. G. Campbell, 1906 – Mt Lofty Ranges and S Flinders Ranges, Adelaide Plain and Kangaroo I, in South Australia.

A. t. dubius Gould, 1837 – Tasmania and islands in Bass Strait.

Descriptive notes. 13–16 cm; male 4–24 g, female 7–16 g. Distinctive, small honeyeater with long, slender decurved bill and moderately long tail. Male nominate race has glossy black forehead to nape, black mask (lores and ear-coverts) joining broad, bold, black crescent at side of breast, isolating dark rufous-brown hindneck-collar and sharply demarcated from white lower face, side of throat and centre of breast, which enclose bold rufous-brown patch on chin and centre of throat that becomes darker, almost black, on lower edge; upperbody largely dark grey-brown, faint rufous wash on mantle, merging to dark greyish rump and uppertail-coverts; upperwing and uppertail blackish, glossy grey secondary coverts and tertials and prominent white corners of tail (largely or wholly concealed when tail folded); underbody pale to dark rufous-brown; underwing largely whitish, with dark brown-grey trailing edge and tip, undertail largely white when closed, with dark

brown-grey base; iris dark red or orange-red; bill black; legs black, grey-black or dark red-brown. Female is like male but slightly smaller, cap much duller, dark grey, typically contrasting with black mask (effects of light can make contrast appear less obvious). Juvenile is more uniform above than adult, with top and side of head and upperbody dark olive, merging to dark olive-grey on uppertail-coverts, whole underbody uniformly light yellow-brown, indistinct light brown fringes on secondary coverts, bill sometimes paler, grey-black, and basal half of lower mandible yellow, gape yellow and swollen, iris black-brown (lacks red colour),

legs paler, greyish-pink; immature like adult. Race *cairnsensis* is similar to nominate in size, male differs in paler and less rufous hindneck, and very pale and diffuse brown centre of lower throat; *dubius* is significantly smaller, male has smaller and much darker throat patch confined to centre of throat (chin white) and grading from dark brown on upper throat to black-brown on lower throat, also slightly broader black crescent at side of breast, stronger rufous-brown on lower underbody; *halmaturinus* is significantly smaller than nominate, male cap slightly paler, grey-black, throat patch paler, white tips of outer rectrices slightly narrower, some variation in size, birds on Kangaroo I smaller but with longer bill than adjacent mainland populations. **VOICE.** Song, from perch and in flight, heard sporadically throughout day (said to sing more often on wet days), fairly loud: a rapid, shrill but musical series of piping notes, “ting, ting, ting...”, usually lasting 4–5 seconds, sometimes longer (20 seconds or more), up to 4–5 songs per minute; varies from rather explosive to soft and wavering. Subdued song during courtship chases. Rapidly repeated 4-note call, last note rather longer than first, apparently given only when breeding; soft metallic call during threat display. Wingbeats make “thirup” sound.

Habitat. Mainly dry, open, sclerophyll forests and woodlands dominated by *Eucalyptus* and with well-developed shrub understorey, often of *Banksia* or other heath species; also dense heath or shrub associations, including shrub-heath, heath-woodland, dense coastal *Leptospermum*-*Banksia* shrubland, and coastal and subcoastal mallee shrubland. Commonly in wet sclerophyll forest in some regions. Often found in orchards, and parks and gardens in cities and urban and regional areas. Occasionally in littoral, subtropical or temperate rainforest and remnant patches of vine forest; often in temperate rainforest dominated by Antarctic beech (*Nothofagus cunninghamii*) in

Tasmania, more rarely so on mainland. Occasionally in subalpine forest or woodland, but rarely in alpine areas (only during snow-free months). Sometimes in introduced pine (*Pinus*) plantations. Sea-level to c. 1200 m, but confined to coastal lowlands in NE.

Food and Feeding. Diet nectar and arthropods (mainly insects) in roughly equal proportions. In two studies, recorded ratios of nectar-foraging to insect-foraging 54:46 and 53:47, though in latter study ratio changed from 80:20 during Feb–Apr to 20:80 in May and to 90:10 in Jun; on Kangaroo I, ratio from smaller and possibly biased sample 20:80. Forages mostly in low shrubs or understorey to middle-storey trees, less often in crowns of tall trees, e.g. at flowering mistletoe (*Loranthaceae*) and profusely flowering eucalypts; in SE New South Wales, mean foraging height 2.2 m, with 99% in shrub layer (up to 4 m) and 1% in subcanopy (4–10 m); very occasionally on ground. Much foraging at flowers, exploiting wide variety, frequently proteaceous shrubs such as *Banksia* and *Lambertia*, and *Amyema* mistletoes. Nectar obtained by probing and sally-hovering. Insects gleaned from foliage, twigs, branches and loose bark, obtained also by sallying, including sally-striking in air and at foliage. When taking nectar from *Epacris* or *Fuchsia* flowers, probes while sally-hovering. Will puncture holes at bases of tubular flowers to reach nectar. Usually singly or in twos (probably pairs), sometimes in loose groups of 3–5 birds, rarely in mixed-species feeding flocks; sometimes associates with Silvereyes (*Zosterops lateralis*), other honeyeaters and gerygones (*Gerygone*).

Breeding. Recorded Aug–May, mainly Oct–Dec; eggs Aug–Feb and rarely May (mostly Sept–Nov), and at site in SE Australia clutches started mid-Sept to mid-Dec; up to four broods. Both sexes collect nesting material but only female builds, construction takes 4–7 days, nest a small, deep cup, usually made of twigs, grass, bark and leaves, bound with spider web, lined with feathers, fine grass and sometimes other soft materials, external diameter 5–8.9 cm, depth 5.1–8 cm, internal diameter 4–5.5 cm, depth 3.8–4 cm, usually suspended by rim from forked branch, occasionally supported, 0.9–18 m (mean 3 m) above ground in dense foliage in upper or outer part of living shrub or tree, often one with prickly foliage, occasionally in dead foliage or vines; new site used for subsequent and replacement clutches. Clutch 1–4 eggs, usually 2 (mean throughout range 2.2); incubation by female alone, male once observed to incubate in Tasmania, period 13–16 days (average 14.4 days); both adults feed nestlings and fledglings and remove faecal sacs; nestling period 12–15 days (average 13.7 days); young fed by both parents for several days, can begin to feed themselves within 8 days of fledging; juveniles disperse from natal territory before adults renest.

Movements. Resident, or partly so, with some local movements. In Blue Mts (New South Wales), winter influx possibly of migrants; occurrence also seasonal or numbers change at some sites. Partial altitudinal migrant in highlands of SE Australia, possibly also in Tasmania, leaving higher country in autumn–winter. Conversely, apparently a partial migrant in high country of New England Tableland, where more numerous in winter and only small resident population present in summer; ringing shows that birds tend to return at similar times of year.

Status and Conservation. Not globally threatened. Locally common. S race *dubius* widespread in Tasmania but rare on King I. No estimates of global population, recorded at densities of up to 0.5 birds/ha. Usually absent from small degraded patches of woodland. Found to be adversely affected by logging at one site in SE Australia, though elsewhere regularly found in dense regrowth 0–6 years after clear-felling and common in regrowth 20–30 years old. Sometimes killed by cats or dogs. Birds feeding on refined sugar at artificial feeders in gardens sometimes die from thiamine deficiency.

2. Western Spinebill

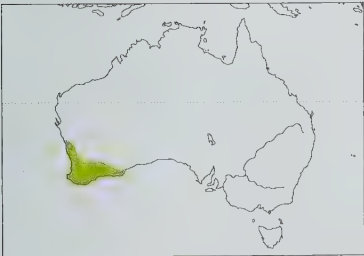

Acanthorhynchus superciliosus

French: Méliphage festonné **German:** Buntkopf-Honigfresser **Spanish:** Picoespina Occidental
Other common names: (White-browed) Spinebill, Western Spinebilled Honeyeater

Taxonomy. *Acanthorhynchus superciliosus* Gould, 1837, Van Diemen’s Land; error = district of Perth, Western Australia.

Forms a superspecies with *A. tenuirostris*. Monotypic.

Distribution. SW Western Australia mainly in coastal and subcoastal regions, from Eneabba S to Pingelly and Fitzgerald R, thence E to Israelite Bay and Cape Arid National Park.

Descriptive notes. 12.5–15.5 cm; male 9–11.5 g, female 8–11 g. Small honeyeater with long slender, decurved bill and moderately long tail. Male is largely olive-grey above and cream below, with bold black facial mask bordered by short, narrow white supercilium (starting from just above eye) and narrow white submoustachial stripe and white chin; broad rufous hindneck-collar joins with rufous bib on throat and upper breast, which in turn bordered below by narrow white band and broader black band across lower breast; upperwing blackish-brown, with dark grey secondary coverts and tertials, fine pale edges of remiges;

uppertail grey-black, bold white corners conspicuous when spread (normally concealed when tail closed); underwing white with dark brown trailing edge and tip; undertail appears mostly white with dark grey base; iris dark red or orange-red; bill black; legs grey-black or black-brown. Female is smaller and much duller than male and lacks distinctive dark mask (lores and ear-coverts as top of head), has supercilium and submoustachial stripe duller, light grey-brown, and more diffuse than male’s, bib duller and less sharply demarcated, chin concolorous with throat, no white and black bands below bib, rufous hindneck-collar slightly duller and less sharply demarcated, and sometimes base of lower mandible paler, greyish. Juvenile is like female but plainer and duller, slightly browner above, especially on rump, no rufous hindneck-collar, faint narrow brown fringes on secondary coverts, slightly paler and more yellowish from lower breast to undertail-coverts, bill black with yellowish base of lower mandible and swollen orange-yellow gape, iris dark red-brown; immature resembles adult of corresponding sex. **Voice.** Song, throughout day when nesting, described as fluted, metallic whistles and twitterings, or squeaky excited whistling; single song or bursts of song given during display-flights. Also loud, repeated “kleat”. Wingbeats in some rapid flights produce audible cracking “purrrr”; clattering sound thought to be made by bill.

Habitat. Mainly habitats dominated by or supporting *Banksia* but also with other Proteaceae, e.g. *Dryandra*, *Grevillea* and *Hakea*. Commonly in heathland, including low open heathland, sandplain heathland, coastal heathland, and montane heathland; also open woodlands dominated by *Banksia* or *Eucalyptus* or both, usually with shrub or heath understorey. Sometimes in mature open *Eucalyptus* forest with diverse shrub or heath understorey; riparian forest or woodland dominated by *Eucalyptus* or paperbark (*Melaleuca*) or both; and in mallee *Eucalyptus* or other scrub. Rarely in urban gardens.

Food and Feeding. Mainly nectar, also small invertebrates (insects). Forages at all levels from ground to canopy (to 30 m or more above ground), mainly in understorey to c. 15 m. Nectar taken by probing from flowers, often *Banksia*, *Dryandra* or other Proteaceae, and *Eucalyptus*; probes tubular flowers. Insects taken by sallying, also gleaned from foliage, branches and trunks. Forages also by sally-hovering, probably for both nectar and insects. When feeding on nectar from *Banksia menziesii*, birds landed on unopened florets at distal end of inflorescence, and leaned forward to probe between most recently opened florets. Usually singly or in pairs, occasionally in small parties; sometimes in mixed flocks with other, predominantly insectivorous, species.

Breeding. Mainly spring–summer, eggs early Aug to late Oct and mid-Dec, nestlings mid-Aug to late Nov and fledglings mid-Sept to early Dec; unspecified breeding noted late Jul and fledglings Jan and Mar. Nest built by female, male once observed to build, a small rounded cup made of grass, bark, and occasionally rootlets, lichen, tendrils and other plant material, bound together with spider web, lined with feathers, plant down or, sometimes, wool or fur, external diameter 7–7.6 cm, depth 5.1 cm, internal diameter 3.2–3.8 cm, depth 3.2 cm; 1–7.6 m (mean 4.1 m) above ground, but recorded also to 12 m, usually among foliage near end of leafy vertical or horizontal branch of shrub or small tree. Clutch 1–2 eggs, mean 1.6 (suggested that early clutches usually of 1 egg and later ones of 2 eggs, but study needed); incubation usually by female, one male observed to incubate, no information on duration; chicks fed by both parents, nestling period 15 days or more; fledglings fed by both sexes. Nests parasitized by Pallid Cuckoo (*Cuculus pallidus*).

Movements. Mainly resident, with some local movements; scattered records N of main range. Some seasonal patterns in abundance, e.g. at one site numbers highest Jan–Mar. In study at Gooseberry Hill, records in all months and maximum numbers usually May–Aug, but much annual variation.

Status and Conservation. Not globally threatened. Reasonably common. No estimates of global population; density 0.004 birds/ha at one site. Has suffered from clearing of native vegetation for agriculture in Wheatbelt, and some indication that adversely affected by fire. In karri (*Eucalyptus diversicolor*) forests near Pemberton, most abundant in mature forest that had not been burnt for at least 3 years. Sometimes killed by flying against windows.

Genus PYCNOPYGIUS Salvadori, 1880

3. Plain Honeyeater

Pycnopygius ixoides

French: Méliphage ocré **German:** Bülbülhonigfresser **Spanish:** Mielero Bulbul
Other common names: (New Guinea) Brown/New Guinea/Nondescript/Olive-brown Honeyeater

Taxonomy. *Ptilotis ? ixoides* Salvadori, 1878, Sorong, Vogelkop Peninsula, New Guinea. Closest to *P. cinereus*. Distributional limits and validity of races poorly known, and listed ranges tentative. Race *cinereifrons* possibly better synonymized with nominate. Proposed race *simplex* (from middle Sepik region, in N New Guinea) considered inseparable from *proximus*. Five subspecies provisionally recognized.

Subspecies and Distribution.

- P. i. ixoides* (Salvadori, 1878) – NW New Guinea E to head of Geelvink Bay and, in S, to about Mimika R and including Weyland Mts.
- P. i. proximus* (Madarász, 1900) – N New Guinea from Mamberamo R E to Astrolabe Bay.
- P. i. unicus* Mayr, 1931 – NE New Guinea (Huon Peninsula and slopes of Herzog Mts).
- P. i. cinereifrons* Salomonsen, 1966 – S New Guinea from Mimika R E to upper reaches of Fly R (absent from S Trans-Fly), and apparently also to Port Moresby district.
- P. i. finschi* (Rothschild & E. J. O. Hartert, 1903) – SE New Guinea on N watershed of ranges from Kumusi R E to Milne Bay and on S watershed E of Port Moresby (usually absent from S coast).

Descriptive notes. 18 cm; male 28–33 g and female 22–31 g (nominate), unsexed 26–34 g (*proximus*). A medium-sized nondescript honeyeater with rather small head, and medium-small and only slightly decurved bill. Nominate race has top of head and neck dark olive-grey, fine blackish-brown mottling or streaking on forehead and forecrown becoming broader and bolder on

brown to reddish-brown; bill black to greyish-black or brownish-black; legs light grey. Sexes alike in plumage, male larger than female. Juvenile undescribed; immature apparently like adult, probably inseparable in field. Race *proximus* is like nominate but darker olive-brown above; *unicus* has more obvious olive tone in grey of top of head and neck, and margins of tail feathers and remiges more buff; *cinereifrons* differs from nominate in having top of head greyer, upperparts less olive-brown, chin and throat rich buff, merging into more grey-buff of breast, underwing darker rufous-buff; *finshi* is distinctive, with bright buff-rufous underbody and slightly more rufous-brown upperparts. Voice. Typically quiet or silent. Calls include "petrt" or "peetrt", similar to call of *P. cinereus*; also distinctive "chi-chup", and hollow "tup". Song described as short burst of loud melodious notes.

Habitat. Forest, including hill forest, also forest edge and tall secondary growth; mainly in old secondary growth in Crater Mountain Wildlife Management Area, and at Brown R always seen in roadside vegetation. Sea-level to c. 1200 m; locally to 1400 m at Mengino, in Eastern Highlands. In Eastern Highlands, altitudinal range overlaps with that of *P. cinereus* at c. 1060–1370 m, around Karimui present species common up to 1190 m, *P. cinereus* extending down to 1110 m.

Food and Feeding. Diet small fruits (including of *Pipturus*) and nectar, and almost certainly small arthropods; described as primarily frugivorous. Swallows fruit of *Pipturus* whole. Mainly in lower canopy and middle and lower levels of vegetation, occasionally descending to understorey, but forages also in upper canopy. Usually in flowering and fruiting trees, particularly sago (*Metroxylon*) in some areas, and in vines. Typically quiet, inconspicuous; rather slow-moving. Usually singly or in twos (probably pairs); occasionally in small parties, e.g. up to twelve in flowering sago, with up to four on same flowering head. Sometimes associates with other species. In Eastern Highlands, commonly displaced by similarly sized *Xanthotis flaviventer* when feeding in flowering trees but seen to forage in large groups with that species on *Pipturus* in garden.

Breeding. No information.

Movements. Probably largely resident throughout range.

Status and Conservation. Not globally threatened. Generally rare, uncommon or sparse to locally common, but said to be easily overlooked. Described as abundant at Baiyer River Sanctuary and in Maprik area; common in lowland forest of E Sepik District, and uncommon in Crater Mountain Wildlife Management Area.

Bibliography. Anon. (1978a), Beehler (1978a), Beehler, Pratt & Zimmerman (1986), Beehler, Sengo *et al.* (1995), Bell (1982c, 1984b), Berggy (1978), Coates (1990), Coates & Peckover (2001), Diamond (1972a), Finch (1980b, 1981c, 1983), Fletcher (2000b), Gilliard & LeCroy (1967a), Gregory (1995b), Gyldestolpe (1955b), Hicks (1988b), Mack & Wright (1996), Mackay (1980), Ogilvie-Grant (1915), Pearson, D.L. (1975), Rand (1942a, 1942b), Rand & Gilliard (1967), Richards & Suryadi (2002), Ripley (1964), Stein (1936), Terborgh & Diamond (1970).

4. Marbled Honeyeater

Pycnopygius cinereus

French: Méliphage marbré **German:** Marmorhönigfresser **Spanish:** Miclero Jaspeado
Other common names: Grey/Grey-fronted/Greyish-brown Honeyeater

Taxonomy. *Ptilotis cinerea* P. L. Selater, 1874, Hatam, Arfak Mountains, north-west New Guinea. Closest to *P. ixoides*. Three subspecies recognized.

Subspecies and Distribution.

P. c. cinereus (P. L. Selater, 1874) – mountains of Vogelkop Peninsula, in NW New Guinea.

P. c. dorsalis Stresemann & Paludan, 1934 – Weyland Mts and S slopes of W Nassau Mts, in W New Guinea.

P. c. marmoratus (Sharpe, 1882) – Central Ranges of New Guinea E from Weyland Mts, also Adelbert Mts and mountains of Huon Peninsula (including Herzog Mts).

whitish malar streak; upperbody rich dark brown (some with olive tinge), feathers of mantle, back and scapulars with pale grey to olive-grey fringes (giving diffusely mottled or streaked pattern); uppertail and upperwing rich brown, fine buff fringes on alula and median and greater secondary coverts, strongly tinged olive on greater primary coverts; fine olive-buff edges on remiges, more strongly tinged olive on secondaries (forming pale panel on folded wing); chin and throat dusky grey, mottled or barred off-white, underbody dusky brownish-grey with faint paler scaling, becoming brownish-grey and diffusely darker-mottled in ventral region; undertail brown-grey to dark olive-brown, underwing largely orange-buff with brownish-grey trailing edge and tip; iris brown, bare postocular skin blue-grey; bill black; legs light blue-grey. Sexes alike in plumage, male slightly larger than female. Juvenile differs from adult in having crown greyer, upperwing-coverts duller brown than rest of upperparts, lacking conspicuous edges on most wing-coverts and primaries (but primary coverts and secondaries have rather bright brownish-olive edges), largely light grey below, with dark grey breast, buff vent and undertail-coverts; immature very similar to adult but with stronger olive tinge, also retains juvenile rectrices and remiges. Race *dorsalis* is very like nomi-

hindcrown to hindneck, diffuse whitish supercilium from above rear of eye to side of nape; lores grey with fine blackish speckling; upperbody olive-brown, diffusely mottled or streaked darker on mantle and back; uppertail and upperwing dark olive-brown, brighter olive edges on rectrices, fine buff tips on lesser and median secondary coverts, fine buff fringes on greater coverts, fine olive-buff edges on remiges (forming large pale panel on folded wing); chin, throat and underparts grey, faint and diffuse dusky streaks on upper breast; undertail dark grey, underwing dull pale rufous with dark grey trailing edge and tip; iris pale

nate, but darker; *marmoratus* has heavier off-white to pale grey scaling across breast and belly, merging into largely pale brownish-grey and diffusely darker-mottled lower underbody, iris light grey to blue-grey. Voice. Largely silent; occasionally a downslurred "tyert", repeated at intervals of 2 seconds.

Habitat. Hill forest and lower and middle montane forest, forest edge and secondary growth, also gardens; on Mt Edward Albert occurs in remnant oak forest and in patch of secondary growth in grassland; in Eastern Highlands mainly at forest edge and in secondary growth, but recorded also in forest interior. Mainly at 1000–2000 m, locally as low as 500 m; tends to be more common at lower levels of altitudinal range, e.g. in Telefomin region upper limits at 1220–1520 m and very uncommon above this.

Food and Feeding. Diet includes nectar, small fruits (2–7 mm in diameter), insects, and parts of flowers. In Eastern Highlands foraged mainly in upper storey in trees with flowers or fruits; on Mt Edward Albert, seen to feed on berries in patch of secondary growth. Usually solitary and typically silent, inconspicuous and rather sluggish. In Eastern Highlands, repeatedly driven from fruiting tree and generally prevented from feeding by *Melidectes torquatus*.

Breeding. Very poorly known. Nestling recorded in Mar, and female with enlarged ovary in Nov. No further relevant information available, although eggs have been described.

Movements. No information; probably sedentary.

Status and Conservation. Not globally threatened. Poorly known; considered patchily common, or generally sparse to locally common; uncommon on Mt Mengam, in Adelbert Range. No estimates of global population.

Bibliography. Beehler (1978a, 1980b), Beehler *et al.* (1986), Bell (1971a), Coates (1990), Coates & Peckover (2001), Diamond (1972a), Gilliard (1950b), Gilliard & LeCroy (1961), Gyldestolpe (1955a, 1955b), Heron (1977a), Mayr & Gilliard (1954), Mayr & Rand (1937), Ogilvie-Grant (1915), Pratt (1982), Rand & Gilliard (1967), Ripley (1964), Stein (1936), Terborgh & Diamond (1970), Tolhurst (1991).

5. Streak-headed Honeyeater

Pycnopygius stictocephalus

French: Méliphage à tête rayée **Spanish:** Miclero Cabecirrayado
German: Strichelkopf-Hönigfresser
Other common names: Streak-capped/Spangle-crowned Honeyeater

Taxonomy. *Pycnonotus* (?) *stictocephalus* Salvadori, 1876, Naiabui, Hall Sound, south-east New Guinea.

Monotypic.

Distribution. Salawati (in West Papuan Is), Aru Is and throughout lowland New Guinea.

Descriptive notes. 21 cm; two males 38 g and 39 g. Medium-sized rather drab honeyeater, with rather small and only slightly decurved bill; appearance much affected by plumage wear and fading. Top of head is blackish-brown with fine and short off-white to greyish-white streaking or speckling; side of head and neck, and chin and upper throat dark brown, conspicuous pale buff to off-white malar streak; upperparts dark brown, slightly darker on wing and tail, and becoming slightly paler with wear; lower throat and underbody buff-brown, underwing rich buff with dark grey trailing edge and tip; iris brown to dark brown or reddish-brown; bill blackish-brown to black, at least some having purplish tinge at base of lower mandible; legs dark grey. Sexes alike in plumage, male larger than female. Juvenile has underbody paler, buff, with grey tinge on breast, rectrices conspicuously edged and tipped pale brown to pale rufous; immature nondescript, differs from adult mainly in having top of head blackish with grey tinge or faint greyish mottling or spotting (not white spotting or streaking), merging to dull black on side of head and dull greyish-black on chin and throat, much less distinct malar stripe, duller brown upperparts and underbody, and (at least when plumage fresh) upperwing-coverts conspicuously edged rufous, also retained juvenile wing and tail with more conspicuous pale edging on rectrices. Voice. Distinctive, loud and rather musical and pleasant. Most frequently heard calls are mimicry of song phrases of Brown Oriole (*Oriolus szalayi*), e.g. "tudi-tudi-tuhifew" (duration c. 1 second), but mimicked phrases weaker and higher-pitched than original. Song described as attractive "tickety-tickety-tickety-teeuw", first and penultimate syllables alike, second a tone lower, final syllable a descending slur, and lasting c. 3 seconds; given during song flight. Also described as bubbling series of 3–12 fairly high-pitched notes, "wchw-wchw-wchw...", c. 4 notes per second, at intervals of a few seconds; or liquid "wheeta wheeta where" or "whita-tea whita-teer" repeated at intervals of c. 2 seconds; subdued "weut-teuk ... weut" (from Manokwari, in Vogelkop) probably also song. Squeaking notes heard at nest on arrival of second bird, but not known if calls of unseen young or quiet calls by one or both adults.

Habitat. Generally a forest-edge specialist. Inhabits mainly disturbed and often open habitats, including tall secondary growth and partly cleared forest, forest edge, gallery vegetation in savanna, dense eucalypt (*Eucalyptus*) savanna woodland, swamp-forest and monsoon woodland or scrub, and gardens; found in rubber plantations around Veimauri-Kuriva (SE New Guinea). Recorded also in primary lowland forest (e.g. E Sepik District), primary hill forest (Ok Menga) and lower levels of dense forest (e.g. at Manokwari). Mainly sea-level to 500 m, locally to 640–750 m (Ok Tedi area) and 1000 m (Adelbert Mts).

Food and Feeding. Diet nectar, small fruits including figs (*Ficus*), insects. Often gleans from foliage, but also probes flowers for nectar. Seen in top branches of tall secondary growth, in upper storey and canopy of lowland forest, also in lower levels of primary forest. Usually singly, sometimes perched conspicuously atop a dead branch; sometimes in twos (possibly pairs) or threes. In flowering or fruiting trees, will drive off other species of similar size or smaller; during 4–5 hours of observation (over two days) of a fruiting tree, repeatedly drove off four species that had same diet, i.e. similarly sized White-bellied Cuckoo-shrike (*Coracina papuensis*) and smaller *Lichenostomus flavescens*, *Myzomela obscura* and *Myzomela adolphinae*, but ignored five species with quite different diets, as well as five larger species (including *Philemon buceroides* and Brown Oriole) with dietary overlap. Visual and vocal similarity to *Philemon buceroides* (especially juvenile) and to latter's visual mimic (Brown Oriole) may allow it to forage in same trees as these other, more pugnacious species without suffering aggressive interactions.

Breeding. Active nest near Finschhafen in early Sept and another near Port Moresby 9th Mar (latter apparently abandoned 4–6 days later). Nest a finely woven cup or basket of fine stems, suspended by rim from fine fork in foliage, near Port Moresby a deep cup of dried material (possibly grass), with exterior an even latticework, appeared to be suspended by two edges and was

overhung by two large leaves, one nest c.12 m above ground near top of tree, another 8 m up in small tree. No other information.

Movements. Poorly known. Resident at Moroka (SE New Guinea). Some indication of at least local movements, apparently associated with flowering: numbers suddenly increased in mid-1978 in Veimauri area, where absent earlier in year; around Veimauri–Kuriva common throughout wet season but absent in dry season. Vagrant at Brown R.

Status and Conservation. Not globally threatened. Poorly known; considered generally scarce to rare but locally common. Fairly common in Veimauri–Kuriva area; uncommon in lowland forest of E Sepik District. No estimates of global population.

Bibliography. Anon. (1978c), Bailey (1992), Beehler & Dumbacher (1996a, 1996b), Beehler, Pratt & Zimmerman (1986), Beehler, Sengo *et al.* (1995), Bell (1970c, 1984b), Coates (1990), Diamond (1982), Finch (1980b, 1983), Gregory (1995b), Gregory *et al.* (1996), Gyldestolpe (1955b), Hoogerwerf (1971), Isles & Menkhurst (1976), Mack & Wright (1996), Mackay (1991), Mayr & Rand (1937), Mees (1982), Murray (1988b), Ogilvie-Grant (1915), Pearson, D.L. (1975), Rand (1942a, 1942b), Rand & Gilliard (1967), Ripley (1964), Schönwetter & Meise (1981), Seale (1980), Stein (1936), Tolhurst (1991).

Genus *CERTHIONYX* Lesson, 1830

6. Pied Honeyeater

Certhionyx variegatus

French: Méliophage varié **German:** Elsterhonigfresser **Spanish:** Mielero Pio
Other common names: Black-and-white/Western Pied Honeyeater

Taxonomy. *Certhionyx variegatus* Lesson, 1830, Timor; error = Shark Bay area, Western Australia. Monotypic.

Distribution. Western Australia (S of S Kimberley Division) E to S Northern Territory, SW Queensland and W New South Wales, S to coastal South Australia and W Victoria.

Descriptive notes. 15–20 cm; male 22–34 g, female 22–29 g. Medium-sized honeyeater with fairly long decurved bill. Male is mostly black on head, neck, upperparts and side of breast, except for small pale blue crescent of bare skin below eye, white lower rump and uppertail-coverts, and uneven long, tapering white stripe down folded wing (formed by white marginal, median and central greater secondary coverts, and white edges of outermost tertial and adjacent few secondaries); uppertail black, broad white bases of all except central feather pair; centre of breast and rest of underbody white, underwing blackish-brown,

undertail white with broad black tip; in flight, white rump patch prominent and upperwing appears largely black with prominent white shoulder patch; iris dark red-brown; bill blue-grey; legs blue-grey to grey-black. Female is much duller than male, head and neck brown, grading to grey-white on chin and throat, with small area of light blue skin below eye (smaller and less conspicuous than male's), diffuse black-brown streaking on top of head and neck, sometimes a weak buff supercilium; upperbody pale brown, flecked and mottled black-brown anteriorly, grading to darker brown with paler brown scaling on rump and uppertail-coverts, broad white scalloping on outer uppertail-coverts; folded wing dark brown, broad white patch on central greater secondary coverts joining narrow white strip on secondaries, and with coarsely marked black-and-white shoulder patch; uppertail dark brown with paler brown edges; breast dirty white, dark brown teardrops on upper

breast grading into dark brown streaks on lower breast, rest of underparts white, underwing with coverts dark brown and remiges grey-brown, undertail grey-brown with paler edges; bare parts as male, or bill paler. Juvenile is like female but less boldly marked, top of head and upperparts plainer, pale brown, with buff rump, breast less strongly marked, also pale margins of wing-coverts tinged yellow-brown to buff, iris brown, small patch of skin below eye yellow, bill brownish or with hint of blue, base of lower mandible and gape yellow. **Voice.** Song a repeated, plaintive, drawn-out piping, e.g. “te-titee-tee-tee” or “titi-te-te”, often of 4–7 (but up to 11) notes, given in display-flight and when perched (possibly more piercing in flights, more plaintive when perched); sings much on arrival in breeding area, largely silent after breeding starts. Female sings from a shrub in response to male's aerial song. Reported as giving single weak piping note.

Habitat. Mainly arid and semi-arid shrublands, often including or dominated by *Eremophila* and *Grevillea*, and with or without sparse overstorey of *Eucalyptus* trees; less often in mulga (*Acacia aneura*) shrublands or woodlands. Occasionally in spinifex (*Triodia*) hummock grassland with scattered shrubs and casuarina trees, or in chenopod shrublands. On inland plains, sandhills, ranges and rocky outcrops; occasionally in coastal regions in W Australia.

Food and Feeding. Mainly nectar, also small arthropods (insects), occasionally fruit and seeds. Forages mainly among foliage and flowers of trees and shrubs, occasionally by sallying; once seen to forage on ground. Forages at flowers, particularly of *Eremophila* and *Eucalyptus*, also other species such as *Grevillea* and *Hakea*; eat fruits of mistletoes (Loranthaceae) and *Rhagodia*. Usually singly, in twos (probably pairs), or in small groups of 6–8 individuals, but gathers in larger numbers in flowering trees or shrubs, e.g. up to 100 feeding on flowering *Grevillea*. Often associates with other species, especially with *Sugomel nigrum* and woodswallows (*Artamus*), and seen in mixed feeding flocks with *Sugomel nigrum* and *Purnella albifrons*.

Breeding. Usually breeds in austral winter–spring, also at other times if conditions suitable; eggs recorded Jul–Nov (once late Jun in W Australia and early Feb in Northern Territory) and nestlings and fledglings late Jul to Oct; unspecified breeding reported Jun–Mar, mainly Aug–Sept. Both sexes collect material and build nest, a shallow cup made of small sticks, grass, plant stalks, rootlets and spider web, lined with similar but finer material as well as woolly seedheads, flowers, wool and feathers, and plant down (sometimes thin-walled and unlined), external diameter 7.6–14 cm, depth 4.7–5.7 cm, internal diameter 4.4–6 cm, depth 2.5–5.1 cm; usually suspended by rim from horizontal or vertical fork low down in live or dead shrub or small tree, up to 4.6 m above ground (21 nests 0.6–2.4 m up, mean 1.28 m). Clutch usually 3 eggs, less frequently 2, occasionally 1, mean throughout range 2.38 (mean in W of range 2.62), once 4 eggs but not known if all laid by same female; incubation by both sexes, period no more than 14 days at one nest; chicks fed by both sexes (male more than female at one nest), nestling period once 12 or 13 days, and a chick 11–12 days old left nest when nest approached; fledglings fed by parents, but roles of sexes not known; both adults perform distraction displays if nest or fledglings threatened.

Movements. Largely erratic, with no obvious pattern in most areas. Occurrence often correlated with flowering of foodplants (especially *Eremophila*) or, in parts of W, reported from some sites only after recent rains; at Broome, in coastal NW, tends to occur only during extended dry periods elsewhere. Occasional irruptions, e.g. large numbers (including flocks of more than 30 individuals) in SW New South Wales Sept–Nov 1995, and large numbers observed SW New South Wales and NW Victoria Sept 1999–Feb 2000. Irregular at or beyond edge of normal range. Resident in L. Frome area of South Australia.

Status and Conservation. Not globally threatened. Locally common. Regarded as “vulnerable” in New South Wales, where considered an ecological specialist with small population. No estimates of global abundance; recorded densities of 0.19–0.72 birds/ha. While broad distribution well known, details of use of its range over time, and movements within that range, poorly known and warrant study.

Genus *PROSTHEMADERA* G. R. Gray, 1840

7. Tui

Prosthemadera novaeseelandiae

French: Méléphage tui **German:** Tui **Spanish:** Mielero Tui
Other common names: Chatham Island Tui

Taxonomy. *Merops novaeSeelandiae* J. F. Gmelin, 1788, Nova Seelandia = Queen Charlotte Sound, South Island, New Zealand. Described race *kermadecensis* (from Kermadec Is) considered inseparable from nominate. Two subspecies recognized.

Subspecies and Distribution.

P. n. novaeseelandiae (J. F. Gmelin, 1788) – Kermadec Is (Raoul I); New Zealand and many inshore islands, including (around North I) Hen and Chickens Group, Mokohinau Group, Great Barrier, Little Barrier, Noises and Tiritiri Matanga and Kapiti I and (around Stewart I) Ruapuke I and Muttonbird Group.

P. n. chathamensis E. J. O. Hartert, 1928 – Chatham Is (Pitt, Mangere, Rangatira).

Descriptive notes. 27–32 cm; male 62–150 g and female 58–105 g (nominate), male 89–240 g and female 89–170 g (*chathamensis*). Large honeyeater with sturdy, slightly decurved bill. Male nominate race is mostly glossy black to black-brown, with strong iridescence on head, neck, upperparts and breast and upper belly (which appear iridescent dark blue, green-violet or even golden, colour varying with light), and with conspicuous pair of white ball-like tufts on side of throat (usually appear as single tuft) and white lacy hindneck-collar extending to side of neck and upper mantle; bold white patch on leading edge of inner wing; lower belly, thighs

and vent black-brown, often with yellowish-brown wash (but no iridescence) on lower belly and vent, flanks dark grey, undertail-coverts iridescent dark green to dark blue, undertail black, underwing blackish with slight dark green to dark blue iridescence on leading edge; iris black-brown; bill black or black-brown; legs black to grey-black. Sexes alike in plumage, male larger than female. Juvenile is much duller than adult, mostly black-brown to grey-black, with greyish throat, often pale patch where white throat-tufts present in adult, frequently faint dark green to dark blue iridescence on scapulars and upperpart-coverts and fine pale streaking on head to upperbody and breast, gape yellowish and swollen (up to c. 5 weeks of age). Race *chathamensis* is larger and heavier than nominate, otherwise separable (in direct comparison) by slightly bluer iridescence overall (never any straw-yellow sheen).

VOICE. Both sexes utter loud, complex and highly varied songs, including rich, liquid warbling notes, bell-like “bong” sounds, chimes, cries, gurgles, whistles, coughs and wheezes. Also soft whisper-song, interspersed with normal song. Duets, in unison or alternating; song conveys individual, group and locality information, varies temporally and geographically. Some notes indistinguishable from those of *Anthornis melanura*. Alarm and distress calls vary, include petulant whine, high-pitched plaintive “ke-e-e-e”, loud piercing shriek, and scolds and guttural squawks. Male gives high-pitched call during pre-copulatory display. Mimics (often with embellishments) almost every bird species with which in contact. Loud whirring “whurrup” wing noise in flight appears to be produced by slots in wing formed by notch in primary P8 (larger in males than in females, lacking in juveniles and immatures); heard during aerial chases and displays. Clicks bill during chases and distraction displays.

Habitat. Mainly mixed, often dense podocarp–broadleaf, podocarp–broadleaf–beech or podocarp–beech forest, often with tall emergents and sometimes with dense understorey, in large tracts and in remnant patches. Also mixed beech forest, though only occasionally in forest dominated by single species of beech; tall kanuka (*Kunzea ericoides*) forest with dense secondary cover; and coastal shrubland and manuka (*Leptospermum scoparium*) scrub; sometimes in rainforest. Often in urban parks and gardens, especially in N of North I, and sometimes in orchards. Occasionally in regrowth forest, and in remnant patches of native vegetation; widely in non-native vegetation, including areas planted with such exotics as privet (*Ligustrum*), oaks (*Quercus*), willows (*Salix*) and eucalypts (*Eucalyptus*). Once in mangroves. On Pitt and Rangatira I (race *chathamensis*) in all habitat types except paddocks, including mixed broadleaf forest. Mostly at lower altitudes, but recorded to nearly 1500 m.

Food and Feeding. Mainly nectar or honeydew, also invertebrates (mainly insects) and fruit seasonally; occasionally seeds and pollen. On Tiritiri Matangi I, nectar major component throughout year, and proportion of arthropods highest summer–autumn and that of fruit highest during autumn; in spring and autumn males took more nectar and females more arthropods, although both foraged in same patches. Honeydew a major food source in most South I forests. On Rangatira I, nectar from New Zealand flax (*Phormium tenax*) was most important food for breeding birds. Forages mostly in canopy and subcanopy, less often in understorey, only occasionally on ground or aerially. Takes nectar by probing flowers, sometimes while hanging upside-down; perches above kowhai (*Sophora microphylla*) flowers and lifts each one by probing deep into it with bill; not seen to probe pendant flowers. Insects usually gleaned, or caught in aerial sallying. When foraging on honeydew, hops up tree trunks, often spiralling. Forages singly or in pairs, sometimes in small family groups; occasionally congregates at abundant sources of food, e.g. flocks of up to c. 200 individuals on Kapiti I. Defends feeding territories.

Breeding. Season spring–summer, onset of breeding likely influenced by flowering of nectar-producing plants, e.g. on Tiritiri Matangi I building coincided with start of nectar production by New Zealand flax and rewarewa (*Knightsia excelsa*); in North I eggs Oct to mid-Jan and nestlings Dec–Jan, with unspecified breeding and records of fledglings Aug–May, and in Kermadec Is eggs late Sept and nestlings Nov, with unspecified breeding or fledglings Sept–Nov; in Chatham Is eggs mid-Nov to early Dec, nestlings late Nov to late Dec and fledglings late Dec to late Jan; sometimes two broods in a season. Both sexes involved in nest-building, but most (sometimes all) work by female; nest a large, untidy shallow cup of twigs, leaves, plant stems, grass and rootlets, sometimes with moss or other soft material, lined with finer twigs, grass, roots, ferns, lichen, sometimes with feathers, external diameter 17.8–30 cm, depth 7.6–30 cm, internal diameter 6–11.4 cm, depth 5.1–7.6 cm; placed 1.5–24.4 m (nominate race) or 1.5–6 m (*chathamensis*) above ground, usually in sheltered site in fork in shrub,

atop sapling, in crotch of branch and main stem in small tree, or in fork near end of branch in canopy of larger tree. Clutch 2–4 eggs, rarely 5; incubation by female, from last egg, period 12–15 days; chicks brooded by female, both sexes feed nestlings but most work done by female, and she is occasionally fed at nest by male; nestling period varies greatly, 11–23 days (mean c. 14–15 days); fledglings fed by both sexes, sometimes by male alone if female lays second clutch, for several weeks, but usually independent 8–14 days after leaving nest. Success variable; for 41 family groups of race *chathamensis* mean minimum number of fledglings per group 2.25.

Movements. Apparently resident, but described also as partly migratory; movements possibly largely local. Seasonal changes at many sites, e.g. movement into some urban areas in winter, and dispersal from other sites during summer. In Chatham Is, most of those breeding Rangatira I winter on nearby Pitt I; often move between Rangatira and Pitt during spring before breeding, and males and non-breeders continue to do so through summer. Leaves Tiritiri Matangi I after breeding; some return briefly during winter whereas others do not, and many return to same home range in each breeding season. Local movements on some islands, e.g. gathers at flowering pohutukawa (*Metrosideros excelsa*) around coast of Little Barrier I during summer.

Status and Conservation. Not globally threatened. Widespread on North I, in N & W of South I and on Stewart I; more scattered elsewhere in New Zealand. Abundant in Kermadec Is (Raoul I). Fairly common in Chatham Is; adult population on Rangatira I in 1998–1999 estimated at 278 individuals. Nominative race recorded Auckland Is in 1972–1973, but not found on main island in Dec 1976; single immature seen Snares Is in 1961. Declined throughout New Zealand in 19th century, and numbers in Kermadecs fell soon after human settlement; formerly widespread on major islands of Chathams, but uncommon on main Chatham I and Pitt I by 1970s, and last seen on Chatham in mid-1990s. Declines probably result of clearing of lowland forest and, on Chatham I, clearance of coastal vegetation for agriculture, but possibly due also to persecution and hunting. Has adapted to foraging in exotic nectar-bearing plants. Introduced predators, e.g. stoats (*Mustela erminea*), cats, possibly rats (*Rattus*), can be a problem; several other introduced species, especially Common Myna (*Acridotheres tristis*), sometimes compete for food, displacing present species, and other possible competitors include Common Blackbird (*Turdus merula*), Common Starling (*Sturnus vulgaris*), Eastern Rosella (*Platycercus eximius*) and Common Chaffinch (*Fringilla coelebs*). Formerly hunted for food, and skins illegally exported for ornamentation. Often kept as pets by early settlers, and sometimes by Maori, and captives much prized for their mimicry; taken to Australia as cagebirds.

Genus *ANTHORNIS* G. R. Gray, 1840

8. New Zealand Bellbird

Anthornis melanura

French: Méléphage carillonneur **German:** Maori-Glockenhonigfresser **Spanish:** Mielero Maori
Other common names: The Bellbird, New Zealand Bell; Three Kings Bellbird (*obscura*); Chatham (Island) Bellbird (*melanocephala*)

Taxonomy. *Certhia melanura* Sparman, 1786, Promontorium Bonae Spei (= foothills Cape of Good Hope); error = Queen Charlotte Sound, New Zealand.

Distinctive Chatham Is race *melanocephala* (large, dark, yellow-eyed), sometimes treated as a separate species, is extinct. Nominative race exhibits slight clinal variation, becoming darker from N to S. Proposed races *dumerilii* (from Bay of Islands, on North I, in New Zealand) and *incoronata* (Auckland Is) considered inseparable from nominate. Three extant subspecies recognized.

Subspecies and Distribution.

A. m. melanura (Sparman, 1786) – New Zealand, including many offshore islands; Auckland Is.

A. m. obscura Falla, 1948 – Three Kings Is, NW of N North I (New Zealand).

A. m. oneho Bartle & Sagar, 1987 – Poor Knights Is, E of N North I.

Descriptive notes. 17–20 cm; male c. 31 g, female c. 24 g. Medium-sized honeyeater with rather long tail fairly narrow at base and flaring widely and deeply notched at tip. Male nominate race is olive-green above and below, slightly darker and with iridescent purple sheen on head and neck, black loreal area; upperpart black-brown with narrow iridescent blue-black edges, upperwing-coverts dark olive-green, remiges black with bluish sheen; pale yellow patch on anterior flanks, grey thighs, pale yellow to off-white vent and undertail-coverts; undertail dark brown; underwing brownish-grey with dark olive leading edge, pale yellow wash on

secondary coverts; iris red; bill black; legs blue-grey. Female is slightly smaller than male, dark olive-brown above and slightly paler below, with weak blue sheen on head and neck (strongest on forehead

On following pages: 9. Orange-cheeked Honeyeater (*Oreornis chrysogenys*); 10. Guadalcanal Honeyeater (*Guadalcanaria inexpectata*); 11. Lewin's Honeyeater (*Meliphaga lewinii*); 12. Yellow-spotted Honeyeater (*Meliphaga notata*); 13. Puff-backed Honeyeater (*Meliphaga aruensis*); 14. Hill-forest Honeyeater (*Meliphaga orientalis*); 15. Mimic Honeyeater (*Meliphaga analoga*); 16. Scrub Honeyeater (*Meliphaga albonotata*); 17. Tagula Honeyeater (*Meliphaga vicina*); 18. Graceful Honeyeater (*Meliphaga gracilis*); 19. Elegant Honeyeater (*Meliphaga cinereifrons*); 20. Spot-breasted Honeyeater (*Meliphaga mimikae*); 21. Forest Honeyeater (*Meliphaga montana*); 22. Yellow-gaped Honeyeater (*Meliphaga flavivictus*).

and crown), uppertail dark brown with olive edges (no iridescence), upperwing as male but all feathers browner and edges of remiges olive, lacking iridescence; thin white moustachial stripe; chin buffish, very pale yellow patch on fore flanks (less prominent than on male), pale olive to off-white vent and undertail-coverts; undertail brownish-grey, underwing much as male; bare parts as male. Juvenile male is duller and greyer than adult, dark grey above and grey below, with olive tinge on head, neck, breast and belly, black lores, short pale yellow moustachial stripe, off-white to pale grey-brown vent and undertail-coverts, no pale patch on flanks, uppertail black-brown with little or no iridescence, upperwing-coverts olive-brown, remiges with little or no iridescence, iris brown, gape yellowish for at least 14 days after fledging; juvenile female like juvenile male but slightly paler and greyer, with brown lores, and uppertail and upperwing as adult female. Race *oneho* is slightly larger than nominate, male has iridescence on head violet-blue, female head sheen greenish-blue; *obscura* is larger than nominate, also slightly darker and less yellow overall, male head sheen violet, female slightly paler underparts. VOICE. Notes simple, like sound of distant bell. Sings all year, less in winter. Song of male fuller and louder, distinguishable in field. Dawn song of 2–6 pure bell-like notes, occasionally interspersed with quieter notes, repeated monotonously for 10–40 minutes throughout day, more so at dawn. Full song includes bell-like notes as well as “chonk”, “clonk” and harsh “jarr” sounds, and quiet notes. Quiet song (whisper-song) audible only to 10 m, of quiet and mellow high-pitched notes, occasionally broadening to bell-like sound, interspersed with “tlank” or “kwak”. Female song of 7–15 fairly pure notes, preceded by tittering phrase. Birds may sing in perfect unison, and partners duet; both members of pair countering with neighbours. Appears to mimic *Prothemadera novaeseelandiae* to some extent. Alarm call of staccato notes or repeated scolding “tink-tink-tink” or chattering; other calls include continuous whistling, also squeaks, and plaintive cry. Loud wing noises in flight.

Habitat. Dense native forest with diverse and dense understorey of shrubs and young canopy trees. Mainly lowland mixed podocarp–hardwood forests, e.g. northern rata (*Metrosideros robusta*) forest, especially dense and diverse stands; often in coastal broadleaf forest, e.g. pohutukawa (*Metrosideros excelsa*) forest; also in mixed beech forests, including at high altitudes, e.g. low forests of bog pine (*Halocarpus bidwillii*), yellow-silver pine (*Lepidothamnus intermedius*) and mountain beech (*Nothofagus solandri*). Persists in small remnants of native forest. In South I, found mainly in coastal forest dominated by rimu (*Dacrydium cupressinum*), northern rata and kamahi (*Weinmannia racemosa*) with closed canopy, abundant epiphytes and dense shrub layer; least often in areas of regenerating forest. Also occupies subalpine shrub and scrub above tree-line; also flax (*Phormium*) and tall grass such as *Festuca arundinacea* near swamps. Common in some urban areas, including parks, gardens and golf courses, and in farmland and orchards. Sometimes in exotic plantations of *Eucalyptus*, *Acacia*, *Pinus* or *Salix*. From coast to at least 1220 m.

Food and Feeding. Mainly nectar, fruit, insects; also insect products, e.g. honeydew from kamahi and southern rata (*Metrosideros umbellata*). Nectar taken throughout year, forming high proportion of diet in spring–summer; insects also all year, forming high proportion in autumn–winter; fruit mainly summer–winter; honeydew in most months, but often only small proportion of diet, though a major food item in much of South I forests. Fruit usually eaten whole, though sometimes squashed to extract juice. Forages at all levels, from upper canopy to ground; among flowers and foliage, on twigs, bark of branches and trunks, in holes and fissures, and on ground. Foraged more on ground in introduced *Pinus* forest than in native forest. Nectar taken by probing flowers; often grasps stems with feet, and hangs while probing. Insects and honeydew usually gleaned from leaves or bark, but also probes crevices in bark, and gleans on ground; also picks insects from substrate by sally-striking and sally-hovering. Forages alone during breeding; at other times usually solitary and, although several may forage in one tree, each defends its own territory within tree. On Tiritiri Matangi I, access to food determined by social hierarchy, with males dominant over females. Often in mixed-species flocks, and often associates with *Prothemadera novaeseelandiae* and Stitchbirds (*Notiomystis cincta*); on Little Barrier I, females join mixed flocks of insectivores.

Breeding. Mainly Sept–Jan, but nestlings as late as early May and fledglings early Apr, sometimes two broods in season or may lay replacement clutch after failure; in Poor Knights Is (race *oneho*) breeds Sept–Dec (peak laying mid-Oct to mid-Nov), and in Three Kings Is (*obscura*) probably similar, with breeding finished by Dec. Female collects material and builds nest, an untidy outer cup of twigs, leaves, rootlets, grass and moss, inner cup of finer grass, moss and tree-fern scales, lining of feathers or moss, diameter c. 15 cm, placed on or close to ground or to 16 m above it (on Poor Knights Is 21–4% of nests on ground), well concealed and sheltered among foliage of tree or dense shrub or creepers, occasionally in crevice in rock, or against trunk or in hole or notch in trunk. Clutch usually 3 eggs, sometimes 4, rarely 5 (mean in Poor Knights Is 2.87, on Tiritiri 3.6); incubation from completion of clutch, by female, fed on nest by male, period 13–15.5 days; chicks brooded by female, fed by both sexes about equally for first 12 days, much more by female thereafter, nestling period c. 14–19 days; fledglings fed by both sexes, for at least 7 days and up to several weeks (e.g. still fed occasionally after 16–17 days), but begin to forage for themselves 3 days after leaving nest. Nests possibly parasitized by Long-tailed Koel (*Eudynamis taitensis*).

Movements. Resident in most of range. Some apparent movements in North I and South I, with seasonal occurrence or increase in lowlands, coast and urban areas in winter; e.g. Buller Valley (South I) may be wintering site for birds from higher altitudes in Ohikanui Valley. Some changes in numbers may be result of juvenile dispersal (e.g. in Dunedin). Claimed that males more mobile than females, but in Poor Knights Is males defend territories all year and females non-territorial after breeding; both sexes move locally to utilize food or water sources. Occasionally visits offshore islands, and scattered records in N North I possibly vagrants.

Status and Conservation. Not globally threatened. Locally common. Widespread New Zealand, including many offshore islands, e.g. Hen and Chickens, Little Barrier and Tiritiri Matangi, and (off Stewart I) Ruapeke, Muttonbird, Codfish, Solander and Little Solander; generally absent from far N (Northland, Auckland and N Waikato regions) despite presence on nearby offshore islands, and in South I largely absent W of Inland Kaikoura Range, lowlands of Canterbury and C Otago. Widespread Auckland Is. Reported Snares I in 1888, but no records since. Formerly occurred throughout Chatham Is, but last recorded in 1906, on Little Mangere I; extinction possibly result of clearing and degradation of forests. Densities on islands can be high, e.g. 16 birds/ha on Three Kings Is and c. 71 birds/ha on Poor Knights Is; 7.41 birds/ha on Cuvier I, with estimated total population c. 600 individuals. Declined rapidly in N North I and on several nearby large islands after c. 1860, and probably locally extinct by 1866, with some declines elsewhere in North I; in South I, declined in Canterbury in late 19th century but began to recover after 1910. Declines possibly due to disease or spread of rats (*Rattus*). Main ongoing threats are logging of native forest and clearance of remnant native vegetation on farms; also degradation of native forests by common brush-tailed possums (*Trichosurus vulpecula*), which destroy emergent rata trees. Several unsuccessful attempts to reintroduce this meliphagid in parts of former range: 22 birds captured Tiritiri Matangi I and Cuvier I and released E Whangaparaoa Peninsula in 1983, and species still present in 1995; failed releases on Waiheke I, near Auckland, in 1988–1991. Recently reintroduced around Wellington city, although appears also to have re-established populations independently, following effective control of possums and rats. Formerly hunted by Maori.

Genus *OREORNIS* van Oort, 1910

9. Orange-cheeked Honeyeater

Oreornis chrysogenys

French: Méléphage des Maoke

Spanish: Mielero Carinaranja

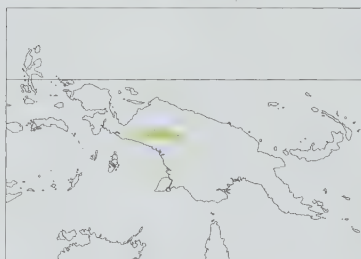

German: Goldwangen-Honigfresser

Other common names: Small Mountain Honeyeater

Taxonomy. *Oreornis chrysogenys* van Oort, 1910, Oranje Mountains (4150 m), New Guinea.

Sometimes placed in genus *Lichenostomus* or *Meliphaga*. Monotypic.

Distribution. Upper slopes of Snow Mts and Oranje Mts (including Mt Carstensz and Mt Wilhelmia), in W New Guinea.

Descriptive notes. 24–26 cm; one male 77 g, one female 62 g. Has head and neck dark olive to olive-grey with dark brown to blackish mottling on top, black fore supercilium and lores enclosing small patch of silvery grey in front of eye, short narrow black streak behind eye, conspicuous golden-yellow to orange-yellow cheek patch extending from beneath eye to rear ear-coverts, finely edged below by diffuse blackish malar area and fine blackish line beneath and behind rear of patch (partly divided by notch of black extending down from eyestripe); silvery grey chin washed olive; upperparts dark olive to olive-grey, paler and greyer on rump and paler olive on uppertail-coverts, diffuse dusky mottling on mantle and back; greater upperwing-coverts dusky, dark yellow-olive outer edges and tips of outer coverts, remiges blackish-brown with conspicuous yellow-olive outer edges (forming largely olive lower wing, contrastingly paler than upperparts); uppertail brownish-olive with dark olive centre, yellow-olive outer edges of rectrices; underbody greyish-olive, paler than upperparts, grading to pale olive-grey on flanks, belly and vent, faintly mottled or streaked slightly darker on throat, breast and fore flanks; undertail-coverts buff with olive wash, thighs yellowish-olive, undertail olive-grey; underwing pale buff, chestnut-orange patch at angle of wing and dark trailing edge and tip; iris red-brown to dark brown or grey-brown; bill black, fine and indistinct yellow gape-line; legs yellow. Sexes alike in plumage, male larger than female. Juvenile undescribed. VOICE. Calls include single bubbling note that rises in pitch, and wheezy downslurred “nnyau”.

Habitat. Subalpine forest and shrubland bordering alpine grassland, and commonly in ecotone between these, also patches of these habitats within grassland. In Mt Carstensz Range, one seen on ground in wet swamp-meadow dominated by tussock grasses and sedge at edge of subalpine forest of *Dacrycarpus compactus*, *Rapanea* and other low moss-covered trees. Recorded at 3225–4000 m, mainly above 3250 m; occasionally as low as 2450 m.

Food and Feeding. Takes fruit, arthropods (insects), and seeds of sedges. Often forages in low shrubland or thickets away from closed forest, and on ground in wet tussock grassland–sedgeland.

Breeding. Poorly known. Male in breeding condition and nest with egg in Aug. Single nest found, a basin-like cup, loosely made outer layer mainly of coarse moss and lichens, firm inner layer mainly of grass stems and some fern stems, thick lining of scales and plant down from fronds of tree-ferns and a few feathers, external diameter 20 cm, depth 11 cm, internal diameter 9.5 cm, depth 5 cm, supported on bases of several fronds of tree-fern 1.5 m above ground in scattered clump in alpine grassland (c. 150 m from forest); contained 1 egg (not certainly known to be complete clutch). No other information.

Movements. Probably sedentary.

Status and Conservation. Not globally threatened. Restricted-range species: present in Central Papuan Mountains EBA. Very poorly known, and no estimates of global population. Described as fairly common at high altitudes.

Bibliography. Beehler *et al.* (1986), Coates (1990), Coates & Peckover (2001), Eastwood (1996a), Rand (1942b), Ripley (1964), Schodde *et al.* (1975), Schönwetter & Meise (1981), Temple (1969).

Genus *GUADALCANARIA* E. J. O. Hartert, 1929

10. Guadalcanal Honeyeater

Guadalcanaria inexpectata

French: Méléphage de Guadalcanal

Spanish: Mielero de Guadalcanal

German: Guadalcanalhonigfresser

Taxonomy. *Guadalcanaria inexpectata* E. J. O. Hartert, 1929, Guadalcanal, Solomon Islands.

Relationships uncertain. Has in the past been placed variously in *Meliphaga* and in *Lichenostomus*, and may belong within *Meliphaga*; sometimes considered close to *Glycifolia*. Retained in present monotypic genus pending resolution of relationships. Monotypic.

Distribution. Guadalcanal, in SE Solomon Is.

Descriptive notes. 18–20 cm; male 41.5–48.5 g, female 37.5–44.5 g. Plumage is slate-grey above, tinged brown on rump and uppertail-coverts, with dark grey lores, silvery grey ear-coverts, conspicuous bright yellow plumes extending from rear malar area and broadening at side of throat; tail brownish-grey with broad yellowish-olive feather edges; upperwing slate-grey, prominent broad yellowish-olive outer edges and tips of remiges and coverts (folded wing largely yellowish-olive);

chin and throat off-white, merging to pale grey on breast, prominent dark grey streaking on lower throat and breast; rest of underbody grey, brownish tinge on vent and undertail-coverts, faint diffuse streaking or mottling; underwing-coverts brownish-grey, diffusely barred darker; iris light to dark brown, sometimes reddish-brown; bill black; legs bluish-grey. Sexes alike in plumage, male noticeably larger and with broader rectrices than female. Juvenile is similar to adult, but throat-tufts paler yellow, streaking below less distinct, iris dark grey-brown, legs tinged brown. VOICE. Usually quiet. Call a loud musical “per-twee per-twee”; once heard to utter single croaky but sonorous “techook” in flight.

Habitat. Montane forest, particularly high moss forest; 950–1565 m, mainly above 1450 m.

Food and Feeding. Diet includes small to medium-sized soft-bodied insects (maximum size noted 17 mm); almost certainly takes nectar, as seen to feed at flowers of trees and epiphytes. Singles and pairs forage unobtrusively in canopy; agile, and can be conspicuous, but usually wary and retiring.

Breeding. No information.

Movements. No information; probably sedentary.

Status and Conservation. Not globally threatened. Restricted-range species: present in Solomon Group EBA. Moderately common to common; fairly common at 1450–1565 m in mountains S of Betilonga. **Bibliography.** Cain & Galbraith (1956), Doughty *et al.* (1999), Dutton (2007a), Galbraith & Galbraith (1962), Gibbs (1996b), Hartert (1929), Mayr (1932, 1945b), Mayr & Diamond (2001), Stattersfield *et al.* (1998).

Genus *MELIPHAGA* Lewin, 1808

11. Lewin’s Honeyeater

Meliphaga lewinii

French: Méléphage de Lewin **German:** Goldohr-Honigfresser **Spanish:** Mielero de Lewin
Other common names: (Greater) Yellow-eared Honeyeater, Lewin’s Meliphaga

Taxonomy. *Ptilotis lewinii* Swainson, 1837, region of Port Jackson, New South Wales, Australia. Molecular evidence suggests that genus consists of two clades; present species forms a group with *M. notata* and *M. aruensis*. Proposed race *nea* (from Dandenong, in Victoria) synonymized with nominate. Three subspecies recognized.

Subspecies and Distribution.

M. l. amphochlora Schodde, 1989 – McIlwraith Range (E Cape York Peninsula), with outliers on summits S to Cooktown, in NE Queensland.

M. l. mab (Mathews, 1912) – coastal NE Queensland from Cooktown S to Dawson–Mackenzie Basin, extending inland to summits of Great Divide.

M. l. lewinii (Swainson, 1837) – coastal E & SE Australia, from Dawson–MacKenzie Basin (Dawes Range) S to Victoria (W Gippsland and Dandenong Ranges), extending inland to summits of Great Divide, with apparently isolated population farther W in North West Slopes and Plains Region of New South Wales.

Descriptive notes. 19–21.5 cm; male 27.5–49.5 g and female 27.3–41.5 g (nominate), male 28–39 g and female 29.6–36.5 g (*mab*), male 31.5 g and female 29 g (*amphochlora*). Nominat race is dark olive above, becoming dark grey on forehead, and with diffuse blackish loreal stripe, prominent yellow crescent-shaped spot on rear ear-coverts (shape varies with posture), short off-white or pale yellow gape-flange (usually paler and duller than ear-spot) joining short yellow rictal streak to form prominent narrow gape-stripe extending back to level with rear of eye; grey anterior ear-coverts continue in diffuse line through malar area (below

gape-stripe), merging into greyish-olive on chin and throat; remiges and edges of tail yellowish-olive, brighter than upperparts; underbody slightly paler than upperparts, olive-grey, with narrow dusky streaking and faint yellowish mottling, strongest on belly; undertail olive-grey, underwing brownish-grey; iris blue-grey to darker grey-brown; bill black; legs pinkish-brown, merging to dark grey on front of tarsus and top of toes. Sexes alike in plumage, male larger than female. Juvenile is very like adult, but browner above, especially forehead, plain dull yellow-olive below (without streaked and mottled appearance of adult), undertail-coverts uniformly straw-yellow, iris dark brown, bill of newly fledged bird has diffuse pale tip. Race *mab* is slightly smaller and slightly paler above than nominate, with more distinct yellow wash on belly; *amphochlora* also is slightly smaller, upperparts and underparts slightly paler, with distinct pale yellowish-olive tone. VOICE. Calls throughout day. Most common call a highly distinctive rapid rattle of staccato notes, duration e.g. 2–30 seconds or longer (typically 2–5 seconds) and e.g. c. 11 notes per second, calling can last for up to 5 minutes (once c. 10 minutes), given in variety of circumstances, including possibly in alarm or as contact. Also repeated loud harsh scolding “schwep” or loud emphatic and somewhat rasping “week” in alarm; occasionally “toc” or “chot”, repeated rather slowly and monotonously at regular intervals (c. 2–2.5 notes per second), usually for several minutes, sometimes longer.

Habitat. Mainly rainforests and wet sclerophyll forests, also dense vegetation at edge of rainforest and in secondary growth. Common also in other vegetation, including tall open sclerophyll forests or woodlands with sparse, patchy or dense and continuous understorey. Often in modified habitats, such as parks and gardens in urban and semi-urban areas, especially if with remnant native vegetation. Occasionally in heathland, mangrove fringes, thickets of paperbarks (*Melaleuca*) and plantations of hoop pine (*Araucaria cunninghamii*) with *Lantana* thickets; visits orchards, particularly in autumn and winter. From coast (where generally common) to 1000 m; mainly above c. 600 m in wet tropics of NE Queensland, though small numbers move to lower altitudes in winter.

Food and Feeding. Mainly fruits, of wide variety of plants, and nectar; also insects, some spiders (Araneae) and molluscs. Forages at all levels, occasionally on ground. Searches among foliage and flowers, less often on bark and trunks. Fruit taken from trees or from ground, or sometimes snatched

in flight from tree, then carried in bill to be eaten at perch. Large soft fruits, particularly figs (*Ficus*), pecked and pierced and small pieces eaten; small fruits swallowed whole, or crushed in bill and all or part swallowed. Nectar obtained by probing flowers. Insects mainly gleaned from foliage, under loose bark and on trunks of trees, obtained also by sally-striking in air. On New England Tableland (NE New South Wales), foraging rates on both nectar and arthropods varied with availability of nectar, lowest on days when nectar availability high. Often utilizes feeding stations in gardens. Usually singly, less often in twos (probably pairs) or in small groups of 6–12 individuals. Sometimes with other birds in fruiting trees, and with other meliphagid species in flowering plants; can feed in same tree without interspecific aggression, but also defends feeding or breeding territories or both, and can be very aggressive to conspecifics and others.

Breeding. In NE of range recorded Jul–Mar, with estimated start of laying Aug–Mar, and in S (SE Queensland S to Victoria) eggs Sept–early Feb, mostly Nov–Jan; possibly double-brooded. Both sexes collect material, nest a large deep cup made of strips of bark, leaves, vine tendrils, grass and epiphytic moss, sometimes scraps of paper, plant and artificial materials, bound with spider web, usually lined with plant down and seeds, external diameter 8.9–11.4 cm, depth 6.4–7.6 cm, internal diameter 5.7–7.6 cm, depth 3.8–5.1 cm; placed 0.2–2.5 m above ground (mean of 57 nests 3.3 m), usually suspended from thin horizontal fork (attached by sides or rim to 2–3 branches or leaves), often among dense foliage in tree or tall shrub, or among vines, rarely beneath house, and often near water (may be linked with denser riparian vegetation, rather than with water itself). Clutch usually 2 eggs, once 4 (mean 2.15); up to four replacements in a season if clutch lost; no information on role of sexes in incubation, period 14–15 days; chicks fed usually by both adults, nesting period at one nest c. 15 days; fledglings fed usually by both parents for at least 1 week and up to 22 days or more after leaving nest. Nests parasitized by Fan-tailed Cuckoo (*Cacomantis flabelliformis*) and Pallid Cuckoo (*Cuculus pallidus*). From 45 eggs (22 clutches), 0.55 fledged young per nest.

Movements. Resident, with some local movements. In NE Queensland, small numbers descend to lower altitudes in winter. Local movements or fluctuations in numbers at some sites, mainly in autumn–winter, e.g. at Wollomombi (NE New South Wales) moves into eucalypt woodland from adjacent gorge in autumn and winter; in Sydney, where generally resident in wetter vegetation, sometimes moves into nearby habitats, including drier forests and woodlands and gardens, in autumn–winter. At some sites recorded only sporadically.

Status and Conservation. Not globally threatened. Uncommon to locally common. Recorded densities of 0.05–0.2 birds/ha. Race *amphochlora* has apparently small population estimated at fewer than 5000 breeding birds (but estimate of low reliability), confined to single location. Seems to have adapted well to widespread habitat clearance by incorporating exotic fruits into diet, and by occupying dense remnant or regrowth vegetation along watercourses; near Sydney, more abundant in plantations 8–12 years old and with about ten retained habitat trees per hectare than in similar plantations with no retained trees or in forest formerly selectively logged; able to live in small rainforest remnants (2.5 ha or smaller). Sometimes considered a pest in cultivated crops of soft fruits; large numbers can gather when fruit ripe, and cause much damage.

12. Yellow-spotted Honeyeater

Meliphaga notata

French: Méléphage marqué **German:** Torreshonigfresser **Spanish:** Mielero Marcado
Other common names: Lesser Lewin/Little Lewin Honeyeater, Yellow-spotted Meliphaga

Taxonomy. *Ptilotis notata* Gould, 1867, Cape York, north Queensland, Australia.

Molecular evidence suggests that genus consists of two clades; present species forms a group with *M. lewinii* and *M. aruensis*. Races intergrade in narrow zone from Cooktown S to about Ayton. Two subspecies recognized.

Subspecies and Distribution.

M. n. notata (Gould, 1867) – islands of C & S Torres Strait; N Queensland S to Archer–Mitchell rivers and Princess Charlotte Bay, with outliers S to around Cooktown–Ayton area.

M. n. mixta (Mathews, 1912) – coastal NE Queensland from Cooktown S to Paluma Range, Townsville and Cape Cleveland, inland to Atherton Tableland; isolated population at Mt Elliot and records farther S (at Haughton R).

Descriptive notes. 16.5–20 cm; male 23.3–33.5 g and female 20.5–26.5 g (nominate), male 23–32.3 g and female 21–30 g (*mixta*). Nominat race has head and neck olive (forehead sometimes faintly darker than crown), grading to paler greyish-olive on chin and throat, with diffusely darker lores, prominent yellow spot on rear ear-coverts (rounded to diamond-shaped, but never crescentic), yellow gape-flange (usually slightly brighter than ear-spot) meeting short pale yellow rictal streak to form prominent gape-stripe; upperparts dark olive, remiges and edges of tail slightly brighter yellow-olive; olive-grey below (slightly paler than upperparts), faint and diffuse

darker streaking and faint yellowish mottling on underbody, diffuse straw-yellow patch on belly; undertail olive-grey, underwing pale grey; iris dark brown; bill black; legs dark grey, pink-brown or yellow-brown at rear tarsus, soles yellow-brown. Sexes alike in plumage, male larger than female. Juvenile apparently undescribed. Race *mixta* is very similar to nominate, but wing shorter, head, neck and most of upperparts slightly darker olive (olive of remiges contrasts less with upperparts), chin and throat duller, breast and belly darker with less distinct yellow mottling, smaller yellow suffusion on belly. VOICE. Most common call loud, petulant, high-pitched, staccato and descending, syllables slow and deliberate, earlier notes with somewhat disyllabic quality, “plisk plisk plisk twik twik...” or “ee-yeu, ee-yeu, ee-yeu, ear ear ear...”; usually 3–10 notes per call, often starting slowly and accelerating slightly. Other calls include monotonous repetition of “plick” 6–12 times at c. 2 notes per second, occasionally preceded by soft chattering “tritch tritch”; harsh scolding rasp or sharp “queak-queak-queak...” in alarm; series of loud ascending notes; repeated clear piercing whistle. Once heard to repeat “tok” slowly and monotonously at regular intervals for more than 15 minutes.

Habitat. Mainly lowland tropical rainforest, including monsoon forest and vine thickets at some sites. Also mangrove forests and woodlands, mixed woodlands and semi-deciduous dune-woodland; open eucalypt (*Eucalyptus*) forests and woodlands adjacent to rainforest, and riverine eucalypt forest with depauperate rainforest understorey; swamp-woodland of *Melaleuca*, *Eucalyptus* and *Banksia*; *Lantana* thickets, especially bordering wetlands or at edges of rainforest. On islands in Torres Strait sometimes in dense dry littoral scrub dominated by casuarina. Often in urban parks and gardens, and in orchards. Occasionally extends into semi-arid areas along rivers. Mainly lowlands and foothills below 600 m, less often in ranges and on tablelands above 600 m.

Food and Feeding. Nectar, fruit and insects. Usually forages in mid-canopy or in shrub layer, at 3–12 m. Searches at flowers and fruits of trees, vines and shrubs, and in foliage; sometimes enters sheds to feed on stored bananas. Probes flowers for nectar; gleans insects from foliage or fruits, sally-hovers to take items from foliage, and sallies for aerial prey. Usually singly, in twos (probably pairs) and occasionally in small parties. Active, aggressive and confiding.

Breeding. Season Aug–Apr. Nest a deep cup, usually of strips of bark and plant fibre and moss, sometimes covered with lichens or large pieces of *Melaleuca* bark, lined with plant down, external diameter 8.9–10.2 cm, depth 4.4–7.6 cm, internal diameter 6.4–7.6 cm, depth 3.8–5.1 cm, suspended from fork in branch 1.5–1.8 m (once 45 cm) above ground and usually well concealed among dense foliage of tree or shrub, often near water. Clutch usually 2 eggs, sometimes 3 (mean 2.04); incubation period c. 15 days, once 14 days; chicks fed by both parents, nestling period at one nest 14–15 days.

Movements. Apparently resident, with some local movements; occasionally visits top of Paluma Range, where usually at lower altitudes.

Status and Conservation. Not globally threatened. Restricted-range species: present in Cape York EBA and in Queensland Wet Tropics EBA. No estimates of abundance; seems to be fairly common. Reported sighting at Wau, in SE New Guinea, considered dubious.

13. Puff-backed Honeyeater

Meliphaga aruensis

French: Méléphage bouffant **German:** Aruhonigfresser **Spanish:** Mielero de las Aru
Other common names: Large-tufted Honeyeater, Puff-backed/Large-tufted Meliphaga

Taxonomy. *Ptilotis aruensis* Sharpe, 1884, Aru Islands.

Molecular evidence suggests genus consists of two clades; present species forms group with *M. lewinii* and *M. notata*. Population in SE New Guinea genetically distinct, and may constitute a separate species; taxon as yet undescribed. Detailed analysis of geographical variation currently in progress, to determine affinities, status and distribution of component forms; E limits of nominate race and W limits of SE form not currently known. Two subspecies currently recognized.

Subspecies and Distribution.

M. a. sharpei (Rothschild & E. J. O. Hartert, 1903) – West Papuan Is (Waigeo, Batanta, Misool), NW & N mainland New Guinea E, including Yapen I and nearby Keboi I (in Geelvink Bay), to at least Kumusi R, and D'Entrecasteaux Archipelago (including Goodenough I and Fergusson I) and Trobriand Is (including Kiriwani).

M. a. aruensis (Sharpe, 1884) – Aru Is, and SW & S New Guinea (E to about Karema and Hall Sound). Also (unnamed form, possibly a separate species) SE New Guinea, in S watershed and lowlands from about Karema and Hall Sound E to Milne Bay.

Descriptive notes. 16.5–18.5 cm; two males 27 g and 29 g and three females 23–27 g (nominate), male 22–30.5 g and female 21–31 g (*sharpei*). Large, rather thickest honeyeater with dense tuft of stiff feathers on rump. Nominative race dark olive-brown to greyish-olive above, crown deeper olive than upperparts, blackish subterminal zone on rump feathers (can appear as indistinct dusky blotching in field); blackish-olive lores, feathers around eye and diffuse streak behind eye, large lemon-yellowish ear-patch (mostly yellow ear-coverts); rich yellow or orange-yellow gape-line merging with distinct pale yellow

rietal streak, which often extends to meet pale ear-patch; upperwing-coverts and alula dark brown with olive fringes, remiges dark brown with yellow-olive outer edges and pale yellowish inner edges; tail feathers dark brown with olive outer edges; mostly grey below, pale olive-yellow tinge on chin to breast, merging into paler grey with yellowish wash on lower belly, and often with brown wash across upper breast; underwing-coverts buff-yellow; iris brown to dark brown or grey-brown; bill greyish-black to black; legs grey or brownish-grey. Sexes alike in plumage, male on average slightly larger than female. Juvenile undescribed. Race *sharpei* has much more elongated ear-patch and tends to be brighter greenish-olive above than nominate, some variation, birds from Batanta darker greyish-olive above than those from mainland, birds from Trans-Fly region have ear-patch more rounded than nominate and not connecting with rictal streak. Voice. Song a rapid low, rising and decelerating trill lasting up to 2 seconds, repeated several times, resembling call of Yellow-billed Kingfisher (*Syma torotoro*); also piping series of short, liquid, upslurred notes, “lip, lip-ki-ki-ki-ki...” (given also by congeners in New Guinea); other calls include short “chup” or “chap”, and low whistled note like call of Spot-winged Monarch (*Monarcha guttula*).

Habitat. Variety of forest habitats, including primary rainforest and low plains forest, also disturbed habitats such as forest edge, secondary forest and tall or old growth; possibly also gardens. Mainly lowlands and foothills, from sea-level to c. 1250 m, locally to 1400 m (e.g. Epe Valley); specimen record at 1580 m in Wahgi Valley, on Batanta, recorded to 450 m.

Food and Feeding. Diet includes fruit, seeds (probably ingested with fruit), and arthropods (mainly insects); probably also nectar, and known to visit inflorescences of *Poikilospermum* and *Syzgium*. Mainly in understorey, lower middle storey and subspaces of forest. Forages mainly by gleaning. Typically shy, and usually singly or in twos (probably pairs); occasionally associated with mixed-species flocks. Once caught together with both *M. gracilis* and *M. analoga* in same mist-net in Varirata National Park.

Breeding. Recorded in most months: eggs mid-Aug and Oct and nestlings mid-Oct, nests or breeding females late Jul and Aug, Oct–Jan, Mar–Apr (egg ready to be laid) and May. Nest a neat cup made of dead leaves (including bamboo), grass and grass-like stems, and fine plant fibres or flakes

of bark, woven with spider web and plant fibres, thickly lined with fine grass-like stems, fibres or rootlets, sometimes untidily covered on outside with dead leaves, one had external diameter 8 cm, depth 8 cm, internal diameter 4.5 cm, depth 4 cm; suspended by rim or edges 0.3–1.2 m above ground in horizontal fork or branches of shrub or sapling. Clutch 1–2 eggs; incubation by female only, young fed by both sexes; no information on duration of incubation and nestling periods.

Movements. Probably largely sedentary, with some local movements.

Status and Conservation. Not globally threatened. No estimates of total population; generally fairly common to common; uncommon at Crater Mt. Retiring and difficult to observe.

Bailey (1992), Beehler (1978a), Beehler, Pratt & Zimmerman (1986), Beehler, Sengo *et al.* (1995), Bell (1970c, 1970d, 1982a, 1982d, 1984b), Bowman *et al.* (1990), Brown & Hopkins (1996), Christidis & Schodde (1993), Coates (1990), Coates & Peckover (2001), Diamond (1972a), Finch (1980b, 1983), Fletcher (2000b), Gilliard & LeCroy (1967a, 1968), Greenway (1966), Gregory (1995b), Gregory *et al.* (1996), Gyldenstolpe (1955b), Hartert (1930), Hicks (1992), Hicks & Burrows (1992), Hoogerwerf (1971), Isles & Menkhurst (1976), LeCroy & Peckover (2000), Mack & Alonso (2000), Mack & Wright (1996), Mayr & Rand (1937), Norman *et al.* (2007), Ogilvie-Grant (1915), Palliser (1989), Pearson, D.L. (1975), Rand (1936a, 1942a, 1942b), Rand & Gilliard (1967), Richards & Suryadi (2002), Ripley (1964), Rothschild *et al.* (1932b), Rowland (1995), Schönwetter & Meise (1981), Wahlberg (1988).

14. Hill-forest Honeyeater

Meliphaga orientalis

French: Méléphage montagnard **German:** Schlankschnabel-Honigfresser **Spanish:** Mielero Montesino

Other common names: Mountain Honeyeater, Mountain Yellow-eared/Small Spotted Honeyeater, Hill-forest/Mountain (Yellow-eared) Meliphaga, Lesser/Small Spot-breasted Honeyeater/Meliphaga

Taxonomy. *Ptilotis flavirictus orientalis* A. B. Meyer, 1894, south-east New Guinea.

On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. analoga*, *M. albonotata*, *M. vicina*, *M. gracilis*, *M. cinereifrons*, *M. mimikae*, *M. montana*, *M. flavirictus*, *M. albilineata*, *M. fordiana* and *M. reticulata*. Race *citreola* originally considered an altitudinal variant of *M. analoga*. Racial identity of populations of Fakfak Mts, Kumawa Mts, Wandammen Mts and Foja Mts not certain; possibly all belong in *facialis*, or Foja birds possibly in *citreola*, or some or all may represent undescribed races. Also, birds of this species recorded in Adelbert Mts of uncertain racial identity, tentatively included in *becki*. Four subspecies currently recognized.

Subspecies and Distribution.

M. o. facialis Rand, 1936 – mountains of Waigeo (West Papuan Is), and of Vogelkop, Fakfak, Kumawa and Wandammen Mts and Central Range of New Guinea (from Weyland Mts and S slopes of Snow Mts) E to Okapa region of Eastern Highlands.

M. o. citreola Rand, 1941 – N slopes of Snow Mts and C North Coastal Range (Bewani Mts, Torricelli Mts and Prince Alexander Mts).

M. o. becki Rand, 1936 – Adelbert Mts and mountains from Huon Peninsula S to Wau region, in NE New Guinea.

M. o. orientalis (A. B. Meyer, 1894) – mountains of SE New Guinea E from Mambere R and, in S, from at least Angabunga R and including Aseki area (Morobe Province).

Descriptive notes. 14–16 cm; 16–20 g, male average 18.6 g and female average 17.6 g (*facialis*), male 17.5–20 g and female 14.8–20 g (*citreola*). Nominative race is dark greyish-olive above, forehead darker olive, dusky blackish-olive lores continued as dusky stripe behind eye, yellow lower ear-coverts forming small rounded patch, and orange-yellow gape merging with narrow and indistinct pale yellow rictal streak (not meeting pale ear-patch); upperwing-coverts and alula dark brown with yellowish-olive outer edges or fringes; remiges dark brown with yellowish-olive outer edges and pale-yellowish or buff-yellow inner edges; tail feathers dark

brown with yellowish-olive outer edges; greyish-olive below, diffuse pale yellow streaking on belly and lower breast, faint dusky mottling on breast and belly; underwing-coverts olive-yellow or buff-yellow; iris brown to grey; bill black; legs leaden or pale bluish. Differs from *M. mimikae* in smaller size, shorter and more slender bill, smaller ear-patch, narrower rictal streak, richer olive (less brown) upperparts, less uniform underparts (with faint dusky mottling). Sexes alike, male averages larger. Juvenile undescribed. Race *facialis* has less dusky lores and postocular area than nominate, less distinct mottling below; *becki* greener above than nominate, with more olive lores and postocular area, less distinct yellow streaking on belly, less distinct dusky mottling on underparts, and yellowish-white (less buff) underwing-coverts; *citreola* lacks obvious dusky mottling below, has stronger yellow wash on upperparts, underparts and underwing-coverts. Voice. Call notes include bright monosyllabic staccato “tup” or “tuck”, probably same as call described as nasal “chup” (more musical than corresponding call of *M. analoga*); short upwardly inflected disyllabic or upslurred note and similar but thinner and downward-inflected disyllabic call (both with more snapped quality than similar calls of *M. analoga*); and repeated querulous piping note. Call described as cheerful “cheeyur” or “weet” or “weeyurt” may or may not refer to one of preceding calls. All calls much quieter than in *M. analoga*.

Habitat. Primary forest (including *Castanopsis* oak forest), forest edge, tall secondary growth, sometimes gardens; mainly in forest interior, rarely in disturbed habitats. Mostly lower and middle mountains, from 550 m to c. 2100 m, and only member of genus common (or present) above 1400 m. Recorded at 1000–1350 m in Foja Mts, 1000–1400 m in Wandammen Mts, 900–1200 m or above in Fakfak Mts, and 800–1450 m in Kumawa Mts; in Eastern Highlands 1110–1890 m, with maximum abundance at 1350–1700 m, and altitudinal range generally above that of congeners; seen at 1000 m in Adelbert Mts (Ilebaguma and Kowat). In lower parts of range co-exists with *M. aruensis*, *M. analoga*, *M. mimikae*, *M. flavirictus* and either *M. albonotata* or *M. montana*.

Food and Feeding. Diet nectar, arthropods (mainly insects), sometimes fruit. Known to feed at inflorescences of *Schefflera* (Araliaceae). Typically forages in outer foliage of canopy; less often in lower storeys, but appears to use these more at forest edges. Active, agile. Usually singly, less often in twos (probably pairs); often feeds with other honeyeaters, at lower altitudes especially with congeners.

Breeding. One nest described, at Crater Mt in mid-May; tightly made, slightly oval cup of plant fibre, twigs and vines, covered externally with live moss and dead bamboo leaves, lined thickly with fluffy plant down, external diameter 7.5 cm, depth 7.5 cm, internal diameter 5.5 × 4.5 cm, depth 4.5 cm; contained 2 eggs, both of which hatched by 13th May, but nest empty on 19th. No other information.

Movements. Resident at Crater Mt and probably at Moroka; probably resident, with some local movements, throughout range.

Status and Conservation. Not globally threatened. Generally common at middle altitudes. No estimates of total population.

Bibliography. Beehler (1978a), Beehler *et al.* (1986), Bell (1984b), Christidis & Schodde (1993), Coates (1990), Coates & Peckover (2001), Diamond (1969, 1972a, 1985), Eastwood (1996a), Finch (1983), Gregory (1995b), Mack (1994), Mack & Alonso (2000), Mack & Wright (1996), Mackay (1991), Mayr & Rand (1937), Murray (1988b), Norman *et al.* (2007), Ogilvie-Grant (1915), Pratt (1982), Rand (1936a, 1941, 1942a, 1942b), Rand & Gilliard (1967), Schönwetter & Meise (1981), Tolhurst (1991).

15. Mimic Honeyeater

Meliphaga analoga

French: Méliphage sosie **German:** Papuahonigfresser **Spanish:** Mielero Imitador
Other common names: Mimic/Yellow-spotted Meliphaga, Mimetic/Allied/Yellow-spotted(!) Honeyeater

Taxonomy. *Ptilotis analoga* Reichenbach, 1852, “Oceanien”; error = Triton Bay, south-east New Guinea. On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. orientalis*, *M. albonotata*, *M. vicina*, *M. gracilis*, *M. cinereifrons*, *M. mimikae*, *M. montana*, *M. flavirictus*, *M. albilineata*, *M. fordiana* and *M. reticulata*. Name *stevensi* (from N watershed of SE New Guinea) has been used for a race variously of present species or of *M. cinereifrons*, and it is not certain at present to which (if either) the type specimen applies; recent genetically based investigations indicate that specimens attributed to *stevensi* include cryptic variants of both species; further study currently in progress. Populations in Baiyer Valley (E New Guinea) probably constitute an as yet unnamed race. Race *citireola* of *M. orientalis* originally treated as an altitudinal variant of present species. Birds from N lowlands (Wewak E to Huon Gulf) described as race *connectens* (from Madang, in Astrolabe Bay) appear indistinguishable from *flavida*; birds from Fly R district E to Hall Sound proposed as race *papuae* (Wuroi, on Oriomo R), but inseparable from nominate. Three subspecies currently recognized.

Subspecies and Distribution.

M. a. analoga (Reichenbach, 1852) – West Papuan Is (Waigeo, Batanta, Salawati, Misool) and most of mainland New Guinea.

M. a. flavida Stresemann & Paludan, 1932 – Yapen I and Meos Num (in Geelvink Bay), and N New Guinea E, including Kairiru I and Mushi I (off Wewak), to Astrolabe Bay.

M. a. longirostris (Ogilvie-Grant, 1911) – Aru Is.

Also (racially distinct, identity uncertain) N watershed of SE New Guinea.

Descriptive notes. 15.5–19.5 cm; male 18.5–30 g and female 18–24 g (nominate), male 18–28.7 g and female 17.8–26 g (*flavida*). Nominate race is generally brownish-olive above, browner on top of head, with blackish-olive lores and vaguely diffuse streak running through eye to above ear-coverts, pale yellow lower ear-coverts forming fairly large, roughly triangular patch; yellow to orange-yellow gape merges with rather narrow pale yellow rictal streak (which does not extend to meet pale ear-patch); upperwing-coverts and alula dark brown with yellowish-olive outer edges or fringes, remiges dark brown with yellowish-olive outer edges and pale yellowish

inner edges; tail feathers dark brown with yellowish-olive outer edges; rather uniformly pale greyish-yellow below, sometimes light grey-brown wash on side of breast; underwing-coverts pale olive-yellow; iris brown to grey-brown or dark grey; bill black, possibly sometimes brownish-black (may be juvenile character); legs blue-grey to brownish-grey, dark olive-grey or fleshy grey. Differs from very similar *M. gracilis* and *M. cinereifrons* in generally slightly larger size, slightly longer and less slender bill, and less dusky side of head (streak behind eye), from latter also in less buff underwing-coverts. Sexes alike in plumage, male on average slightly larger than female; iris reported as green-brown in one female. Juvenile not properly described, said to be like adult but paler. Race *flavida* is brighter yellowish-olive above and has more yellow tinge below than nominate, also greyer iris; *longirostris* has slightly longer bill than nominate. **VOICE.** Call notes include shrill or staccato “tup”; short, bright disyllabic or upslurred note and similar but thinner and downwardly inflected disyllabic call; repeated querulous piping note. Calls much louder than those of *M. orientalis*.

Habitat. Primary forest and forest edge, secondary forest, tall secondary growth, scrub and scrub-forest, riparian and roadside vegetation, in some areas also coffee plantations, gardens and garden trees at forest edge, and tidal mangroves. In lowland Madang Province, seen in swamp island in savanna and grassland in Ramu Valley; in canopy of open woodland in lowland Western Province. Sea-level to 1250 m, to 1450 m near Telefomin; recorded to 990 m in Eastern Highlands; on Batanta, at 300–460 m on slopes of Mt Besar.

Food and Feeding. Diet includes arthropods (insects), fruit (including of *Symplocos*), seeds (probably ingested with fruit), and nectar from flowering trees (including *Syzygium*). Seen to feed on small caterpillars in a poinciana tree (*Delonix*). Gleans from branches, twigs and foliage in lower and middle storeys, often in understorey at forest edge; sometimes in canopy. Usually singly, in twos (probably often pairs) or in small groups of 5–6 individuals; sometimes with other honeyeaters. Once caught together with both *M. gracilis* and *M. ariensis* in same mist-net in Varirata National Park.

Breeding. Breeding birds Aug–Dec and (race *flavida*) Mar–May. Described nest claimed as being of present species considered more likely that of *M. albonotata*. No other information.

Movements. Probably largely sedentary, with some local movements.

Status and Conservation. Not globally threatened. Generally common, especially in S. No estimates of total population. Probably the easiest member of genus to observe in New Guinea.

Bibliography. Bailey (1992), Beehler, Pratt & Zimmerman (1986), Beehler, Sengo *et al.* (1995), Bell (1970c, 1982a, 1982d, 1984b), Bellchambers *et al.* (1994), Bowman *et al.* (1990), Brown & Hopkins (1996), Burrows (1993), Christidis & Schodde (1993), Clapp (1987b, 1992), Coates (1990), Coates & Peckover (2001), Diamond (1969, 1972a, 1985), Finch (1980b, 1993), Fletcher (2000b), Gilliard & LeCroy (1961, 1966, 1967a, 1968), Greenway (1966), Gyldestolpe (1955b), Hartert (1930), Hicks & Burrows (1992), Hoogerwerf (1971), Iova (1993), Mack & Wright (1996), Mayr & Rand (1937), Mees (1982), Norman *et al.* (2007), Ogilvie-Grant (1915), Pratt (1982), Rand (1936a, 1942a, 1942b), Rand & Gilliard (1967), Richards & Suryadi (2002), Rothschild *et al.* (1932b), Rowland (1995), Salomonsen (1966a), Schodde & Hitchcock (1968), Schönwetter & Meise (1981), Tolhurst (1991).

16. Scrub Honeyeater

Meliphaga albonotata

French: Méliphage buissonnier **German:** Schneehor-Honigfresser **Spanish:** Mielero Matorralero

Other common names: (Scrub/Southern) White-eared/(Scrub) White-marked Honeyeater/Meliphaga, Scrub White-eyed/Southern/Diamond Honeyeater, Scrub Mountain-honeyeater/-meliphaga

Taxonomy. *Ptilotis albonotata* Salvadori, 1876, Naiabui, Hall Sound, south-east New Guinea.

On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. orientalis*, *M. analoga*, *M. vicina*, *M. gracilis*, *M. cinereifrons*, *M. mimikae*, *M. montana*, *M. flavirictus*, *M. albilineata*, *M. fordiana* and *M. reticulata*. Formerly treated as conspecific with *M. montana*. Proposed races *setekwa* (from upper Setekwa R, in Nassau Range), *auga* (Mafulu, in Central Division) and *gretae* (Nondugl, on Wahgi R, in Central Highlands), all considered insufficiently differentiated from birds in rest of species’ range to warrant recognition. Treated as monotypic.

Distribution. Mainly hills and lower mountains, less often lowlands, of Vogelkop, Weyland, Nassau and Oranje Mts, Huon Peninsula, and SC & SE New Guinea.

Descriptive notes. 17–19 cm; male 27–34 g, female 20–29 g. Has top and side of head and neck and entire upperbody greyish-olive, with blackish lores, white lower ear-coverts forming small rounded ear-patch, and bright yellow or orange-yellow gape merging with narrow and contrastingly paler (pale yellow or cream) rictal streak (which does not meet pale ear-patch); upperwing-coverts and alula dark brown with yellowish-olive fringes, remiges dark brown with yellowish-olive outer edges and pale yellowish-buff inner edges; tail feathers dark brown with yellowish-olive outer edges; rather uniform light olive-grey below, pale yellow tinge or diffuse streaking on breast and belly; underwing-coverts olive-yellowish or buff; iris grey to grey-brown or dark brown; bill black to brownish-black (descriptions as greyish-brown may represent juvenile character); legs grey to grey-brown or dark olive-grey. Differs from similar *M. montana* mainly in brighter green crown and upperparts, yellowish or creamy (not white) rictal streak, yellowish or yellowish-olive fringes and edges on upperwing and tail, plainer underparts, and richer yellow gape. Sexes alike in plumage, male on average larger than female. Juvenile differs from adult in having yellow tinge in ear-patch, dark olive-brown upperparts, and irregular darker olive-brown band across breast. **VOICE.** Song of 10–12 rapidly uttered thin notes (c. 5 per second), often rising in pitch and then becoming lower towards end; described also as slow trilling “wheel”. Call a brief, fairly loud and musical cheery “chip, tup, chop” or “chirrup” with sucked-in quality, similar to that of several congeners (but “chop” said to be more musical), and similar loud disyllabic note; call described as loud, rather sharply whistled “kit” or “kit kit” may refer to one of these calls.

Habitat. Typically in disturbed habitats, including secondary growth and forest edge, forest remnants along creeks, marginal primary forest, mid-montane scrub, anthropogenic grasslands, plantations, and town and village gardens; apparently absent from interior of forest. Mainly foothills and lower mountains, less often in lowlands; sea-level to c. 1950 m, with possible records at 2900 m (between Laiagam and Kanep).

Food and Feeding. Diet includes insects, nectar and some fruit. Usually forages in understorey (e.g. frequently up to 5 m above ground), but visits flowering and fruiting trees. Forages by gleaning, including hover-gleaning; seen to forage at flowers of *Rhus taitensis* (Anacardiaceae), and to hover at papayas (*Carica*) partly eaten by fruit-bats (Pteropodidae) to feed on pulp. Usually singly or in twos (probably pairs); seen to feed in flowering tree with other species, including three species of *Myzomela*.

Breeding. Recorded in dry season and middle of wet season: eggs in early Mar and Sept, nestlings late Jul, late Sept and late Oct, and fledglings late Aug, Sept, Feb and May. Nest a neat cup of fine fibres, moss, grasses, bark and much animal silk, lined with thread-like woody fibres, plant down and fluffy cotton-like seed material, external diameter c. 8 cm, depth 6.4–8 cm, internal diameter 5–7 cm, depth c. 3.5 cm, suspended 1–5 m (sometimes higher, to 11 m) above ground from horizontal fork in small tree, in shrub or in bamboo thicket. Clutch 1–2 eggs; no information on incubation and nestling periods; chicks fed by both parents.

Movements. Resident at Crater Mt, in Tabubil region and around Brown R, and probably at Moroka; probably resident throughout range.

Status and Conservation. Not globally threatened. Fairly common to abundant at higher altitudes, and uncommon in lowlands; scarce on Sogeri Plateau. A species of disturbed habitats, has successfully invaded highland areas where there has been extensive destruction of original forest habitat; appears to have invaded Wau Valley since 1932.

Bibliography. Beehler (1978a, 1978c, 1980b), Beehler, Pratt & Zimmerman (1986), Beehler, Sengo *et al.* (1995), Bell (1970c, 1982a, 1982d, 1984b), Christidis & Schodde (1993), Coates (1990), Coates & Peckover (2001), Diamond (1972a, 1985), Finch (1980b, 1983), Gilliard & LeCroy (1967a), Gregory (1995b), Gyldestolpe (1955a), Hoogerwerf (1971), Isles & Menkhurst (1976), Mack & Wright (1996), Mayr & Rand (1937), Murray (1988b), Norman *et al.* (2007), Ogilvie-Grant (1915), Rand (1936a, 1942a), Schodde & Hitchcock (1968), Stein (1936), Symes & Marsden (2005), Wahlberg (1988), Weston (1976b).

17. Tagula Honeyeater

Meliphaga vicina

French: Méliphage de Tagula **German:** Tagulahonigfresser **Spanish:** Mielero de la Tagula
Other common names: Tagula/Louisiades/Sudest Meliphaga, Louisiades/Sudest Honeyeater

Taxonomy. *Ptilotis analoga vicina* Rothschild and E. J. O. Hartert, 1912, Sudest Island = Tagula Island, Louisiade Archipelago, New Guinea.

On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. orientalis*, *M. analoga*, *M. albonotata*, *M. gracilis*, *M. cinereifrons*, *M. mimikae*, *M. montana*, *M. flavirictus*, *M. albilineata*, *M. fordiana* and *M. reticulata*. Appears to be close to, and may be conspecific with, either *M. analoga* or *M. gracilis*. Monotypic.

Distribution. Tagula I, in Louisiade Archipelago, off SE New Guinea.

Descriptive notes. 16.5–17 cm. Mostly olive above, with greyish forehead, small pale yellow rictal streak, rounded yellow ear-patch; soft rump-tuft of greyish feathers with olive tips; yellowish-white inner edges of remiges; light greyish-buff below, yellower on belly, buff underwing-coverts; iris dark brown to grey-brown; bill black or blackish (possibly blackish-brown); legs slate-blue. Sexes apparently alike in plumage, male larger than female. Juvenile undescribed. **VOICE.** Undescribed.

Habitat. Thought to inhabit forest and forest edge; lowlands and hills, to 600–800 m.

Food and Feeding. No information.

Breeding. No information.

Movements. Not known; probably sedentary.

Status and Conservation. Data-deficient. Restricted-range species; present in Louisiade Archipelago EBA. Very poorly known; nothing known of ecology and adaptability to habitat alteration. Over half of the forest on Tagula already degraded, and logging remains a threat to remaining lowland forest.

Bibliography. Anon. (2007a), Beehler (1993), Beehler *et al.* (1986), Butchart & Stattersfield (2004), Christidis & Schodde (1993), Coates (1990), Coates & Peckover (2001), Norman *et al.* (2007), Ogilvie-Grant (1915), Rand (1936a), Rand & Gilliard (1967), Schodde (1978b), Stattersfield & Capper (2000), Stattersfield *et al.* (1998).

18. Graceful Honeyeater

Meliphaga gracilis

French: Méléphage gracie **German:** Feenhonigfresser **Spanish:** Mielero Grácil
Other common names: Graceful/Slender-billed Meliphaga, Southern Graceful/Slender-billed/Grey-breasted/Lesser Yellow-spotted/Little Yellow-spotted/Eastern Graceful Honeyeater

Taxonomy. *Ptilotis gracilis* Gould, 1866, Cape York, north Queensland, Australia.

On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. orientalis*, *M. analoga*, *M. albonotata*, *M. vicina*, *M. cinereifrons*, *M. mimikae*, *M. montana*, *M. flavivirctus*, *M. albilineata*, *M. fordiana* and *M. reticulata*. Sometimes treated as conspecific with *M. cinereifrons*. In NE Australia (N Queensland) races possibly intergrade in narrow zone roughly between Cooktown and Ayton. Two subspecies recognized.

Subspecies and Distribution.

M. g. gracilis (Gould, 1866) – Aru Is, S New Guinea (Triton Bay E to Purari Delta), Bristow I (off Daru, in extreme N Torres Strait), and coastal and subcoastal NE Australia (N Queensland from Cape York S to Archer–Mitchell rivers and, in E, to Princess Charlotte Bay and Cooktown–Ayton region). *M. g. imitatrix* (Mathews, 1912) – coastal NE Queensland from around Princess Charlotte Bay and Cooktown S to Halifax Bay and S Paluma Range, and inland to Atherton Tableland.

Descriptive notes. 15–17 cm; male 14–17 g and female 12.5–16.5 g (n nominate), male 14–17 g and female 12.5–17 g (*imitatrix*). N nominate race is mostly dark olive above, sometimes faintly darker on forehead, grading across side of head to paler greyish-olive on chin and throat (in best views yellow tinge on chin may be visible), with diffusely darker lores, prominent yellow spot on rear ear-coverts (varying from rounded to diamond-shaped, never crescentic), short yellow to orange-yellow gape (usually brighter and more orange than ear-spot) that meets short, thin pale yellow rictal streak; remiges and edges of tail brighter yellow-olive than upperparts; underparts pale olive-grey, slightly paler than upperparts, with narrow and inconspicuous yellowish stripe in centre of belly; undertail olive-grey, underwing pale grey; iris grey-brown or bluish-grey; bill black; legs pale to dark grey or greyish-brown. Sexes alike in plumage, male slightly larger than female. Juvenile is very like adult, but mantle, back, scapulars and rump washed brown, moustachial stripe less distinct. Race *imitatrix* is very like nominate, but top of head and most of upperbody slightly darker, yellow of chin and throat richer, breast darker and area of yellow on belly smaller, also male has shorter wing. **Voice.** Rather noisy. Throughout range, “chip” appears to be most common call: in Australia a soft, melodious “plit” or “chip” (occasionally sharper-sounding variant, “plik”), uttered once or at intervals (e.g. every c. 20 seconds); in New Guinea and Aru Is as sharp or staccato “kip”, “tchick”, “tick”, “tuk”, “tup” or “chup”. Also high-pitched ascending whistled “wip-wip wip...” or “whit-whit-whit...” series of 4–12 notes (c. 4 per second), common in Cape York Peninsula but not heard in wet tropics of NE Queensland; in New Guinea as “ki-ki-ki...” or as series of clear querulous piping notes; on Aru Is as up to 8 identically repeated whistled upslurs. Other vocalizations include slightly harsh series of 4–8 “pick” notes at c. 2 per second (again, heard Cape York Peninsula but not wet tropics), rapid series of up to 7 identical snapped notes from Aru Is probably same call; peevish, whining scolding note; slow “reet-reet-reet...” of c. 5 notes; quicker “preep-preep-preep...”, also of c. 5 syllables (common Cape York, rare in wet tropics); series of notes similar to “chuck” call of Slender-billed Cuckoo (*Coracina tenuirostris*); high-pitched rapid chattering sometimes heard Cape York; repeated “tswee” in Aru Is; and thin trill ending in upward note, heard in New Guinea but only rarely.

Habitat. In Australia, rainforest or forest edge, including vine scrubs and regrowth rainforest, and in adjoining open forests and woodlands of *Eucalyptus* and *Melaleuca* with sclerophyllous, grassy or rainforest understorey; also *Melaleuca* swamp-woodland, semi-deciduous dune-woodland, and sometimes mangroves or *Lantana* thickets, especially beside wetlands or rainforests. In New Guinea, mangroves, secondary growth, forest edge, primary forest, monsoon forest, savanna woodland, riverine forest and lightly timbered country; also sago (*Metroxylon*) scrub. Often in gardens and orchards in towns and villages. Lowlands in New Guinea; in Australia from coast to foothills and ranges, occasionally tablelands, mostly below 500 m, rarely to c. 800 m.

Food and Feeding. Nectar, fruit and insects. Forages in canopy, mid-canopy (including in crowns of substage trees) and understorey shrubs, usually 2–18 m above ground. Searches at flowers, twigs and small branches, fruit and foliage, tangles of vines, and on epiphytes; sometimes at flowers of exotic trees and shrubs in gardens and at flowers of *Amyema* mistletoe; probably also on tree trunks occasionally. In New Guinea, forages at flowering sago. Nectar obtained by probing flowers; insects obtained mainly by gleaning, less often by sally-striking in air, sally-hovering at outer foliage or at spider webs, probably also by flutter-chasing. Usually singly or in twos (probably pairs); occasionally in small parties or associated with other honeyeaters in flowering trees or other food sources. Once caught together with both *M. aruensis* and *M. analoga* in same mist-net in Varirata National Park, in New Guinea.

Breeding. In NE Australia breeds Sept–Feb, with estimated start of laying Oct–Nov and Jan–Feb and nestlings late Oct to early Jan; one active nest late Aug in New Guinea. Nest a neat cup typically of moss, vines, roots, bark fibre, thin strips of paperbark or other plant material, covered with moss, lichen, small pieces of bark or occasionally insect cocoons or bound with spider web, lined with plant down or other fibres or vines, external diameter 6–4–7–6 cm, depth 4–4–7–6 cm, internal diameter 5–7–6–4 cm, depth 3–8 cm, usually suspended by rim from small forked branch in outer foliage of live plant, sometimes overhanging water, generally 0.75–3 m (mean 1–5 m) above ground but up to 15 m in Australia and once at 21 m in New Guinea. Clutch usually 2 eggs; estimated incubation period at one nest 15 days, and two estimates of nestling period c. 10 days and c. 11 days; no information on roles of sexes.

Movements. Apparently resident, but some local movements.

Status and Conservation. Not assessed. Probably not globally threatened. Considered generally common in New Guinea. Recorded density of 0–16 birds/ha in NE Queensland. No information on current status in Torres Strait islands; historical record on Moa I.

Bibliography. Anon. (1978a, 1978b), Barrett *et al.* (2003), Beehler, Pratt & Zimmerman (1986), Beehler, Sengo *et al.* (1995), Blakers *et al.* (1984), Boles & Longmore (1989), Burrows (1993), Campbell (1900), Campbell & Barnard (1917), Christidis & Schodde (1993), Coates (1990), Coates & Peckover (2001), Colston (1974), Cooney *et al.* (2006), Crome (1978), Diamond & Bishop (1994), Draffan *et al.* (1983), Finch (1983), Fisher & Fisher (1996), Forshaw & Muller (1978), Frith & Frith (1993a), Gannon (1962), Garnett & Bredl (1985), Gill, H.B. 19. Elegant Honeyeater

Meliphaga cinereifrons

French: Méléphage de Rand **German:** Graustirn-Honigfresser **Spanish:** Mielero Elegante
Other common names: Eastern Graceful/Stevens’s Honeyeater

Taxonomy. *Meliphaga gracilis cinereifrons* Rand, 1936, Rona, south-east New Guinea.

On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. orientalis*, *M. analoga*, *M. albonotata*, *M. vicina*, *M. gracilis*, *M. mimikae*, *M. montana*, *M. flavivirctus*, *M. albilineata*, *M. fordiana* and *M. reticulata*. Sometimes considered conspecific with *M. gracilis*. Name *stevensi* (from N watershed of SE New Guinea) has been used for a race variously of present species or of *M. analoga*, and it is not certain at present to which (if either) the type specimen applies; recent genetically based investigations indicate that specimens attributed to *stevensi* include cryptic variants of both species; further study currently in progress. Temporarily treated as monotypic, pending identification of northern form.

Distribution. Foothills and coasts of SE New Guinea E to Milne Bay (including Sariba I), in N from at least Goodenough Bay (Nowata), and in S from Malalaua. Also (racially distinct, identity uncertain) N watershed of SE New Guinea.

Descriptive notes. 14–18 cm; 22 g. N nominate race is generally dark olive above, somewhat darker on forehead and top of head, and with diffusely darker blackish-olive lores and vaguely diffuse crescent behind and behind rear lower quadrant of eye, extending as diffuse streak above pale ear-coverts and behind ear-plate; fine pale grey eyering around rear of eye, pale yellow rear ear-coverts forming fairly large prominent patch (typically rounded but usually extending in lobe upwards behind eye, often curving slightly towards rear of eye), and yellow to orange-yellow gape that merges with rather thin, contrastingly paler yellow rictal streak; upwrepping-coverts and alula dark brown with yellowish-olive outer edges or fringes, remiges dark brown with yellowish-olive outer edges (slightly brighter olive than upperparts) and pale yellowish inner edges; tail feathers dark brown with yellowish-olive outer edges; pale yellowish-grey below (yellowish tinge strongest at side of upper breast); underwing-coverts strongly buff-yellow, tinged olive; iris brown to grey; bill black; legs blue-grey to grey or fleshy grey. Sexes alike in plumage, male on average larger than female. Juvenile undescribed. **Voice.** Usual call a sharp “tchick”, “tick” or “tuk”; also thin trill ending in upwardly inflected note, and a repeated high “ki-ki-ki-ki...” in alarm.

Habitat. Mainly lowland rainforest edge and secondary growth; also monsoon rainforest, including patches in savanna woodland and gallery forests, scrubby swamp-forest with sago (*Metroxylon*), dense savanna woodland, mangroves; often in gardens. Mainly lowlands to 600 m, locally to 900 m. Unidentified race from N watershed frequently in hill forest, up to 1200 m.

Food and Feeding. Nectar, fruit and insects. Forages from canopy to shrub layer, mainly in understorey and middle storey; apparently mainly by gleaning. Active. Usually singly or in twos (probably pairs), sometimes in small parties.

Breeding. Eggs in Oct and early Feb, fledglings in late Mar, and female with enlarged gonads early Sept. Nest a deep cup of grass, leaves and spider web, lined with down from seed pods, external diameter 6–4 cm, depth 7 cm, internal diameter 5–1 cm, depth 4–5 cm; suspended by rim from thin fork near end of branch or in vine, near ground or up to 6 m above it. Clutch 2 eggs; incubation period 12–13 or 13–14 days; no information on nestling period.

Movements. No indication of any movements.

Status and Conservation. Not assessed. Probably not globally threatened. No estimates of abundance levels; generally considered fairly common to common.

Bibliography. Beehler (1978a), Beehler *et al.* (1986), Bell (1982a, 1982d, 1984b), Christidis & Schodde (1993), Coates (1990), Coates & Peckover (2001), Heron (1974), Le Souef (1900), Mayr & Rand (1937), Norman *et al.* (2007), Rand (1936a), Rand & Gilliard (1967), Watson *et al.* (1962).

20. Spot-breasted Honeyeater

Meliphaga mimikae

French: Méléphage de Mimika **German:** Mimikahonigfresser **Spanish:** Mielero del Mimika
Other common names: (Greater/Large) Spot-breasted/Mottle-breasted Meliphaga, Large Spot-breasted/Greater Spot-breasted/Mottle-breasted Honeyeater, Large Meliphaga

Taxonomy. *Ptilotis mimikae* Ogilvie-Grant, 1911, Mimika River, south New Guinea.

On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. orientalis*, *M. analoga*, *M. albonotata*, *M. vicina*, *M. gracilis*, *M. cinereifrons*, *M. montana*, *M. flavivirctus*, *M. albilineata*, *M. fordiana* and *M. reticulata*. Proposed race *rara*, described from single specimen among a collection of *M. analoga flavida* from lowlands of Idenburg R (upper Mamberamo Basin, in N New Guinea), considered of doubtful validity. Three subspecies recognized.

Subspecies and Distribution.

M. m. mimikae (Ogilvie-Grant, 1911) – S slopes of Central Range and lowlands of SW & SC New Guinea from at least Mimika R and Snow Mts E (including along rivers Kapare, Wataikwa, Iwaka, Setekwa, Utakwa and Noord) to upper Fly R.

M. m. bastille Diamond, 1967 – S slopes of Eastern Highlands.

M. m. granti Rand, 1936 – S slopes of mountains of SE New Guinea from upper Angabunga R E at least to Sogerih Plateau, and in Hydrographer Range on N watershed.

Descriptive notes. 16.5–17 cm; male 24–32.5 g, female 22–29 g (*bastille*). N nominate race has top and side of head and neck and upperparts dark greyish-olive to brownish-olive, with grey tinge on

or brownish-grey; bill blackish; legs grey. Differs from *M. orientalis* in larger size, more robust bill and finer rictal streak; from *M. montana* in yellow (not white) ear-patch and pale yellow (not white) rictal streak. Sexes alike in plumage, male on average larger than female. Juvenile undescribed. Race *granti* is larger than nominate, has greener upperparts, greyer forehead, more prominent mottling on underparts; *bastille* is similar in size to nominate but darker, and with more prominent mottling below. VOICE. Loud, short “tuck” or “chip” or “chup” note, similar to those of congeners; race *granti* (and possibly other races) utters repeated nasal piping, likened to call of Eurasian Bullfinch (*Pyrrhula pyrrhula*).

Habitat. Forest, mainly in foothills and lower montane slopes, c. 150 m to 1150 m, locally down to sea-level and as high as 1800 m. Nominate race recorded from sea-level to 900 m, mainly in hills; *bastille* at 400–1370 m; *granti* above 750 m, to 1800 m.

Food and Feeding. Diet includes fruit, arthropods (mainly insects) and almost certainly nectar. Forages mainly in shrubby understorey and lower middle storey, also among inflorescences of canopy epiphyte *Schefflera* (Araliaceae) and *Piper* (Piperaceae); sometimes on ground. Difficult to observe but not shy; typically very active. Singly or in twos (probably pairs); seen to forage in large flowering tree with other honeyeaters and sunbirds (Nectariniidae).

Breeding. Details from two nests in Crater Mt, in mid-Mar and late Apr. Nest a slightly oval open cup made of fine plant fibres, twigs and vines, thickly covered externally with live moss and fern, thickly lined with loose, shredded and fluffy plant down (partly covered eggs when adult off nest), external diameter 7.5–9 cm, depth 7.5 cm, internal diameter 4.5–5 cm, depth 4.5 cm, placed 1.7 m and 2 m above ground in horizontal fork of branch of understorey tree. Each nest contained 2 eggs. No other information.

Movements. Resident at Crater Mt; probably sedentary throughout range, with some local movements.

Status and Conservation. Not globally threatened. Generally fairly common to abundant, infrequently observed. One of the most abundant forest birds at Karimui, and the most common of the six closely similar species of this genus in the basin.

Bibliography. Beehler (1980a), Beehler *et al.* (1986), Brown & Hopkins (1996), Christidis & Schodde (1993), Coates (1990), Coates & Peckover (2001), Diamond (1967, 1972a, 1985), Finch (1983), Gregory (1995b), Mack (1994), Mack & Wright (1996), Mayr & Rand (1937), Norman *et al.* (2007), Ogilvie-Grant (1915), Rand (1936a, 1942a), Rand & Gilliard (1967), Salomonsen (1966a).

21. Forest Honeyeater

Meliphaga montana

French: Méléphage forestier **German:** Bergwaldhonigfresser **Spanish:** Mielero Montano
Other common names: (Forest) White-eared/(White-eared) Mountain/White-marked Scrub/Black-fronted Honeyeater, (Forest) White-eared/(White-eared) Mountain Meliphaga

Taxonomy. *Ptilotis montana* Salvadori, 1880, Arfak Mountains, New Guinea.

On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. orientalis*, *M. analoga*, *M. albonotata*, *M. vicina*, *M. gracilis*, *M. cinereifrons*, *M. mimikae*, *M. flavirictus*, *M. albilineata*, *M. fordiana* and *M. reticulata*. Previously considered conspecific with *M. albonotata*. Validity of some races, e.g. *margaretae*, possibly questionable. Birds of this species in Van Rees Mts and Foja Mts of uncertain racial identity, provisionally included in *sepik*. Seven subspecies tentatively recognized.

Subspecies and Distribution.

M. m. margaretae Greenway, 1966 – mountains of Batanta, in West Papuan Is.

M. m. montana (Salvadori, 1880) – mountains of Vogelkop, Onin Peninsula and Bomberai Peninsula, and Weyland Mts, in NW New Guinea.

M. m. steini Stresemann & Paludan, 1932 – Yapen I, in Geelvink Bay.

M. m. sepik Rand, 1936 – Van Rees Mts, Foja Mts, North Coastal Range, and N slopes of Central Range from Idenburg R E to Schrader Mts.

M. m. germanorum E. J. O. Hartert, 1930 – Cyclops Mts, in N New Guinea.

M. m. huonensis Rand, 1936 – Adelbert Mts and Huon Peninsula, in NE New Guinea.

M. m. aicora Rand, 1936 – N slopes in SE New Guinea (E to Sibium Mts and Goodenough Bay), also in S at Cape Rodney.

outer edges and pale buff inner edges; tail feathers dark brown with dull olive-grey outer edges; greyish-olive or pale greyish below, darker grey on breast and with indistinct yellowish streaking or tinge on belly, sometimes apparently faint darker mottling on breast; underwing-coverts orange-buff; iris brown to greyish; bill blackish-brown to black; legs blue-grey. Differs from *M. albonotata* in darker olive-brown upperparts and crown, much less distinct and duller olive edges and fringes

forehead; blackish-olive lores, pale olive eyering, yellow lower ear-coverts (forming fairly large patch), and yellow to dull orange gape that meets fairly narrow and contrastingly paler yellow rictal streak (not extending to pale ear-patch); upperwing-coverts and alula dark brown with dark olive-green fringes, remiges dark brown with olive-green outer edges and olive-buff or pale buff inner edges; tail feathers dark brown with yellow-olive outer edges; olive-grey below, pale yellowish tinge or faint streaking on belly, and with darker brownish mottling on chin to upper belly; underwing-coverts olive-ochre to olive-yellow; iris brown

in wing, darker and greyer underparts (particularly breast); distinguished from all other New Guinean congeners by much paler, white, ear-spot. Sexes alike in plumage, male slightly larger than female. Juvenile is poorly known, like adult but has yellowish tinge in ear-patch. Races differ in tone and colour of plumage: *aicora* is distinctive, with darker, more olive, upperparts, richer yellowish tinge below, and slightly longer bill than nominate; *germanorum* has darker upperparts than nominate, less yellowish tinge on darker grey underparts, brownish wash on side of breast; *huonensis* has most pronounced mottling or streaking on breast, and slightly longer bill than nominate; *margaretae* is greener above than nominate, but with grey tinge on forehead, diffusely scaly or spotted appearance of crown, and has underparts and bill length similar to previous (or bill slightly longer); *steini* has darker head than nominate, also darker and more greenish-olive upperparts, and clearer grey underparts lacking yellowish wash; *sepik* is similar to last, but darker upperparts and yellowish wash on underparts. Voice. Main call a loud, slightly hoarse and upslurred “wheep”, similar to upslurred notes of congeners.

Habitat. Interior of undisturbed hill and lower montane primary forest; found also in tall secondary forest and occasionally in shrubby secondary growth (contrary to earlier claims that it occurs only in undisturbed forest). Mainly between c. 400 m and 1500 m: 560–930 m in Fakfak Mts; 400–750 m in Kumawa Mts; 800–1400 m on Yapen I; 600–1000 m (occasionally to 1200 m) in Foja Mts; at 360 m in Van Rees Mts; 600–1200 m (occasionally to 1400 m) in North Coastal Range. Single specimen from near sea-level at Cape Rodney, on S coast of SE New Guinea.

Food and Feeding. Diet includes fruit, seeds (possibly ingested with fruit) and arthropods (mainly insects); probably also nectar, but said rarely, if ever, to visit flowering trees. Forages mainly in middle storey, 3–12 m above ground, less often in understorey, by gleaning and hover-gleaning. Shy, difficult to observe. Usually singly, sometimes in twos (probably pairs); occasionally joins mixed flocks, but does not congregate in flowering trees.

Breeding. No information. Some published details referring to this species thought to relate to *M. albonotata*.

Movements. Nothing known; probably sedentary with some local movements.

Status and Conservation. Not globally threatened. No estimates of population, but considered common at various sites throughout range.

Bibliography. Beehler (1978a), Beehler *et al.* (1986), Christidis & Schodde (1993), Clapp (1987a), Coates (1990), Coates & Peckover (2001), Diamond (1972a, 1985), Finch (1980a), Gilliard & LeCroy (1961, 1967a, 1970), Greenway (1966), Hartert (1930), Lamothe (1979), Mack & Alonso (2000), Norman *et al.* (2007), Pratt (1982), Rand (1936a, 1942b), Rand & Gilliard (1967), Richards & Suryadi (2002), Rothschild *et al.* (1932b), Rowland (1995), Stein (1936).

22. Yellow-gaped Honeyeater

Meliphaga flavirictus

French: Méléphage souriant **German:** Gelbkinn-Honigfresser **Spanish:** Mielero Sonriente
Other common names: Yellow-gaped Meliphaga

Taxonomy. *Ptilotis flavirictus* Salvadori, 1880, Fly River, south New Guinea.

On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. orientalis*, *M. analoga*, *M. albonotata*, *M. vicina*, *M. gracilis*, *M. cinereifrons*, *M. mimikae*, *M. montana*, *M. albilineata*, *M. fordiana* and *M. reticulata*. Races intergrade on S slopes of Snow Mts. Two subspecies recognized.

Subspecies and Distribution.

M. f. crockettorum Mayr & Meyer de Schauensee, 1939 – W & N New Guinea from Vogelkop E to Sepik R and Herzog Mts and, in S, to Utakwa R (Nassau Mts), Snow Mts and probably farther E towards Fly R.

M. f. flavirictus (Salvadori, 1880) – S watershed of Central Range from middle and lower Fly R E to S slopes of SE New Guinea.

Descriptive notes. 15 cm; one male 20 g, one unsexed 17 g (nominate), one male 22 g (*crockettorum*). Nominate race is rather pale greyish-olive above, side of head greyer, and with dark greyish lores, pale yellow or yellowish-white lower ear-coverts (forming small patch), and prominent bright yellow gape that merges with conspicuous yellowish-white to pale orange-yellow rictal streak, latter bordered below by narrow pale olive malar stripe and only narrowly separated from pale ear-patch; upperwing dark brown, coverts and alula with olive fringes, remiges with olive outer edges and yellowish-white inner edges; tail feathers dark brown with olive outer edges; greyish-white below, yellowish wash on chin and throat, underwing-coverts yellowish-white; iris light grey-brown or brownish; bill blackish to grey-brown; legs yellowish-olive. Differs from *M. albonotata* in smaller size, more slender bill, smaller ear-patch, greyer (less green) upperparts, more prominent rictal streak. Sexes alike in plumage, male slightly larger than female. Juvenile undescribed. Race *crockettorum* differs from nominate in richer olive-green upperparts, larger and more rounded yellow ear-patch, rictal streak brighter than ear-patch, darker lores, darker underparts, paler yellow underwing-coverts, blacker bill, greyish legs. Voice. Single-note nasal “kwek”; series of short, bubbling and descending “chip” or “chirp” notes (similar to those of *Lichenostomus obscurus*), which may be same as a series of short dry notes (said to be most distinctive call).

Habitat. Primary forest and edge, including foothill forest and monsoon rainforest; nominate race also in savanna. Sea-level to c. 1400 m.

Food and Feeding. Arthropods (mainly insects), and almost certainly fruit and nectar. Forages in canopy, often in flowering or fruiting trees (e.g. among inflorescences of *Eugenia*). Difficult to observe, but said to be more vocal than congeners. Usually singly or in small groups; sometimes with other honeyeaters, including *M. gracilis* and *M. analoga*.

Breeding. No information.

Movements. Resident at Crater Mt and probably throughout range; some local movements.

Status and Conservation. Not globally threatened. No estimates of total population but apparently generally rather rare, or at least easily overlooked. Considered possibly the rarest of the New Guinean members of genus.

Bibliography. Bailey (1992), Beehler (1978a), Beehler *et al.* (1986), Christidis & Schodde (1993), Coates (1990), Coates & Peckover (2001), Diamond (1972a), Eastwood (1996a), Finch (1983), Gilliard & LeCroy (1966), Mack & Wright (1996), Norman *et al.* (2007), Pälliser (1989), Rand (1936a, 1942a, 1942b), Rand & Gilliard (1967), Richards & Suryadi (2002), Rowland (1995).

Family MELIPHAGIDAE (HONEYEATERS) SPECIES ACCOUNTS

PLATE 40

23. White-lined Honeyeater

Meliphaga albilineata

French: Méléphage à boucle blanche **German:** Weißbart-Honigfresser **Spanish:** Mielero Listado
Other common names: White-striped Honeyeater

Taxonomy. *Ptilotis albilineata* H. L. White, 1917, King River, Northern Territory, Australia. On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. orientalis*, *M. analoga*, *M. albonotata*, *M. vicina*, *M. gracilis*, *M. cinereifrons*, *M. mimikae*, *M. montana*, *M. flaviviridis*, *M. fordiana* and *M. reticulata*. Previously considered conspecific with *M. fordiana*; recent molecular analyses indicate that both are closely aligned also to *M. reticulata* and that these are best treated as three separate species. Monotypic.

Distribution. N Northern Territory in W Arnhem Land (Wellington Range and Mt Borradaile S to E headwaters of Mary R and to Katherine Gorge, E to Mann R), in N Australia.

Descriptive notes. 17–20.5 cm; male 22.3–29.9 g, female 19–23.5 g. Medium-sized slim honeyeater with short, slender and slightly decurved bill. Has head, neck and upperparts mostly dark brownish-grey, merging to sooty grey on face, with small but prominent yellow gape, and thin white moustachial stripe extending from gape backwards below eye to meet narrow white ear-plume across rear ear-coverts (plume and stripe can appear separate, and plume sometimes indistinct); larger secondary upperwing-coverts mottled slightly darker, median coverts with narrow pale grey-brown fringes, greater coverts with narrow yellow fringes, and remiges edged pale yellow-green (forming diffuse panel on folded wing); rectrices also edged pale yellow-green; off-white chin and throat sometimes diffusely streaked brownish-grey; underbody off-white, grey-brown mottling across breast becoming solid wash at side of breast, diffuse brownish-grey streaks on lower breast, belly and flanks; undertail brownish-grey; underwing buff with broad brownish-grey trailing edge and tip; iris whitish-grey to pale blue-grey; bill black; legs grey to brown. Sexes alike in plumage, male larger than female. Juvenile is similar to adult but

with no moustachial stripe, larger and yellow-white ear-plume, upperwing-coverts tinged rufous, only faint mottling or streaking on lower throat and breast, pale buff-grey lower underbody without streaking. **Voice.** Various described as quiet or noisy. Song, given at most times of day and throughout year, of 2–3 extended loud, clear, melodious whistles, sometimes repeated, “too-ep”, “too-in”, or “tue-ee-ee”, “tu-i-in”, second and third syllables higher-pitched; first whistle with rising inflexion, second (sometimes omitted) undulates and usually falls, third (strongest) usually rises before falling away; described as ventriloquial. Calls include series of loud rapid chipping notes, given for 1 minute or longer at dusk by pair settling at roost; and chattering in agitation in presence of Southern Boobook (*Ninox boobook*).

Habitat. Vegetated gorges, gulleys, cliffs and plateaux of rugged sandstone escarpments and ranges, mostly in broadleaf scrub and thickets of *Xanthostemon*, *Terminalia* and *Gardenia*; sometimes in eucalypt woodland with thickets of acacias and figs (*Ficus*), gallery paperbark (*Melaleuca*) forest on valley floors, and patches of monsoon rainforest topographically protected from fire and with high availability of moisture all year (e.g. floors of valleys and gulleys in sandstone ranges). In study of monsoon rainforest patches, most abundant in sandstone spring and escarpment patches, with few in subcoastal patches, and none in coastal, lowland spring or rock outcrop patches; significantly more abundant in large (more than 2 ha) patches than in small ones. Also sometimes on floodplains near base of cliffs of escarpments.

Food and Feeding. Diet includes invertebrates, mainly insects, some spiders (Araneae), also nectar, fruit and some seeds. Forages in dense upper branches of vegetation (which often low); among foliage and at flowers and fruits of trees. Active, moving rapidly through foliage. Gleans items from foliage and large branches of trees and shrubs, probes in narrow crevices in rocks; also catches insects by sally-hovering and sally-striking. Often secretive and wary. Usually seen singly or in twos (probably pairs), occasionally in small parties (e.g. of five) at food sources; said also to associate with other species of honeyeater in flowering trees or other sources of food, and seen to behave aggressively towards smaller competitors.

Breeding. Few details. Eggs recorded in Sept, newly hatched nestlings early Oct, recently vacated nest mid-Jan, and two fledglings 23 Jan; from gonadal condition, season thought to be mainly Oct–Jan. Three nests described, each cup-shaped, made of fine branches and stems and interwoven strands of vine-like creeper, two were lined with fine long grasses, plant stems and fibre (one unlined), bound or reinforced at rim with cobweb, spider web or cotton-like vegetable material, external diameter 7.5–9.6 cm, depth 5.8–8.7 cm, internal diameter 5.5–7 cm, depth 5–6.3 cm; supported by branchlets or suspended by rim (or both) 1.2–5 m above ground in outer branches and twigs of small shrub or tree. Only one clutch found, of 2 eggs; male seen to feed fledglings, but not known if female also feeds. No other information.

Movements. Apparently sedentary, possibly with some local movements.
Status and Conservation. Not assessed. Probably not globally threatened. Restricted-range species: present in North-west Australia EBA. Not well known; perhaps locally common. Often secretive and easily overlooked; best detected by vocalizations.
Bibliography. Barrett *et al.* (2003), Blakers *et al.* (1984), Christidis & Schodde (1993), Colston (1974), Deignan (1964), Ford, J.R. 24. Kimberley Honeyeater

Meliphaga fordiana

French: Méléphage du Kimberley **German:** Kimberleyhonigfresser **Spanish:** Mielero de Kimberley
Other common names: White-striped Honeyeater

Taxonomy. *Meliphaga fordiana* Schodde, 1989, Mitchell River Falls, Mitchell Plateau, Kimberley Division, north-west Australia.

On basis of molecular evidence, genus consists of two clades; present species is part of group which contains also *M. orientalis*, *M. analoga*, *M. albonotata*, *M. vicina*, *M. gracilis*, *M. cinereifrons*, *M. mimikae*, *M. montana*, *M. flavivictus*, *M. albilineata* and *M. reticulata*. Until recently treated as conspecific with *M. albilineata*; molecular analyses indicate that both are closely aligned also to *M. reticulata* and that these are best treated as three separate species. Monotypic.

Distribution. N Western Australia: Kimberley Division from Admiralty Gulf and Drysdale R S to King Leopold Ranges, E to Drysdale River National Park, and including islands off NW coast (Boongaree, Bigge and Wollaston, in Bonaparte Archipelago).

Descriptive notes. c. 18.5 cm; male 27.2–30.5 g, female 19.5–26.5 g. Medium-sized slim honeyeater with short, slender and slightly decurved bill, differing only subtly from *M. albilineata*. Head, neck and upperparts are mostly dark brownish-grey, merging to sooty grey on face, with small but prominent pale yellow to whitish gape and thin white moustachial stripe extending backwards below eye to meet narrow white ear-plume across rear ear-coverts (plume and stripe can appear separate, plume sometimes indistinct); larger secondary upwringing-coverts mottled slightly darker, median coverts with narrow pale grey-brown

fringes, greater coverts with indistinct fine dull yellow fringes; remiges and rectrices concolorous with upperparts; off-white chin and throat sometimes diffusely streaked brownish-grey; underbody off-white, grading to paler white on belly, grey-brown mottling across breast becoming solid wash at side of breast, diffuse brownish-grey streaks on lower breast, belly and flanks; undertail brownish-grey; underwing pale creamy buff with broad brownish-grey trailing edge and tip; iris whitish-grey to pale blue-grey; bill black; legs grey to brown. Differs from very similar *M. albilineata* in lacking yellow edges on remiges and rectrices. Sexes alike in plumage, male larger than female. Juvenile is similar to adult, but with no moustachial stripe, larger and yellow-white ear-plume, upwringing-coverts tinged rufous, only faint mottling or streaking on lower throat and breast, and unstreaked pale buff-grey lower underbody. Voice. Poorly known. Song of powerful fluting notes, described as up to 12 upslurred and downslurred, chirruping whistles in rapid bursts. Chattering call in presence of Southern Boobook (*Ninox boobook*).

Habitat. Deep rugged sandstone gorges, gulleys, creek-lines and cliffs with sparse woodland of *Eucalyptus*, *Acacia* and figs (*Ficus*), with dense spinifex (*Triodia*) between sandstone slabs and boulders, and in patches of monsoon rainforest; apparently also broadleaf scrub and thickets. Possibly sometimes on floodplains near escarpments and gallery paperbark forests or woodlands, but confirmation required.

Food and Feeding. Very poorly known. Diet nectar (including of *Eucalyptus*, *Melaleuca*, *Xanthostemon*), also invertebrates, including ants (Formicidae); probably also fruit and seeds. Forages actively among foliage and at flowers and fruits. Gleans fruit and invertebrates from foliage and large branches of trees and shrubs, and probes in narrow crevices in rocks; catches insects also by sally-hovering and sally-striking. Usually singly or in twos (probably pairs); probably also forms small loose parties when foraging.

Breeding. No information.

Movements. No information; probably sedentary.

Status and Conservation. Not assessed. Probably not globally threatened. Restricted-range species: present in North-west Australia EBA. No estimates of abundance levels, but considered moderately common. Poorly known species, only recently described.

Bibliography. Barrett *et al.* (2003), Blakers *et al.* (1984), Brown *et al.* (1997), Christidis & Schodde (1993), Ford, J.R. (1978a, 1987c), Higgins *et al.* (2001), Johnstone & Burbridge (1991), Johnstone & Smith (1981), Johnstone & Storr (2004), Johnstone *et al.* (1977), Norman *et al.* (2007), Schodde (1989), Schodde & Mason (1975, 1999), Smith & Johnstone (1974), Smith *et al.* (1978), Stattersfield *et al.* (1998), Storr *et al.* (1975).

25. Streak-breasted Honeyeater

Meliphaga reticulata

French: Méléphage réticulé **German:** Temminckhonigfresser **Spanish:** Mielero Reticulado
Other common names: Streak-breasted/Timor Meliphaga, Reticulated/Temminck's/Timor Honeyeater

Taxonomy. *Meliphaga reticulata* Temminck, 1820, Timor.

On basis of molecular evidence, genus consists of two clades: present species is part of group which contains also *M. orientalis*, *M. analoga*, *M. albonotata*, *M. vicina*, *M. gracilis*, *M. cinereifrons*, *M. mimikae*, *M. montana*, *M. flavivictus*, *M. albilineata* and *M. fordiana*. Present species has in the past been placed in genus *Lichenostomus*, and formerly suggested as being close to *Xanthotis*. Molecular evidence and plumage similarities indicate that it is closely aligned with *M. albilineata* and *M. fordiana*. Monotypic.

Distribution. Timor and Semau, in E Lesser Sundas.

Descriptive notes. c. 15.5 cm. Distinctive medium-small honeyeater with rather short, stout and decurved bill. Male is greyish-olive above, with diffuse blackish loral stripe extending narrowly below and behind eye, prominent bright orange-yellow oval to crescent-shaped plume on rear ear-coverts, broad white submoustachial stripe extending from base of bill to level with rear of eye; anterior ear-coverts streaked grey and whitish, merging with dusky-olive malar stripe separating whitish submoustachial stripe from unmarked white to off-white chin and throat; upwringing and tail slightly browner than upperparts, yellowish-olive edges on remiges

and side of tail; underbody off-white to white, with bold but rather messy brownish-olive streaking from breast to undertail-coverts, weaker and more diffuse on lower underbody, yellow wash on belly; undertail dark olive-grey, underwing brownish-grey; iris blue-grey; bill black; legs dark grey. Sexes alike in plumage, male larger than female. Juvenile undescribed. Voice. Calls consist of a series of 9–10 plaintive and slightly upslurred “wheep” notes, beginning rapidly and then slowing, lasting for c. 5 seconds; monotonous, rapidly repeated and high-pitched series of 3–5 notes, “week week week...”, each note with rising inflection; and lower-pitched “work-work”.

Habitat. Primary and secondary forest, both deciduous and evergreen or semi-evergreen (including monsoon forest), degraded forest, scrub, semi-cultivated land, urban gardens; occasionally mangrove associations. Lowlands to 1300 m.

Food and Feeding. Diet includes insects and nectar, and possibly fruit. Occurs singly, in twos (probably pairs) and in small groups of 3–6 individuals. Noisy but often inconspicuous, foraging mostly at flowers of *Eucalyptus*.

Breeding. Estimated laying Mar–Apr and Sept, based on fledgling in late May, dependent juveniles mid-Nov, other juveniles late May and mid-Jun. No other information.

Movements. Presumably resident, possibly with some local movements.

Status and Conservation. Not globally threatened. Restricted-range species: present in Timor and Wetar EBA. Generally widespread and common on Timor. No estimates of abundance. Formerly considered Near-threatened.

Bibliography. Bruce (1987), Coates & Bishop (1997), Hellmayr (1914), Mayr (1944a), Norman *et al.* (2007), Noske (1995a, 2003), Noske & Saleh (1996, 1997), Stattersfield *et al.* (1998), White & Bruce (1986).

Genus *LICHENOSTOMUS* Cabanis, 1851

26. Black-throated Honeyeater

Lichenostomus subfrenatus

French: Méléphage à gorge noire **German:** Goldstreif-Honigfresser **Spanish:** Mielero Gorjinegro
Other common names: Black-fronted/Sub-bridled Honeyeater

Taxonomy. *Ptilotis subfrenata* Salvadori, 1876, Hatam, Arfak Mountains, Vogelkop, north-west New Guinea.

Genus often subsumed in *Meliphaga*. Present species sometimes placed in *Oreornis*. Forms a distinctive species group with *L. obscurus*, *L. frenatus*, *L. hindwoodi* and *L. chrysops*, and all sometimes combined in a separate genus, *Caligavis*. *Meliphaga albilineata* and *Meliphaga fordiana* once considered to be closely related to present species. Geographical variation partly clinal, plumage becoming darker from W to E. Four subspecies recognized.

Subspecies and Distribution.

L. s. subfrenatus (Salvadori, 1876) – Arfak Mts, in NW New Guinea.

L. s. utakwensis (Ogilvie-Grant, 1915) – Weyland Mts and S slopes of Central Ranges (including Nassau Mts and Oranje Mts) E to Hindenburg Range, in WC New Guinea.

L. s. melanolaemus (Reichenow, 1915) – N slopes of Central Ranges (including Nassau and Oranje Ranges) E to Victor Emanuel and Schrader Ranges.

L. s. salvadorii (E. J. O. Hartert, 1896) – mountains of E New Guinea (E from Wharton, Bismarck, Kubor and Saruwaged Ranges).

Descriptive notes. 20.5–22 cm; male 29–36 g and female 25–29 g (*melanolaemus*), male 32–37 g and female 26–28 g (*salvadorii*). Nominative race has forehead grey, top of head and neck olive-tinged grey-brown, diffusely streaked or mottled darker; lores and rest of head and neck blackish-grey, with distinctive facial pattern of prominent swollen yellow gape narrowly joining (beneath eye) broad crescent-shaped patch of bare golden-yellow to dull yellow skin that curves up behind eye, this patch bordered below by black, white and golden-yellow streak arising beneath eye and curving up in short tuft behind ear-coverts to side of

neck; large irregular white to off-white patch on side of neck, and diffuse off-white to yellowish patch or fine streaking on side of lower throat; upperparts olive-brown, yellow-olive wash on outer webs of upwringing-coverts, dull yellow-olive outer edges of remiges (olive panel on folded wing), dull yellow-olive outer edges of rectrices; underbody paler and browner than upperparts, merging to paler olive-brown with off-white mottling in centre of belly, and with diffuse darker mottling throughout; undertail and underwing grey-brown, buff underwing-coverts and bases of remiges; iris grey to dark brown, black eyering; bill black; legs bright to dull yellow or olive-yellow. Sexes alike in plumage, male larger than female. Juvenile is not properly known, very like adult but slightly warmer brown (and less olive) above and below. Races vary mainly in tone of plumage, nominate palest: *melanolaemus* is somewhat darker than nominate, top of head and neck dark olive-brown, lores and

rest of head and neck (except for yellow parts) black; salvadorii is generally darker than previous, upperparts dark grey-olive, chin and throat blackish, underbody dark brownish-olive to greyish-olive (less brown-toned); utakwensis is similar to last but more olive-toned above and below, forehead and upperparts olive and underparts greenish-olive, with less blackish chin and throat. Voice. Song a pleasant, rich and loud, rapid bubbling series that rises and falls in pitch and gradually slows, and sometimes ends with few downslurred notes, song repeated 1–3 times; described also as series of short trills in changing key, or as cheerful series of “chip” notes that falls and then rises, falls and rises again, and descends to end with short flourish. Dual singing frequent when several birds in same tree, one sings identical song to another, starting several notes after the first bird starts; suggested that singing is competitive. At Dokfuma (Star Mts), most common call a complicated tuneful series of whistles, audible at some distance; when feeding young or disturbed by human observers, adults uttered harsh churring sound. Another call described as “whik whik...”, 6 notes per 10 seconds; loud, harsh “wit” calls by adults, when in vicinity of dependent young, may be same call.

Habitat. Primary montane forest (mainly middle to upper montane forest), including moss forest, forest edge, secondary growth and subalpine shrubland; at Dokfuma, in subalpine herb field with dense mat of ferns, small stands of tree-ferns and shrubs, and bordered by open Dacrycarpus woodland and some stands of mossy upper montane forest in sheltered areas. Occurs to tree-line; typically from 1350 m to 3700 m, more commonly above 2000 m, but as low as 1070 m in Huon Peninsula, and specimen collected at 1460 m in Victor Emanuel Mts; 1450 m in SE New Guinea.

Food and Feeding. Diet includes nectar, small arthropods (insects) and fruit. Forages mainly in canopy, but will descend to substage up to c. 3 m above ground and, rarely, to understorey; once seen on ground. Takes nectar from flowering trees (including Xanthomyrtus papuanis); insects mainly gleaned from outer foliage and twigs of canopy, also from branches and trunks of trees, and occasionally taken in air by sallying. One seen to hop clumsily up trunk of tree, probing bark and slipping occasionally, before flying to base of another tree and repeating ascent. Active, aggressive and conspicuous. Usually singly; sometimes associates in flowering trees with other species, including Melidectes rufocrissalis, with which it interacts aggressively, and Myzomela rosenbergii.

Breeding. Adults feeding fledglings in mid-Nov in Star Mts; adults carrying nesting material and females with enlarged gonads Apr, Jun–Sept and in early wet season, and single breeding birds Oct and Nov. No further information.

Movements. No information; probably sedentary. Status and Conservation. Not globally threatened. No estimates of global abundance; considered generally common above 2000 m.

27. Obscure Honeyeater

Lichenostomus obscurus

French: Méléphage obscur German: Laubhönigfresser Spanish: Mielero Oscuro
Other common names: Lemon-checked Honeyeater

Taxonomy. Pitlotis obscura De Vis, 1897, Mount Scratchley, south-east New Guinea. Genus often subsumed in Meliphaga. Present species sometimes placed in Oreornis. Forms a distinctive species group with L. subfrenatus, L. frenatus, L. hindwoodi and L. chrysops, and all sometimes combined in a separate genus, Caligavis. Populations of Weyland Mts intermediate between nominate race and viridifrons. Two subspecies recognized.

Subspecies and Distribution. L. o. viridifrons (Salomonsen, 1966) – mountains of Vogelkop, in NW New Guinea. L. o. obscurus (De Vis, 1897) – patchily distributed on lower slopes of N, C & SE New Guinea E from Weyland Mts.

Descriptive notes. 18.5–19 cm; male 24–31 g, female 24–27 g, mean of 20 unsexed 26.5 g (nominate). Nominate race has forehead and forecrown dusky grey, merging to olive-grey on hindcrown to hindneck, and to blackish on upper lores, supercilium and upper side of neck behind eye; face distinctively marked with varying off-white to yellow gape and triangular patch on lores, which meets narrow yellowish partial orbital ring under eye, this broadening behind eye (forming small yellow patch at upper rear quadrant of eye, narrowly separated from orbital ring below eye by small patch of pale bare skin); pale yellow to yellow

patch or tuft on upper ear-coverts extending forwards to meet orbital ring beneath eye, and bordered behind by large white patch on side of neck; dark grey stripe across malar area and lower ear-coverts, narrowly and incompletely separated from dark grey side of lower throat by yellow line curving up towards ear-coverts from yellow chin and upper throat; upperparts olive-brown to brownish-olive, diffusely mottled darker brown on mantle, back and scapulars; yellow-green edges of rectrices and remiges (slightly contrasting panel on folded wing), sometimes an indistinct and broken buff bar across outer median secondary coverts, at least in fresh plumage; underbody paler than upperparts, greyish-olive, with olive-brown tinge across lower breast merging to off-white in centre of belly, and diffuse dark mottling throughout; undertail and underwing dark grey-brown, buff underwing-coverts; iris dark grey-brown to brown, black eyering; bill black; legs light blue-grey to grey, light brown rear of tarsus. Sexes alike in plumage, male larger than female. Juvenile is very like adult, but top of head olive-brown to brownish-olive, as upperparts, which also lack darker mottling, and rump and uppertail-coverts warmer brown, may also lack pale bar across upperwing-coverts. Race viridifrons differs from nominate in having olive-brown to brownish-olive forehead and crown, concolorous with upperparts. Voice. Often quiet. Song ebullient, of 2 notes (second lower than first) followed by 4 rapid and higher-pitched “cheep” notes on descending scale, which are repeated 2–3 times (somewhat like song of L. subfrenatus); other calls include bubbling series of “cheep” syllables, rising and falling in pitch, and a soft “ssit” repeated at intervals of 3–4 seconds during foraging. Call, or song, also described as loud, distinctive, descending set of “chip” notes in series of descending sets, each of lower pitch than preceding set.

Habitat. Primary forest (rainforest), mainly hill forest, less often in secondary growth and disturbed habitats such as gardens. At Lakekamu, recorded only in primary forest, and not in edge or non-forest habitat. Mainly in hills between 200 m and 1100 m, occasionally as high as 1400 m; locally in lowlands (to 100 m) bordering hills.

Food and Feeding. Diet includes nectar, small arthropods (insects) and fruit (including of Ficus). Forages mainly in lower and middle stages of forest, particularly understorey, but will search in crowns of large flowering trees; at Karimui and Soliabada (Eastern Highlands), noted foraging strictly in lower branches and middle storey. Seen to visit inflorescences of canopy epiphytes Schefflera and of Poikilospermum. Unobtrusive, rather sluggish and often quiet. Usually singly or in twos (probably pairs). Associates with other species in flowering or fruiting plants; in Eastern Highlands, recorded with up to eleven other meliphagid species, and at Karimui was one of a group of five honeyeaters that occurred together in most fruiting and flowering trees.

Breeding. Two active nests known, one in SW (Mimika R) at end Aug and the other in E (Crater Mt) in mid-Oct; seven specimens from Eastern Highlands had non-enlarged gonads in Jul–Aug. Nest cup-shaped, though one tilted and with rim built up on higher side and forming partial dome (covering almost one-quarter of cup), other made of moss and small dry twigs and lined with finer material, suspended by rim from horizontal fork only 15 cm above ground in small shrub. Two clutches each of 2 eggs. No other information.

Movements. Resident at Crater Mountain Wildlife Management Area; possibly vagrant near Brown R. Occurrence in lowlands adjacent to hills indicates some local movements.

Status and Conservation. Not globally threatened. Generally uncommon, but can be locally common or abundant (e.g. Crater Mt, Eloa Valley, and in SW of range). Best detected by vocalizations, but often quiet, e.g. no vocalizations heard from this species in long-term study in Eastern Highlands. Local sex ratios vary and unbalanced in Eastern Highlands.

Bibliography. Beehler, Pratt & Zimmerman (1986), Beehler, Sengo et al. (1995), Bell (1982a), Coates (1990), Coates & Peckover (2001), De Vis (1897), Diamond (1972a), Finch (1980b, 1983), Gregory (1995b), Longmore & Boles (1983), Mack (1994), Mack & Wright (1996), Ogilvie-Grant (1915), Rand (1942b), Rand & Gilliard (1967), Salomonsen (1966a), Schodde & Hitchcock (1968), Terborgh & Diamond (1970).

28. Bridled Honeyeater

Lichenostomus frenatus

French: Méléphage bridé German: Buntschnabel-Honigfresser Spanish: Mielero Embridado
Other common names: Broadbent’s/Mountain Honeyeater

Taxonomy. Pitlotis frenata E. P. Ramsay, 1874, Cardwell, north Queensland, Australia. Genus often subsumed in Meliphaga. Forms a distinctive species group with L. subfrenatus, L. obscurus, L. hindwoodi and L. chrysops, and all sometimes combined in a separate genus, Caligavis. Present species formerly included L. hindwoodi as an outlying population. Monotypic. Distribution. NE Queensland on E Great Divide from Mt Amos (S of Cooktown) S to S Paluma Range and Mt Elliot (SW of Townsville) including coastal islands, and extending inland to Windsor and Atherton Tablelands, in NE Australia.

Descriptive notes. 20–22 cm; male 34–43 g female 28–44 g, unsexed 28–44 g. Plumage is dark grey-brown above, merging to blackish-brown lores and blackish malar area and ear-coverts, and with prominent narrow, curving off-white moustachial stripe from gape joining short, narrow, bare orange patch beneath and behind eye, in turn meeting large white blotch above and behind eye; indistinct small yellow patch on upper rear corner of ear-coverts, large light grey patch on side of neck, and indistinct yellow throat-stripe; edges of rectrices and remiges dull yellow-green (dull wash on folded wing), can also have indistinct

off-white bar across outer median coverts in fresh plumage; underside paler grey-brown than upperparts, with slightly darker brown chin and off-white centre of belly, and diffusely mottled darker throughout; undertail and underwing dark grey-brown, buff underwing-coverts; iris and narrow orbital ring blue-grey (orbital ring merging to off-white where abutting white blotch behind eye); bill tip black, clearly demarcated from bright yellow basal half (which merges with whitish gape); legs dark grey or brownish-grey. Sexes alike in plumage, male larger than female. Juvenile is very like adult, but slightly warmer rufous-brown above (especially rump) and below, no pale wingbar. Voice. Rather quiet, though flocks in flowering trees can be noisy. Song described as rippling chirps run rapidly together and usually descending but sometimes rising and falling, “tchew-tchew-tchew...”. Calls include harsh scolding “chaaah” when feeding, and loud double or treble notes, e.g. “we-are” and “wachita-wachita”.

Habitat. Mainly higher-altitude tropical rainforests, including regrowth rainforest, but recorded also in tall open eucalypt forest adjacent to rainforest, in forest remnants in farmland, in gallery forest that extends into dry tropical woodlands, and occasionally in swamp-woodland; sometimes in towns, and in orchards or plantations near rainforest. At low altitudes, recorded in mangroves at mouth of creek. Mostly in uplands, from 600 m to 1500 m; occasionally near coast, e.g. at sea-level at Cape Tribulation.

Food and Feeding. Includes insects, nectar and fruit. In Paluma Range, diet changed from mainly nectarivorous in dry season (Aug–Nov) to mainly insectivorous during wet season (Dec–Mar). Forages mostly in canopy, less often at lower levels; of 127 observations of foraging in Paluma Range, 37% in lower canopy (10–17.5 m), 29.9% in upper canopy (17.5–25 m) and 14.2% in emergent trees (above 25 m), with only 17.3% in subcanopy (5–10 m), and 1.6% in understorey shrubs (1–3 m above ground). Forages in foliage, at flowers and, less so, on trunks of trees. Takes nectar and fruit from variety of rainforest trees, also at flowers of eucalypts, paperbarks (Melaleuca) and mistletoe (Loranthaceae); also from exotic trees and shrubs in towns. Sometimes feeds at sap-flows from incisions cut into red mahogany (Eucalyptus resinifera) trunks by yellow-bellied gliders (Petaurus australis). Mostly probes flowers for nectar; also gleans insects from foliage and branches of rainforest trees, sometimes while hanging in various positions. In Paluma, most insects gleaned (96% of 127 observations), remainder taken in sally (sally-striking at foliage, branches and trunks, or in air) and sally-hover. Visits picnic areas, investigates rubbish. Usually singly or in twos (probably pairs), sometimes in large numbers in flowering trees, e.g. on flower-spikes of umbrella tree (Schefflera actinophylla), when noisy and aggressive.

Breeding. Nest-building and unspecified breeding details reported Sept–Dec, dependent fledglings mid-Oct, and females with brood patches recorded Sept–Dec. Nest cup-shaped, made of long stems of a climbing plant and stems of fern, lined with vegetable fibre, external diameter 11.4 cm, depth 6.6 cm, internal diameter 6.4 cm, depth 4.1 cm; placed in tangle of creepers or vines or in mistletoe, said also to be placed in leafy twigs of tree or shrub, one c. 0.9 m above ground and reported as nesting up to 8 m above ground. Clutch usually 2 eggs; young fed for some time after fledging. No other details. In ringing studies, maximum longevity 7 years 7 months; estimated mean annual survival 64–73%.

Movements. Largely resident, with some local dispersion; part of population of uplands descends in winter to lower altitudes (e.g. Cape Tribulation, Tully Gorge) or to drier W areas (e.g. Mitchell R, Mt Garnet). At Paluma some shifts between rainforest and ecotone habitats dominated by flooded gum (*Eucalyptus grandis*), primarily to W during cooler months; nearby resident population sometimes augmented by influxes in Apr–Jun (though possibly only recently established as resident in Paluma). Also enters towns in winter (e.g. Atherton).

Status and Conservation. Not globally threatened. Restricted-range species: present in Queensland Wet Tropics EBA. No estimates of abundance levels. Seems to be fairly common.

29. Eungella Honeyeater

Lichenostomus hindwoodi

French: Méliphage de Hindwood **German:** Eungellahonigfresser **Spanish:** Mielero de Hindwood
Other common names: Mountain Honeyeater

Taxonomy. *Meliphaga hindwoodi* Longmore and Boles, 1983, Massey Creek, Clarke Range, east Queensland, Australia.

Genus often subsumed in *Meliphaga*. Forms a distinctive species group with *L. subfrenatus*, *L. obscurus*, *L. frenatus* and *L. chrysops*, and all sometimes combined in a separate genus, *Caligavis*. Present species formerly considered to be an outlying population of *L. frenatus*. Monotypic.

Distribution. SE Clarke (Eungella) Range, near Mackay (E Queensland), in NE Australia.

Descriptive notes. 17.2–19.7 cm; male 20–27.2 g, female 19.7–24 g. Plumage is dark grey-brown above, with fine pale grey scalloping on forehead and crown, fine pale grey streaking on mantle, back and scapulars; blackish face with narrow off-white gape and moustachial stripe extending below and behind eye and almost meeting small off-white patch at upper rear edge of eye; narrow upswept off-white plume on rear ear-coverts, finely bordered in front by yellow (difficult to see in field); tail feathers have dull yellow-olive edges; fine pale streaking on secondary upperwing-coverts and fine white tips on outer few median coverts, weak yellow-olive

wash on secondaries, fine off-white edges on primaries; underbody slightly paler grey-brown than upperparts, finely streaked off-white throughout; undertail brownish-grey, underwing largely brownish-grey with buff lining; iris blue-grey to greenish-blue; bill black; legs bluish-grey. Sexes alike in plumage, male larger than female. Juvenile is like adult, but with rufous-brown wash on top of head, and browner lower rump and uppertail-coverts. **Voice.** Typically quiet, but can be noisy at flowering trees. Vocalizations loud, strong and varied. Song a varying but short series of metallic notes, beginning with rather harsh rattle. Soft “chip” contact call; also a short sharp “chip”, “tick” or “churr”.

Habitat. Mainly higher-altitude rainforest; sometimes at edge; visits lowland eucalypt and casuarina forests and woodlands, and gardens. Usually above 900 m, but recorded as low as 150 m.

Food and Feeding. Diet mainly nectar and fruit, also some insects and parts of flowers. Forages mainly in canopy, among foliage of trees and in climbing plants, less often in understorey trees and shrubs. Nectar taken by probing flowers, including *Amyema* mistletoes and climbing pandanus (*Freyinetia excelsa*); insects and lerp gleaned from bark or beneath loose bark and in other crevices, and branches of trees and shrubs; captures insects also by sally-striking, often then bringing item back to perch to be eaten. Also takes fruits (e.g. of mistletoe) and eats flowers, e.g. tearing long, soft fleshy segments from centre of pandanus flowers and swallowing them whole. Usually singly or in twos (probably pairs); sometimes in small groups in flowering trees.

Breeding. Few details of season, but appears to be centred on spring, with building noted late Aug and mid-Oct, eggs Oct and nestlings Oct–Nov. Nest built by both sexes, a deep cup of fine plant fibre, covered with moss on outside, one with external diameter 7.6–8.9 cm, depth 6.4 cm, suspended 4.2–20 m (average 12.8 m) above ground, at least sometimes from horizontal twigs at end of tree branch, where well hidden in foliage, reported also in mistletoe, and sometimes on steep slope. One nest held 2 eggs (not known if clutch complete); incubation probably by only one of the pair, period probably 13–14 days; chicks fed by both parents, nestling period probably 14–15 days at one nest, more than 9 days at another; fledglings fed by both parents.

Movements. Resident; some local movements, including descent to lower altitudes in winter by some individuals.

Status and Conservation. Not globally threatened. Restricted-range species: present in Clarke Range Secondary Area. No estimates of abundance levels; once, c. 100 individuals recorded in one day. Global range tiny, and numbers presumably small. Found mainly in rainforest; dependent on protection within Eungella National Park.

Bibliography. Barrett *et al.* (2003), Blakers *et al.* (1984), Chisholm (1966), Cooney *et al.* (2006), Garnett (1993), Higgins *et al.* (2001), Longmore (1991a), Longmore & Boles (1983), Robertson (1962), Shields (1984), Stattersfield *et al.* (1998), Storr (1984).

30. Yellow-faced Honeyeater

Lichenostomus chrysops

French: Méliphage à joues d’or **German:** Dreistreifen-Honigfresser **Spanish:** Mielero Carigualdo
Other common names: Yellow-gaped Honeyeater

Taxonomy. *Sylvia chrysops* Latham, 1801, Nova Hollandia = region of Port Jackson, New South Wales, Australia. Genus often subsumed in *Meliphaga*. Forms a distinctive species group with *L. subfrenatus*, *L. obscurus*, *L. frenatus* and *L. hindwoodi*, and all sometimes combined in a separate genus, *Caligavis*. Poorly differentiated race *barroni* possibly not worthy of recognition; further studies pending. Three subspecies provisionally recognized.

Subspecies and Distribution.

L. c. barroni (Mathews, 1912) – montane NE Queensland from Shiptons Flat–Mt Amos–Mt Finnigan (near Cooktown) S, including Atherton and Windsor–Carbine Tablelands, to Clarke–Connors Ranges, in NE Australia.

L. c. chrysops (Latham, 1801) – NE Queensland (Dawson–Mackenzie Basin) S, inland to W slopes of Great Divide (scattered records W of this range), to Victoria and SE South Australia.

L. c. samueli (Mathews, 1912) – S Flinders Ranges, Mt Lofty Ranges and Fleurieu Peninsula, in SE South Australia.

Descriptive notes. 15–17.5 cm; male 12–20.5 g and female 15–20 g (nominate), two males 17–17.5 g and female 15–16 g (*samueli*), male 14–17.2 g and female 13.8–15.8 g (*barroni*). Nominat race is greyish-brown to olive-brown above, with diffuse darker mottling or streaking on top of head, hindneck, mantle, back and scapulars; broad curving yellow stripe from gape backwards below eye and across upper ear-coverts to meet small white patch on rear ear-coverts, and bordered above by black eyestripe (broken above rear edge of eye by small yellow to off-white patch) and below by black submoustachial stripe; uppertail brown; upperwing-coverts greyish-brown to olive-brown, broad off-white tips on outer median and secondary coverts and olive tips on primary coverts; remiges brown with fine olive outer edges (forming faint olive panel); chin, throat and underbody pale greyish-brown, slightly darker on breast, with slightly darker streaking on chin and throat and paler off-white streaking elsewhere; undertail greyish-brown, underwing pale rufous with darker, brown, trailing edge and tip; iris dusky blue, brown in some (possibly immatures); bill black; legs dark grey. Sexes alike in plumage, male slightly larger than female. Juvenile is very similar to adult, but paler and unstreaked above, rump and uppertail-coverts browner, underparts paler (breast unstreaked), bill black with orange-brown tip, gape may be slightly more yellow at least initially. Races vary little: *samueli* is significantly smaller than nominate, slightly paler and less mottled above, with more off-white bill; *barroni* is very similar to previous, but slightly paler above and below. **Voice.** Typical daytime song 1.8–2.6 seconds in duration, of 4–6 brief syllables, e.g. “chick-up”, at maximum of 15–17 per minute; infrequent throughout day, slightly more often in first hour of daylight and towards sunset. Dawn song a social chorus starting 35–20 minutes before sunrise and stopping 14–8 minutes before it, a major part of dawn chorus Aug–Jan; individual dawn song rendered as “chee-chitty di-chitty-tee-tee”, duration just over 1 second, at rate of 12–16 per minute. Countersinging, possibly between males, frequent. Calls include repeated, somewhat plaintive but harsh “chip” or “cheep”, uttered on autumn migration, in flight and while perched, migratory flocks producing distinctive chattering; harsh “kheer”. Snaps bill in aggression.

Habitat. Dry, open sclerophyll forests and woodlands dominated by *Eucalyptus*, including savanna and riverine woodlands, with understorey varying from dense to sparse shrubs, including heath, to sparse open grasses; less often in forests and woodlands dominated by *Angophora*, *Acacia*, *Banksia*, casuarina or cypress-pine (*Callitris*) and, in NE Queensland (race *barroni*), swamp-woodland dominated by *Lophostemon*. Sometimes in wet sclerophyll forests, more so when these heavily flowering. Tends to prefer mature forests and woodlands. Commonly also in coastal heathland or shrubland, particularly with flowering *Banksia*; and often in urban and suburban parks and gardens, and even found along streets. Also in remnant patches of forest or woodland in agricultural landscapes. Sometimes in mangrove associations, and in plantations of exotic pines (*Pinus*) and orchards. Occasionally in rainforests (but apparently not in NE Queensland). From coasts to high-altitude subalpine zone.

Food and Feeding. Wide range of items, including nectar (often of *Eucalyptus*, *Banksia*) and pollen, fruit and seeds, manna, and lerp and honeydew; also arthropods, mainly insects, also some spiders (Araneae) and millipedes (Diplopoda). Primarily arboreal, foraging at all levels, also aerially and, occasionally, on ground; proportion of time spent at different levels varies among studies, but often in subcanopy and canopy. Forages among foliage and at flowers of trees, shrubs and mistletoe (Loranthaceae); less often on bark of trees. Gleans from foliage and bark; probes various substrates, including flowers (for nectar) and bark (for invertebrates, such as insect and their products); sallies to capture prey in air or from foliage. Proportions of different methods vary, but gleanings usually constitutes a large proportion. Active, conspicuous. Tends to forage singly, in twos or in small loose groups of up to ten individuals; larger flocks during migration. Occasionally in mixed flocks dominated by insectivorous birds.

Breeding. Season broadly Jul–Mar, with clutches early Aug to late Feb and nestlings reported until early Mar. Nest built by female, often accompanied by male, a fine and fragile, neat woven cup, sometimes with swollen sides or narrower at rim (contents often visible through base or wall), often made of, or covered with, green materials, especially grass or moss, less often including bark or bark fibre, lichens, rootlets, plant stems, fibre or down, leaves, and wool, fur or hair, bound together and to nest plant with spider web, usually lined with very fine rootlets, grass or feathers or other soft plant material, external diameter 3.8–9.5 cm, depth 4.8–10.7 cm, internal diameter 4.3–7.3 cm, depth 3.5–9.5 cm; placed 0.15–25 m (mean 2.3 m) above ground, usually suspended from thin horizontal or vertical fork, or from foliage or shoots, usually among foliage and twigs of live understorey shrub, sometimes in tree or sapling or, less often, in mistletoe, ferns or mangrove, sometimes in dead vegetation, and often near or overhanging water; within a season, second and third nests tend to be higher than earlier ones. Clutch 2–3 eggs, rarely 1 (mean 2.35); incubation by female, period 13–15 days, though said to be as long as 17 days; chicks brooded probably by female alone, fed by both parents, nestling period 11–14 days, once 17 days; fledglings tended by both parents. Nests parasitized by Shining (*Chrysococcyx lucidus*) and Horsfield’s Bronze-cuckoos (*Chrysococcyx basalis*), and Fan-tailed (*Cacomantis flabelliformis*), Brush (*Cacomantis variolosus*) and Pallid Cuckoos (*Cuculus pallidus*). Success rate for 508 eggs in 235 nests was 0.35 fledged young per nest, and of 401 nests where outcome known 41.9% produced at least one fledged young; in one study, 89% of failures attributed to predation.

Movements. Nominat race partly migratory; isolated breeding populations of NE Queensland (*barroni*) and South Australia (*samueli*) appear sedentary. Part of nominate race migrates to and from SE Australia, N passage in autumn (Mar–May) and return in late winter–spring (S passage less conspicuous). Main stream follows Great Divide and E coast, on N passage tending NE during early autumn, then NW from about SE Queensland during late autumn–early winter; leaves Great Divide of N Victoria–S New South Wales and its tablelands in winter and moves to N New South Wales and inland, with decrease noted in coastal Victoria, and estimates of at least 20% of population moving, most between Mar and Jun. Migrates by day, in small to large flocks moving in one general direction (though can be seen to move in opposite direction to expected passage at some sites), usually at treetop level; migratory flocks usually of fewer than 100 individuals but can be larger, and several records of flocks of c. 1000. Large numbers observed on N passage, typically in successive flocks, e.g. at Wellington Point (SE Queensland) mean of 555 birds/hour (26–2355). Sometimes travels in mixed flocks, often with *Melithreptus lunatus*. Vagrant on islands of Bass Strait (mostly King I) and once on mainland Tasmania; vagrant at Iron Range, in far NE Queensland. Doubtful report of two individuals in New Zealand.

Status and Conservation. Not globally threatened. Common in most of range. No estimates of total population; recorded densities of 0.01–2.2 birds/ha and 0.25–1.52 pairs/ha. Formerly considered a pest in commercial fruit orchards.

Bibliography. 31. Singing Honeyeater
Lichenostomus virescens

French: Méléphage chanteur **German:** Pfeifhönigfresser **Spanish:** Mielero Cantarín
Other common names: Black-faced/Large-striped/Forrest's Honeyeater

Taxonomy. *Melithreptus virescens* Vieillot, 1817, Nouvelle Hollande = Shark Bay, Western Australia. Forms a superspecies with *L. versicolor* and *L. fasciularis*; once considered conspecific with former. Races intergrade where they meet: *cooperi* intergrades with *forresti* in N Northern Territory; *forresti* intergrades with *sonorus* in narrow band from N Queensland (E drainage of Gulf of Carpentaria) S through C Cooper Creek Drainage to N Flinders Ranges and Gawler Ranges (South Australia), and with nominate from W Western Australia (between North West Cape and Shark Bay) E to W Eyre Peninsula (South Australia); in S South Australia, nominate, *forresti* and *sonorus* overlap in three-way melange SW of Gawler Ranges. Proposed race *insularis* (from Rottnest I, off Perth, in Western Australia) considered indistinguishable from nominate, and *westwoodia* (Westwood, in S Queensland) synonymized with *sonorus*. Four subspecies recognized.

Subspecies and Distribution.

L. v. cooperi (Mathews, 1912) – Tiwi Is (Bathurst I, Melville I) and N Northern Territory (S to Victoria R and SW Gulf of Carpentaria, including Groote Eylandt and Sir Edward Pellew Is), in N Australia.

L. v. forresti (Ingram, 1906) – Western Australia from Kimberley Division S to Shark Bay and Wheatbelt, E to SE Gulf of Carpentaria and NC Queensland, South Australia (N Eyre Peninsula and N Flinders Ranges) and NW New South Wales.

L. v. sonorus (Gould, 1841) – CN Queensland (Burdekin–Flinders rivers to Dawson–Mackenzie Basin), S, W of Great Divide, to SE South Australia (E from Eyre Peninsula) and W Victoria (W of Westernport Bay).

L. v. virescens (Vieillot, 1817) – coastal and subcoastal SW & S Western Australia, from Carnarvon–Shark Bay S (including Rottnest I) to SW capes (absent from wetter far SW), inland to Wheatbelt, and E to SC South Australia (E to W Eyre Peninsula).

Descriptive notes. 16–24 cm; 29.3 g (nominate), male 20–28 g (*cooperi*), male 24.2–35 g and female 21–34 g (*sonorus*), male 21.8–29.7 g and female 19.1–26.5 g (*forresti*). Nominant race has greyish-brown head and neck, faintly streaked darker brown on top of head, black mask (extending across upper ear-coverts to shoulder) bordered below by yellow moustachial stripe that meets broad yellow stripe across lower ear-coverts, which in turn largely covers a white tuft that appears as white tip of posterior ear-coverts, and with diffuse greyish-white submoustachial stripe; upper-body deep greyish-brown with faint olive suffusion; uppertail and upperside greyish-brown to brown, yellow-olive outer edges of rectrices (forming narrow yellowish sides on folded tail), yellow-olive outer edges of secondaries and primaries (conspicuous panel on folded wing); off-white below, faint yellow wash on throat, fine pale brown streaks on chin and upper throat, streaks becoming heavy, dense and conspicuous on breast, flanks and upper belly; underwing creamy, orange-buff wash on coverts, brown trailing edge and tip; iris black-brown; bill black, gape colour varies from off-white to black (possibly breeding) to yellow (possibly non-breeding); legs dark grey. Sexes similar. Juvenile is similar to adult, but paler above (upperbody slightly darker than head), mask slightly narrower and duller, chin and upper throat tinged cream, underbody pale buffish-brown and mottled darker (not streaked), base of lower mandible dull pink, gape swollen and deep yellow, and iris dull dark brown. Races differ mainly in size (N populations tend to be smaller than S ones), darkness of plumage (correlated with average annual rainfall and humidity) and streaking on breast, also birds from offshore islands tend to be larger and darker than adjacent mainland ones: *sonorus* is smaller than nominate, with proportionately longer bill, slightly broader and longer mask, drab grey-brown upperparts lacking olive tinge, no yellow wash on throat, less densely streaked below; *forresti* is smaller than previous, with proportionately short bill, much paler above and below, dull creamy chin and throat lacking streaking, paler streaking on rest of underside; *cooperi* is similar to nominate, but with slightly less dense

and more diffuse streaking below. **VOICE.** One of first birds to call in morning, male singing from roost 30–20 minutes before dawn. Song at dawn, infrequently at other times, a fairly loud, rather high musical phrase of several notes or double notes; varies geographically; used in territorial defence, and during fights. In Western Australia, individuals sang only one song type, often shared by several others in neighbouring territories; individuals can modify songs to match those of neighbours. Most common call a repeated, fairly loud, drawn-out “preet”, “queek” or “sheek”; sharp, loud rippling or trilling “rer-er-er-er-er”, “te-e-e-e-e-e” or “chirr-r-r-r” whistle in alarm, also other alarm notes; territory defence accompanied by several calls, including intense chattering and continuous chirping. Range of other calls includes animated “terric, terric, terric...”, also drawn-out call (sound between a hiss and a snarl) when driving off independent young. Snaps bill in aggression.

Habitat. Open wooded habitats. Primarily open shrublands and low open woodlands, frequently dominated by *Acacia*, less often in patches of *Acacia*, or other species such as paperbarks (*Melaleuca*) or cypress-pines (*Callitris*), in grassland or savanna; often in low open chenopod shrublands or sparse lignum (*Muehlenbeckia*) shrubland, on plains, around swamps or other wetlands, in depressions, on claypans or flats, along bore drains or channels, and small creeks and other drainage lines; also in coastal shrubland, but not commonly in heathland. Less often in open woodlands or savanna dominated by *Eucalyptus*, *Banksia*, *Melaleuca*, casuarinas or cypress-pines, including open mallee woodland and low riparian paperbark woodlands. Often in parks and gardens in towns, suburbs and around homesteads; also in remnant woodland in partly cleared agricultural land. Sometimes in mangroves or in ecotone with coastal scrub. Very occasionally in open eucalypt forest, riverine *Eucalyptus* woodlands, e.g. those dominated by river red gum (*Eucalyptus camaldulensis*), and monsoon forest and vine thickets.

Food and Feeding. Diet includes nectar, invertebrates (mainly insects, also spiders and molluscs) and fruit; ratio of nectar to invertebrates estimated at 26:74 and 16:84 in two studies, but consumes much fruit at times. Reported also as taking eggs and nestlings of Zebra Finch (*Taeniopygia guttata*) and Double-barred Finch (*Taeniopygia bichenovii*). Forages at all levels, but usually in low shrubs and on ground, and generally at lower levels than those exploited by many other honeyeaters; proportions of foraging observations below 3 m in various studies 67–88%, with up to 22% on ground. Feeds at flowers (including of *Eucalyptus*, *Hakea*, *Grevillea*, *Calothamnus*, *Callistemon*), from foliage and bark of branches and trunks of trees and shrubs. Probes flowers for nectar and possibly invertebrates; invertebrates obtained mostly by gleaning and sallying, mostly sally-striking in air but also sally-pouncing and sally-striking at substrates; also gleans fruit and probes bark. Rubs bees (Apidae) against a hard surface before swallowing them. Active, conspicuous and gregarious. Usually singly, in twos (probably pairs) or in groups of 4–6 individuals (at least some of which are family parties), but tends to forage solitarily; occasionally in groups of up to twelve, or with other species, such as *Acanthagenys rufogularis* and *Lichenostomus leucotis*, in flowering plants; in NE Queensland seen in 58% of 127 mixed-species flocks.

Breeding. Breeds in all months; of 219 clutches, most (72.6%) mid-Aug to late Nov. Nest an open cup, typically substantial (at least in W of range), sometimes flimsy (at least in E), usually of woven grass or leaves, or both, matted and bound with spider web or wool (sometimes incorporates rootlets and twigs, occasionally spider egg sacs, flowers, bark, rarely string, paper or moss), lined with wool, hair or fur or rootlets, occasionally plant down or fine grass or vine tendrils, sometimes unlined, external diameter 6.4–10.8 cm, depth 3.2–7.6 cm, internal diameter 5.1–6 cm, depth 2.5–4.5 cm; placed 0.05–20 m (average 2 m) above ground and usually suspended from horizontal or vertical fork or from small twigs or foliage, usually in low shrub, often with thorns or prickles, or in dense foliage of mistletoes or vines, less often in low tree, sometimes supported (22% of 188 nests). Clutch 1–3 eggs, usually 2 (mean 2.2); incubation probably by female alone, period 12–14 days, once more than 14 days; chicks brooded probably by female, fed by both sexes, nestling period 11–16 days; fledglings fed by both parents. Nests parasitized by Pallid Cuckoo (*Cuculus pallidus*). From 249 eggs in 118 nests, 0.69 fledged young per nest; of 199 nests, 54.3% fledged at least one young.

Movements. Resident, usually with some local movements or fluctuation in numbers at specific locations. At some sites where apparently sedentary there is constant or large turnover of individuals. Vagrant at many sites at edge of or beyond normal range, e.g. in E New South Wales (mainly late Aug to early Oct), and on Kangaroo I, in South Australia (Sept and Jan–Feb).

Status and Conservation. Not globally threatened. Locally common; recorded densities of up to 4.33 birds/ha and 1.3 breeding pairs/ha. Declines reported in some areas but may have increased in others; may have benefited from clearance and fragmentation of vegetation in parts of SW Australia. In Wheatbelt of Western Australia readily flies over open agricultural land, so not highly susceptible to population fragmentation; in SW Australia, abundance similar in road verges and agroforestry sites but numbers much lower in wandoo (*Eucalyptus wandoo*) woodland and reforested sites.

Bibliography. ssp. carteri

32. Varied Honeyeater

Lichenostomus versicolor

French: Méliphage versicolore **German:** Pirolhonigfresser **Spanish:** Mielerro Versicolor
Other common names: Yellow-streaked Honeyeater

Taxonomy. *Ptilotis versicolor* Gould, 1843, Cape York Peninsula, north-east Queensland, Australia. Forms a superspecies with *L. virescens* and *L. fasciolaris*. Previously considered conspecific with former; has sometimes been considered conspecific with latter, with which it apparently hybridizes to limited extent in S of range (near Townsville). In New Guinea, other proposed races are *intermedius* (originally described from Samarai I, off SE coast) and *vulgaris* (described from Finschhafen, in Huon Peninsula), both synonymized with *sonoroides* but perhaps worthy of recognition; further study required. Two subspecies currently recognized.

Subspecies and Distribution.

L. v. sonoroides (G.R. Gray, 1862) – West Papuan Is (Waigeo, Batanta, Salawati, Schildpad, Misool), and patchily coastal N New Guinea from Vogelkop E (including cities of Lae and Madang) to Milne Bay, and associated offshore islands of Yapen (in Geelvink Bay), Fergusson (in D’Entrecasteaux Is) and other islands off SE peninsula (including Killerton, Samarai and Doi). *L. v. versicolor* (Gould, 1843) – coastal S New Guinea from Merauke E (including some islands, e.g. Wallai I) at least to Port Moresby and probably farther (to Milne Bay); islands of Torres Strait (including Boigu, Saibai, Daru, Yam and Possession); and NE Australia S in coastal NE Queensland (including islands of Great Barrier Reef) to Townsville.

Descriptive notes. 19–24 cm; one male 35.5 g and two females 32.5 g and 33 g (nominate). Nominate race has top of head and neck olive, finely streaked darker, with dark grey forehead; dark mask (combination of black stripe across lores, over eye and extending well down side of neck, with grey upper ear-coverts), bordered below by conspicuous yellow stripe (combination of yellow gape, moustachial stripe and lower ear-coverts) that ends in small white tuft (white tips of rear lower ear-coverts), and with large dirty white patch on lower side of neck; upperbody olive with diffuse brown mottling, merging into brownish on rump and uppertail-coverts, latter mottled olive; tail brownish-olive with olive-green sides; upperwing brown, with olive margins of coverts (smaller coverts appearing mottled) and tertials, and yellow-olive outer edges of secondaries and primaries (forming pale panel); largely yellow below, with strong olive-green streaking, vent cream; undertail olive-grey, underwing creamy buff with olive-grey trailing edge and tip; iris dark red-brown or blackish-brown; bill black; legs blue-grey to dark grey. Sexes alike in plumage, male slightly larger than female. Juvenile is much paler and plainer than adult, top of head slightly paler and unstreaked, upperbody light brown and largely unstreaked, underbody paler with more diffuse streaking, bill grey-black with dull pink base of lower mandible, gape yellow to orange-yellow and swollen. Race *sonoroides* differs from nominate in much more greyish-brown upperparts, duller off-white to greyish-white underbody streaked greyish-brown, only faint yellow wash on breast. **Voice.** In Australia song loud, powerful, resonant and melodious whistles. In New Guinea loud, mellow and musical bubbling series, rising and falling in pitch, or cheerful, loud, varied, bubbling mellow syllables and disyllables, sometimes given only once but usually repeated rapidly several times (e.g. around Madang), phrases mostly of three syllables of low and high pitch, e.g. as repeated “tjo tja hü, tjo tja hü, tjo tja hü”. Often duets in New Guinea, singer responds to another’s song with same song, often starting before first bird finishes; possibly duets in Australia. Other calls reported in Australia include loud distress or alarm cries, excited chattering and loud calls when mobbing owl (Strigiformes), and hissing and chirping in response to dead goshawk (*Accipiter*); in New Guinea, repeated harsh note when scolding.

Habitat. In Australia, mainly in mangroves fringing coasts, estuaries and islands; also in coastal shrubland or scrub adjacent to mangroves or on coral cays, including vegetation dominated by paperbarks (*Melaleuca*), *Banksia*, *Acacia* or casuarinas, or associations including *Terminalia*, *Mimusops*, *Planchonia* with thickets of khoa (*Cordia subcordata*) and scattered shrubs; commonly in parks, gardens and seafront vegetation of coastal towns and villages; rarely in rainforest or eucalypt forests and woodlands. In New Guinea, coconut plantations and groves, mangroves, coastal vegetation, and gardens around houses, and in villages and towns; often on offshore islands. Coastal lowlands; exceptionally, recorded at 700 m at Wanuma (Adelbert Range), in N New Guinea.

Food and Feeding. Nectar and insects; said to take some crustaceans from mud at low tide. Forages by gleanings and probing in outer foliage of mangroves and other trees, and among lower aerial roots and trunks of mangroves. Often probes flowers, including flowering mangroves (e.g. *Sonneratia alba*), *Sesuvium portulacastrum*, umbrella tree (*Schefflera actinophylla*), *Melaleuca*, *Leptospermum*, coconut palms (*Cocos nucifera*), and exotic garden plants such as oleander (*Thevetia*), probably mainly for nectar. Gleans insects; seen also to search for prey on spider webs inside buildings. Noisy; often tame, but can be wary. Forages singly, in twos (probably pairs), and in small, noisy parties of up to ten or occasionally 15 individuals in flowering trees.

Breeding. Poorly known in New Guinea, with unspecified nesting in Jun, laying in Jan, nestlings Mar and Jul, and juvenile mid-Feb; apparently dry season in Australia, where reported Mar–Apr, Jun–Jul and Sept–Oct. Nest a deep but scanty open cup (Australia) or a shallow loose bowl or flat cup (New Guinea) made of rootlets and sometimes grass, bound with plant down and spider web, sparsely lined with fine rootlets, plant fibre and silky plant down, sometimes spider egg sacs attached to outside, one nest with external diameter 9.5 cm, depth 5.7 cm, internal diameter 7.6 cm, depth 3.8 cm, suspended near end of thin horizontal or drooping branch, one secured by one side of rim only, at 0.6–3.6 m (mean 2.5 m) above ground in mangrove, often close to sea or above tidal waters, but reported also in mistletoe (Loranthaceae). Clutch 2 eggs; no information on incubation and nestling periods; both sexes feed nestlings and fledglings.

Movements. Resident.

Status and Conservation. Not globally threatened. Generally common to very common. Abundant in some coastal towns in N New Guinea (e.g. Madang); abundant also on islands in Torres Strait, although generally uncommon on Saibai. No estimates of numbers.
